Conservative treatment (i.e., preserving the tube and not performing a salpingectomy) for an unruptured ectopic pregnancy has been considered to be the method of choice for women who desire future fertility. Only recently has the first prospective randomized trial been completed, which suggested similar long-term pregnancies rates for salpingostomy versus salpingectomy and a somewhat increased rate of retained trophoblastic tissue after salpingostomy (Mol, 2014). However, in a large review by Yao and Tulandi of women with an ectopic pregnancy attempting to conceive after salpingostomy, 60% had an IUP and 15% an ectopic pregnancy. After salpingectomy, 38% had an IUP and 10% an ectopic pregnancy (Yao, 1997). The conservative surgical techniques used include salpingotomy (in which the tubal incision is closed primarily but is unnecessary and has worse subsequent pregnancy rates [discussed later]), salpingostomy (in which the tubal incision is allowed to close by secondary intention), fimbrial evacuation, and partial salpingectomy, also called *segmental resection* of the portion of the tube containing the ectopic pregnancy. Fimbrial evacuation usually traumatizes the endosalpinx and is associated with a high rate of recurrent ectopic pregnancy (24%), about twice as high as the rate after salpingectomy. In addition, this procedure may not remove the entire tubal gestation, and another procedure may be required a few days later. The best results of conservative management occur after salpingostomy (Fig. 17.18) (Leach, 1989). Tulandi and Guralnick reported that the 2-year cumulative rates of IUP after salpingotomy and salpingostomy were similar, about 45%, but the 1-year rates were twice as great when salpingostomy was performed (45% versus 21%), indicating that there is a more rapid return of normal tubal function when the incision heals by secondary intention than when it is sutured (Fig. 17.19) (Tulandi, 1991).

These techniques can be used to treat the majority of unruptured tubal pregnancies, although this long-held belief has been challenged with the randomized trial referred to earlier (Mol, 2014).

If a woman who is nulliparous has an unruptured ectopic pregnancy and strongly desires a conservative approach, salpingostomy should seriously be considered. The findings of the randomized trial

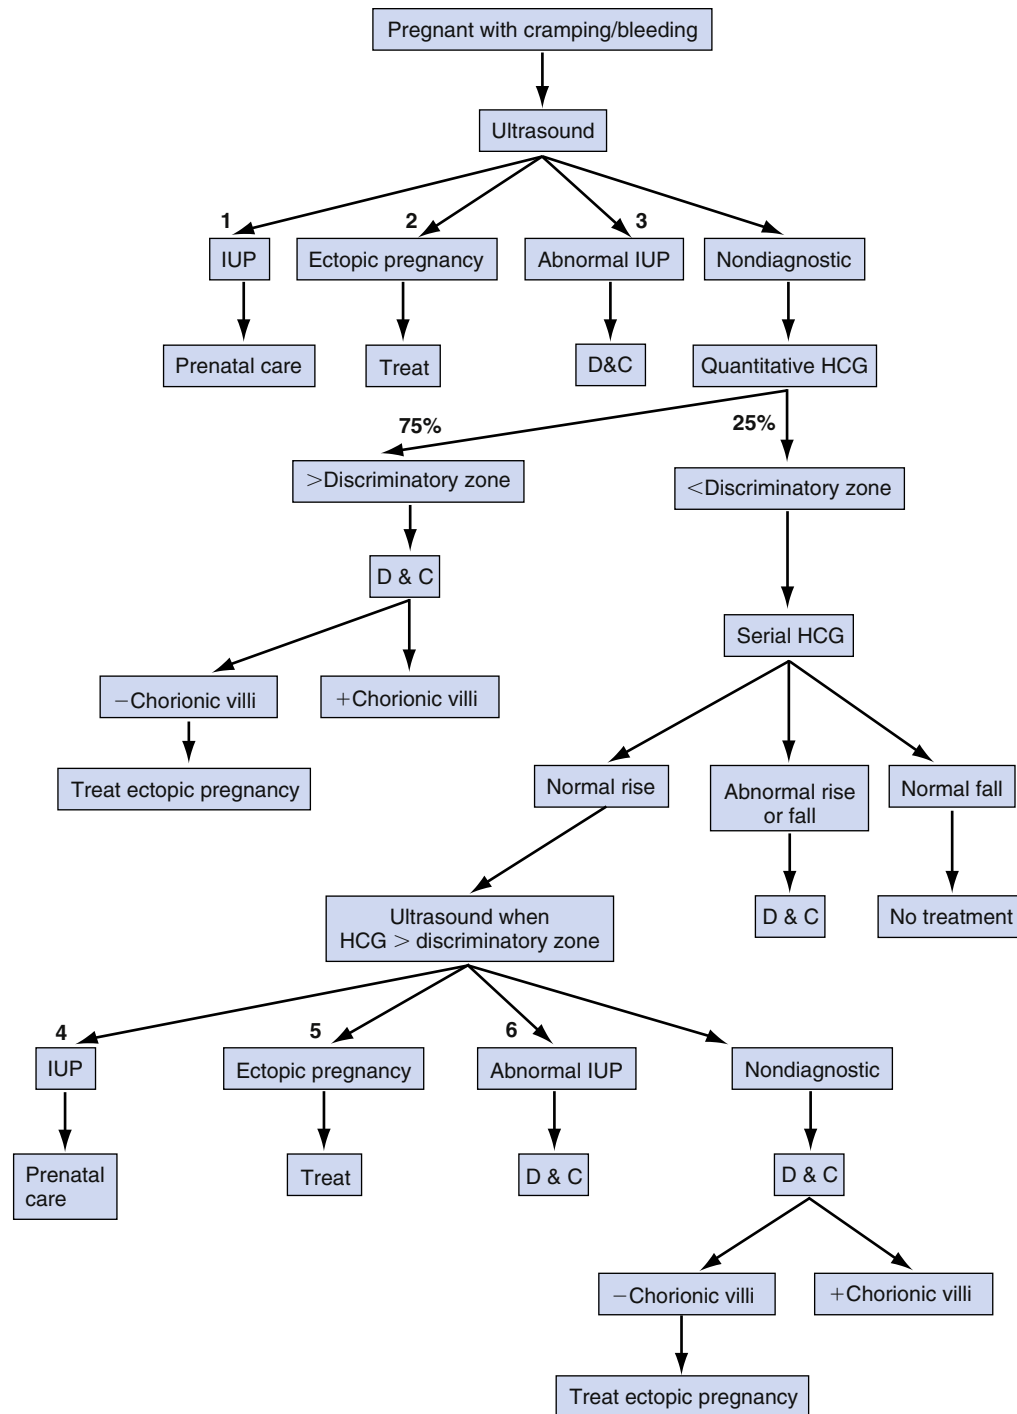

Figure 17.17 Sample schematic of strategy 1. Numbers refer to probabilities. D&C, Dilatation and curettage; IUP, intrauterine pregnancy. (From Gracia C, Barnhart KT. Diagnosing ectopic pregnancy. *Obstet Gynecol.* 2001;97:465.)

showing equal future pregnancy rates even if salpingectomy is carried out (Mol, 2014) (Fig. 17.20) should also be weighed into the decision making.

Interstitial Pregnancy

An **interstitial pregnancy** in the cornual area of the uterus can be treated laparoscopically; but it may require laparotomy with

resection. A deep cornual resection is not deemed necessary and surprisingly does not decrease the risk of recurrent ectopic pregnancy. It has been proposed that a laparoscopic cornuotomy using a temporary tourniquet suture and diluted vasopressin injection can be effective for these cases (Fig. 17.21; see also Video 17.2 of laparoscopic surgery). Choi and colleagues described eight cases of patients who have undergone this technique. They described a low

Figure 17.18 **A**, Incision is made into the antimesenteric border of the fallopian tube. **B**, Ectopic pregnancy is gently removed from within the fallopian tube. **C**, Salpingostomy site is allowed to heal by secondary intention. **D**, Salpingostomy is completed by primary closure. (From Leach RE, Ory SJ. Modern management of ectopic pregnancy. *J Reprod Med*. 1989;34:325.)

Figure 17.19 Cumulative probability of intrauterine pregnancy after conservative surgical treatment of tubal ectopic pregnancy by salpingostomy without tubal suturing, salpingostomy with tubal suturing, and after salpingectomy. (From Tulandi T, Guralnick M. Treatment of tubal ectopic pregnancy by salpingostomy with or without tubal suturing and salpingectomy. *Fertil Steril*. 1991;55:53. Copyright 1991, The American Society for Reproductive Medicine.)

estimated blood loss (50 ± 22 mL) without major complications such as hemorrhage, and no postoperative adjuvant therapy was required. They concluded that this procedure is safe and effective in interstitial pregnancy with the advantage of preserving reproductive function compared with cornual resection (Choi, 2009).

Subsequent intrauterine pregnancies after previous cornual ectopic pregnancy should be delivered by C-section.

Ovarian Pregnancy

Rare ovarian pregnancies can be treated by laparoscopic surgical excision. Many times this occurs when the expected surgery is for a ruptured tubal ectopic pregnancy or hemorrhagic corpus luteum. The surgical treatment alternatives include an ovarian wedge resection or unilateral salpingo-oophorectomy. The latter involving oophorectomy should be avoided and does not improve the subsequent pregnancy rate or lower the risk of recurrence.

Abdominal Pregnancy

This is a rare situation; from an analysis of 11 abdominal pregnancy-related deaths and an estimated 5221 abdominal pregnancies in the United States, it has been estimated that there were 10.9 abdominal pregnancies per 100,000 live births and 9.2 per 1000 ectopic pregnancies; the mortality rate was 5.1 per 1000 cases. Hymel found 31 cases of late abdominal pregnancies (more than 20 weeks' gestation) from 1965 to 2012, in a literature review (Hymel, 2015). The most common sites of placental implantation were in the uterus or adnexa (47.8%), bowel (30%), and the potential spaces surrounding the uterus (8.7%). There were five cases of an intraabdominal abscess in the 14 patients in whom the placenta had been left in situ. Maternal outcomes were documented in 26 cases with seven deaths; 27 fetal outcomes were documented in 22 cases with three fetal deaths (13.6%). Treatment is always surgical and interventional radiology and endovascular surgery must be considered for assistance.

Cervical Pregnancy

Surgical treatment of cervical ectopic pregnancies consists of evacuation with dilatation and curettage or vacuum aspiration. This often occurs after methotrexate treatment, which facilitates the decrease in size and vascularity of the pregnancy. What must be considered is the risk of hemorrhage. This can be avoided by a prophylactic suture ligation of the cervical branches of the uterine artery, with absorbable sutures, at 3 and 9 o'clock under transabdominal ultrasound guidance and a running-lock absorbable suture around the entire edge of the cervix.

Cesarean Scar Pregnancy

Surgical treatment of cesarean scar pregnancies also consists of evacuation with dilatation and curettage or vacuum aspiration under transabdominal ultrasound guidance. To prevent hemorrhage, temporary laparoscopic bilateral artery occlusion with silicone tubing has been described (Wang, 2015). Hysteroscopy coupled with curettage followed by uterine artery embolization is also an alternative surgical approach for these cases (Qian, 2015).

PERSISTENT ECTOPIC PREGNANCY

With increasing use of conservative surgical treatment instead of salpingectomy for the treatment of ectopic pregnancy, the entity of persistent ectopic pregnancy (PEP) is becoming more common. The overall mean incidence of PEP after linear salpingostomy is about 5%, being higher when the procedure is

Figure 17.20 Kaplan-Meier curves for time to ongoing pregnancy by natural conception. Shaded areas show 95% confidence interval (CI). Median time to ongoing pregnancy by natural conception after salpingotomy was 20 months (95% CI, 17-23) and after salpingectomy was 26 months (95% CI, 15-37); cumulative rate of ongoing pregnancy by natural conception after 36 months was 60 × 7% after salpingotomy and 56 × 2% after salpingectomy. log rank $P = 0.678$; $\chi^2 = 0.172$ (one degree of freedom). (From Mol F, van Mello NM, Strandell A, et al. Salpingostomy versus salpingectomy in women with tubal pregnancy [ESEP study]: an open-label, multicentre, randomised controlled trial. *Lancet*. 2014;383[9927]:1483-1489.)

performed laparoscopically and lower when performed by laparotomy. After fimbrial expression or tubal abortion, the incidence of persistence ranges from 12% to 15%.

PEP is uncommon when the preoperative HCG level is below 3000 mIU/mL. When preoperative HCG levels are greater than 3000 mIU/mL, the incidence of PEP has been reported to range from about 22% to 42%. If the HCG level is above 1000 mIU/mL 7 days after surgery or is more than 15% of the original level

at this time, PEP is nearly always present. If the day 7 HCG level is under 1000 mIU/mL or less than 15% of the initial value, PEP is unlikely. Vermesh and associates measured both HCG and progesterone levels preoperatively and every 3 days after conservative tubal surgery for an unruptured ectopic gestation in a group of 114 women (Vermesh 1988). Of this group, six (5.3%) had PEP, all of whom had an initial sharp drop in HCG levels to 25% of the pretreatment levels 6 days after surgery, similar to

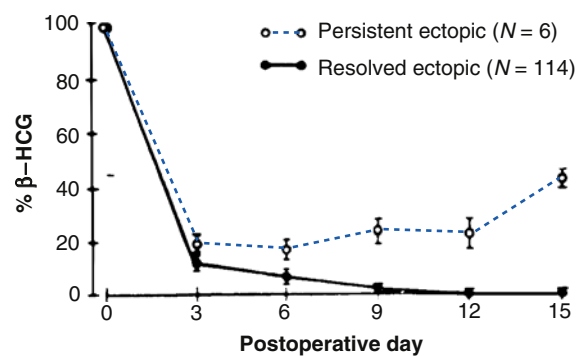

Figure 17.22 Serum β -human chorionic gonadotropin (β -HCG) patterns in persistent and resolved ectopic gestations after conservative surgery. (From Vermesh M, Silva PD, Rosen GF, et al. Persistent tubal ectopic gestation: patterns of circulating beta-human chorionic gonadotropin and progesterone, and management options. *Fertil Steril.* 1988;50:584. Copyright 1988, The American Society for Reproductive Medicine.)

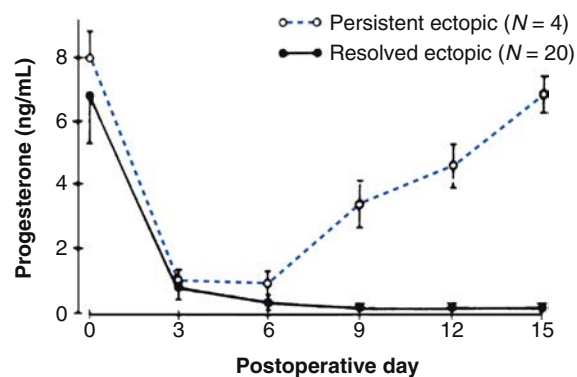

Figure 17.23 Serum progesterone patterns in persistent and resolved ectopic gestations after conservative surgery. (From Vermesh M, Silva PD, Rosen GF, et al: Persistent tubal ectopic gestation: Patterns of circulating beta-human chorionic gonadotropin and progesterone, and management options. *Fertil Steril.* 1988;50:584. Copyright 1988, The American Society for Reproductive Medicine.)

the remainder of the group who did not have PEP. After 6 days, titers of the former group plateaued or rose slightly (Fig. 17.22). Based on these data, PEP is presumed to be present if a day 9 serum HCG level is more than 10% of the initial level or a day 9 serum progesterone level is higher than 1.5 ng/mL (Fig. 17.23). It is now recommended that after linear salpingostomy either HCG or progesterone levels be measured initially on day 6 postoperatively and at 3-day intervals thereafter. Increasing levels of either of these hormones beyond day 6 or a day 6 level of HCG more than 1000 mIU/mL, or more than 15% of the original value are all indicators of persistent ectopic pregnancy. Because tubal rupture is likely to occur with PEP, it is best to treat the entity before this emergency situation occurs.

Methods used to treat PEP include salpingectomy, salpingostomy, methotrexate, or expectant management. Expectant management is usually reserved for the asymptomatic woman whose HCG titers plateau but do not rise. Surgical management should be utilized for women who develop symptoms of persistent lower abdominal pain. The remaining women with PEP are best treated

Table 17.4 Multiple-Dose MTX Treatment Protocol

Treatment Day	Laboratory Evaluation	Intervention
Pretreatment	HCG, CBC with differential, liver function tests, creatinine, blood type and antibody screen	Rule out spontaneous Ab Rhogam if Rh negative
1	HCG	MTX 1.0 mg/kg IM
2		LEU 0.1 mg/kg IM
3		MTX 1.0 mg/kg IM if <15% decline days 1-3 If >15%, stop treatment and start surveillance
4	HCG	LEU 0.1 mg/kg IM
5		MTX 1.0 mg/kg IM if <15% decline days 3-5 If >15%, stop treatment and start surveillance
6		LEU 0.1 mg/kg IM
7	HCG	MTX 1.0 mg/kg IM if <15% decline days 5-7 If >15%, stop treatment and start surveillance
8		LEU 0.1 mg/kg IM

with methotrexate. A single dose of 50 mg/m² of methotrexate is usually sufficient to resolve PEP. Graczykowski and Mishell performed a randomized trial in which a single dose of methotrexate or placebo was given within 24 hours after salpingostomy. The use of methotrexate reduced the risk of developing PEP by nearly 90%. The prophylactic use of a single dose of methotrexate may be considered in women with larger ectopics, higher initial levels of HCG, or when the surgery had been difficult.

Medical Treatment

Methotrexate (MTX) has become established as a reasonable primary treatment for ectopic pregnancy and is comparable with surgical therapy in observational studies. For medical and surgical therapy, rates of tubal pregnancy (62% to 90%) and recurrence rates (8% to 15%) are comparable.

MTX should be used in asymptomatic women who qualify for such treatment (see Fig. 17.16) and who have no contraindications (see Table 17.3) (Practice Committee ASRM, 2008). Prior to treatment, several tests should be obtained, including a complete blood count (CBC) test, liver function test, blood urea nitrogen (BUN) test, and tests of creatinine, blood type, and Rh.

There are two main protocols for MTX: multidose and single-dose regimens (Tables 17.4 and 17.5) (Practice Committee ASRM, 2008). There is also an intermediate two-dose regimen, which will be discussed later. The multidose regimen is more successful but involves more dosing and therefore potentially has more side effects. It also includes the use of leukovorin (folinic acid), an antagonist to

Table 17.5 Single-Dose MTX Treatment Protocol

Treatment Day	Laboratory Evaluation	Intervention
Pretreatment	HCG, CBC with differential, liver function tests, creatinine, blood type, and antibody screen	Rule out spontaneous Ab Rhogam if Rh negative

MTX, to reduce the risk of side effects. As shown in Table 17.4, the multidose regimen can be stopped if there is an appropriate decrease in HCG with treatment. The complications of MTX are listed in Box 17.1. In all regimens, the reduction in HCG is key to success, but complete resolution of HCG usually takes 2 to 3 weeks and can linger for up to 8 weeks after treatment.

Meta-analyses have confirmed the overall success of MTX to be 78% to 96%. The single-dose regimen has been reported to have a success of 88.1% (86 to 90), and the multiple-dose regimen was significantly more successful: 92 to 79 (89% to 96%). It is clear that there is a high failure rate with the single-dose regimen, and this is clearly related to the viability of the ectopic, based on its size and the level of HCG (Box 17.2). Seeing a yoke sac in the adnexa and a level of HCG >5000 mIU/mL affords a poorer prognosis of MTX single-dose therapy. Mol and associates performed a systematic review and meta-analysis comparing laparoscopic salpingostomy and methotrexate. They concluded that the clinical treatment is more cost effective with less hospitalization, faster recovery, and no significant difference in subsequent spontaneous conception rates or recurrent ectopic pregnancies (Mol, 2008).

Box 17.2 Predictors of MTX Treatment Failure

Adnexal fetal cardiac activity
Size and volume of the gestational mass (>4 cm)
High initial HCG concentration (>5000 mIU/mL)
Presence of free peritoneal blood
Rapidly increasing HCG concentrations (>50%/48 hours) before MTX
Continued rapid rise in HCG concentrations during MTX

From The Practice Committee of the American Society for Reproductive Medicine. Medical treatment of ectopic pregnancy. *Fertil Steril*. 2008;90(5 Suppl):S206-S212.

Figure 17.24 Single-dose MTX treatment failure based on HCG level. (From The Practice Committee of the American Society for Reproductive Medicine. Medical treatment of ectopic pregnancy. *Fertil Steril*. 2008;90[5 Suppl]:S206-S212.)

Figure 17.24 provides the correlation of failure rates with high levels of HCG (Practice Committee ASRM, 2008). Box 17.2 lists the predictors of failed responses. A two-dose regimen has been proposed as well, which is intermediate between the high and multiple-dose regimens. MTX (50 mg/m²) is administered on days 1 and 4 without leukovorin. This regimen may be considered for patients who have HCG levels above 5000 mIU/mL.

About 85% of patients treated with methotrexate have a transient rise in HCG level between 1 and 4 days after treatment. Between 4 and 7 days after methotrexate is administered, the HCG levels should fall at least 15%. If this amount of decrease does not occur or there is less than a 15% decrease in HCG levels in each subsequent week, an additional dose of methotrexate should be given for a maximum of three doses. If after three doses of methotrexate HCG levels do not decline by 15% weekly, a surgical procedure should be performed. Serum progesterone levels fall more rapidly than HCG levels after methotrexate, and a progesterone level of less than 1.5 ng/mL has been found to be an excellent predictor of resolution of the ectopic pregnancy. Between 3 and 7 days after initiating therapy, severe pelvic pain lasting up to 12 hours frequently occurs. This symptom, probably caused by tubal abortion, must be differentiated from the symptoms of tubal rupture. Serial monitoring of vital signs and measurement of hematocrit levels are helpful. If the woman remains hemodynamically stable and the pain disappears, a tubal abortion has probably taken place and no further therapy is necessary.

To avoid the toxicity of systemic methotrexate administration, a smaller dose of the drug has been administered directly into the tube with either laparoscopic or ultrasound visualization. In a summary of 11 series involving 295 women treated

with tubal injection of methotrexate, 83% had successful resolution of the ectopic pregnancy, and subsequent tubal patency rates were 88% and fertility rates were 82%.

Because of the lower success rate and need for direct needle placement with local injection, most clinicians are now using systemic methotrexate. There have also been several reports of direct intratubal injection of other substances, including potassium chloride, hypertonic glucose, and prostaglandins, but use of these agents is generally less successful than the use of methotrexate.

Methotrexate plays an important role in the treatment of the nontubal ectopic pregnancies. It can be used be administrated intramuscularly or intraamniotically and may also be combined with other therapeutic means, such as intraamniotic administration of potassium chloride, vaginal mifepristone, or uterine artery embolization. If the treatment is considered incomplete in the patient's follow-up, additional treatments such as curettage, hysteroscopy, or even hysterectomy can be considered.

Some new drugs are being studied for the clinical management of the ectopic pregnancies, with drugs such as selective progesterone receptor modulators (i.e., mifepristone) and epidermal growth factor receptor inhibitors combined with methotrexate. Further studies are required to confirm the efficacy of these medications.

Expectant Management

Although this is not a preferred plan of management, it is useful to know that certain ectopics may resolve without treatment. An overall success rate of 69% has been reported for expectant management. The lower the initial HCG level, the greater the success with spontaneous resolution.

Trio and coworkers, using multivariate analysis, reported that an initial HCG titer of less than 1000 mIU/mL and a decrease in HCG levels between the initial serum sample and one obtained a few days later were each independent predictors of successful spontaneous resolution, whereas sonographic visualization of an ectopic gestational sac was not an independent predictor of failure. In their series of 49 women managed expectantly, 88% of those with an initial HCG level of less than 1000 mIU/mL had successful resolution.

Korhonen and associates measured serial HCG levels before and during outpatient expectant management in a group of 118 women with ectopic pregnancies. This group comprised one fourth of all the women with the diagnosis of ectopic pregnancy seen at their institution during 3 years. When spontaneous resolution occurred, HCG levels declined to undetectable levels in 4 to 67 days, with a mean of 20 days. A distinct difference in the rate of decline of HCG levels in those who did and did not require surgery was not observed until 7 days after the initial examination (Fig. 17.25) (Korhonen, 1994). If HCG levels had not fallen more than two thirds of the initial level in 7 days, two thirds of this group of women needed surgical treatment for rising HCG levels, clinical symptoms, or sonographic findings of intraperitoneal bleeding. It has been reported that when serial sonography is performed, some of the tubal pregnancies can increase in size and become more vascular as they resolve. Although knowledge of these facts is important, if an unruptured ectopic pregnancy is diagnosed by β -HCG and ultrasound, it is still preferable to treat with methotrexate or perform laparoscopy, depending on the clinical situation as discussed earlier.

Figure 17.25 Mean value and 95% confidence limits for ratio of serum human chorionic gonadotropin (HCG) concentrations to starting value during expectant management in patients with a spontaneous resolution (blue circles) and in those later treated by laparoscopy (black circles). The two groups diverged at 7 days. (From Korhonen J, Stenman UH, Ylöstalo P. Serum human chorionic gonadotropin dynamics during spontaneous resolution of ectopic pregnancy. *Fertil Steril.* 1994;61:632. Copyright 1994, The American Society for Reproductive Medicine.)

DIAGNOSIS IN WOMEN WITH A HISTORY OF INFERTILITY

In women with a history of infertility, the diagnosis of ectopic pregnancy has been subjected to a risk-scoring assessment (Fig. 17.26) (Coste, 1998). In this scenario, methotrexate therapy is preferred unless the ectopic pregnancy involves a known hydrosalpinx, in which case salpingectomy should be preferred. The Cochrane database has shown that methotrexate therapy is equivalent to laparoscopic surgery; it has also been deemed more cost effective.

PROGNOSIS FOR SUBSEQUENT FERTILITY

If a woman wishes to conceive after having an ectopic pregnancy, three possibilities exist: she may remain infertile, she may conceive and have an intrauterine gestation (with a viable birth or spontaneous abortion), or she may conceive and have an ectopic gestation. Overall, the subsequent conception rate in women following all ectopic pregnancies is about 60%, with the other 40% remaining infertile. About one third of the pregnancies occurring after the initial ectopic pregnancy or another ectopic pregnancy, and one sixth are spontaneous abortions. Therefore only about half the pregnancies are viable, and only one third of all women with an ectopic pregnancy have a subsequent live birth. However, these overall figures are modified by several factors, particularly age, parity, history of infertility, evidence of contralateral tubal disease, whether the ectopic pregnancy is ruptured or intact, and use of an intrauterine device (IUD) at the time of the ectopic gestation. The subsequent fertility rate is significantly

1. Calculate the score (number of points) for each risk factor:

Age (years)	Points	Smoking (cig/d)	Points	Other factors	Points	
<35	0	0	0		YES	NO
35–39	3	1–20	2	EP history	10	0
40	6	>20	4	Endometriosis	9	0
				History of infection ¹	8	0
				Clomiphene	7	0
				Tubal surgery	4	0

¹Salpingitis history (confirmed or not), and/or positive serology for *Chlamydia trachomatis* (1/64)

2. Add the points and read the absolute risk of EP according to the number of points

0	2	4	6	8	10	12	14	16	18	20	22	24	26	28	30	32	34	36	38	40	42	44	46	48
1%	2%	2%	3%	5%	7%	11%	15%	21%	28%	37%	47%	57%	66%	74%	81%	87%	91%	93%	96%	97%	98%	99%	99%	99%

For example, a woman aged 36 years, smoking 25 cigarettes/day, with an EP history and a pregnancy induced by clomiphene would have a score of 3 + 4 + 10 + 7 = 24, for an EP risk of 57%.

Figure 17.26 Ectopic pregnancy (EP) risk scale. (From Coste J, Bouyer J, Fernandez H, Job-Spira N. Predicting the risk of extra-uterine pregnancy: construction and validation of a French risk scale. *Contracept Fertil Sex*. 1998;26:643.)

higher in parous women younger than age 30. However, if the ectopic pregnancy occurs in a woman's first pregnancy, her overall subsequent conception rate is only about 35%, being lower with a history of infertility and higher with no such history. On the other hand, women with high parity (more than three births) who develop an ectopic pregnancy have a relatively high rate, about 80%, of subsequent conception. The subsequent conception rate is lower in women who have a history of salpingitis, as well as those who have visual evidence of pathologic changes in the opposite oviduct as a result of previous salpingitis. Several studies have reported that women who were using an IUD at the time of ectopic pregnancy have normal rates of subsequent fertility and no increased risk of a subsequent ectopic pregnancy. Future fertility is significantly higher in women who have an unruptured tubal pregnancy than in those with tubal rupture, so early diagnosis is desirable. Only 65% of women with a ruptured ectopic pregnancy subsequently conceive, whereas the conception rate in women with an unruptured tubal pregnancy is approximately 82%.

In two large groups of women with unruptured ectopic pregnancy treated by conservative surgery, a high incidence of subsequent fertility (80% to 86%) and a low incidence of subsequent ectopic pregnancy (11% to 22%) have been reported. The intra-uterine pregnancy (IUP) rates were 64% to 70%. In both series, the IUP rates were highest (82% to 86%) in women with no history of infertility or gross evidence of prior salpingitis. The IUP rates were significantly lower (41% to 56%) in women with infertility. It has been shown that in women with evidence of prior tubal infection or a history of infertility, subsequent IUP rates were higher when they were treated with salpingostomy (73% to 76%) than when treated with salpingectomy (43% to 44%). Most studies in the literature indicate that the overall subsequent ectopic pregnancy rate is similar among women treated by salpingostomy or salpingectomy, and the data suggest that

conservative surgery is most beneficial for women with evidence of contralateral tubal damage or a history of infertility.

When comparing salpingostomy outcomes after laparoscopy or laparotomy, the women treated by laparoscopy conceived sooner than those treated by laparotomy, and there were more ectopic pregnancies in the latter group. Overall, 68% and 71% of women in the two groups, respectively, had an IUP, and 5% and 19%, respectively, had an ectopic pregnancy.

In women with an unruptured ectopic a history of infertility (particularly resulting from tubal disease), previous salpingitis, a prior ectopic pregnancy, or the presence of only one tube were each independent factors that decreased the rate of subsequent fertility and also increased the risk of subsequent ectopic pregnancy (Fig. 17.27). It has been suggested therefore that if more than one of these factors were present it would be preferable to perform a salpingectomy than to perform a salpingostomy, as 80% of the recurrent ectopic pregnancies occurred in the same tube as the initial ectopic pregnancy.

The rate of repeat ectopic pregnancies after a single ectopic pregnancy ranges from 8% to 27%, with a mean of about 20%. Because the overall pregnancy rate is in the 60% to 80% range, about one of three to four conceptions after an ectopic pregnancy is a repeat ectopic pregnancy.

Women with an ectopic pregnancy who become pregnant again should be monitored by ultrasound early in pregnancy. Only about one of three nulliparous women who have had an ectopic pregnancy ever conceives again (35%), and about one third of these conceptions are an ectopic pregnancy, for an overall rate of 13%. Risk factors for a repeat ectopic pregnancy were ectopic pregnancy as the first pregnancy, age younger than 25, evidence of tubal infection, and history of infertility (see Table 17.1). With two ectopic pregnancies, the subsequent fertility rate decreases even further. Of women who have had two consecutive ectopic pregnancies treated by

Figure 17.27 Cumulative pregnancy rate according to the patients' history. *IUP*, Intrauterine pregnancy.

salpingostomy, about half will subsequently conceive, but the majority of these will be a repeat ectopic pregnancy. There have been several reports on salpingostomy or salpingotomy in women with an unruptured tubal pregnancy in the only remaining tube. In the great majority of the subjects, the other tube had been removed because of another ectopic gestation. Of 90 women so treated in six different centers, the conception rate was 81%, with an IUP rate of 57%. About one fourth of the women who conceived had a subsequent ectopic pregnancy, which is similar to the rate among all ectopic

pregnancies. Thus conservative surgery or medical therapy may be considered when an unruptured ectopic pregnancy occurs in the only remaining tube.

More recently, Lund Karhus and colleagues performed a study of long-term reproductive outcomes in women whose first pregnancy was an ectopic. They concluded that when compared with women with a first miscarriage, women with a first ectopic pregnancy had a relative risk of a term pregnancy of 0.55, for miscarriages of 0.46, for induced abortions of 0.72, and a 4.7-fold increased risk of further ectopic pregnancy (Lund Karhus, 2013).

KEY POINTS

- The rate of ectopic pregnancy in the United States has remained fairly constant since the early 2000s and is approximately 6.6/1000 pregnancies in women aged 15 to 24.
- The mortality rate has decreased over time and is approximately 0.5 deaths per 1000 per year.
- Risks of ectopic pregnancy include age, pelvic inflammatory disease, prior tubal surgery, smoking, and infertility.
- About 85% of women with an ectopic pregnancy have serum HCG levels lower than in normal pregnancy; the normal HCG doubling time is 1.4 to 3 days in early pregnancy. In 85% of pregnancies, there is a 66% increase every 48 hours; a rise less than 53% in 48 hours is 99% sensitive for an abnormal pregnancy.
- An intrauterine sac should be seen in a normal pregnancy when HCG levels reach 1500 to 2500 mIU/mL. The so-called discriminatory zone is a gestational age over 38 days.
- Progesterone levels below 5 ng/mL indicate an abnormal pregnancy, and levels above 25 ng/mL indicate a normal pregnancy.
- Overall, the subsequent conception rate in women with an ectopic pregnancy is about 60%. A little less than half of these pregnancies terminate in another ectopic pregnancy or spontaneous abortion; so only

about one third of women with an ectopic pregnancy have a subsequent live birth.

- In women with one remaining tube, when an unruptured ectopic pregnancy is treated by salpingostomy, the conception rate is 81% with an IUP rate of 56% and a subsequent ectopic gestation rate of 24%.
- Randomized trial data suggest there is no difference in overall subsequent pregnancy outcomes between women who are treated by salpingostomy versus salpingectomy.
- The overall risk of ectopic pregnancy if a pregnancy occurs after tubal sterilization is about 30%, reaching 50% if the sterilization technique was bilateral tubal fulguration.
- The incidence of heterotopic ectopic pregnancy is about 1% of all pregnancies and is more likely to occur after ART or in vitro fertilization.
- Asymptomatic persistent ectopic pregnancy can be treated expectantly or with methotrexate (MTX). Several regimens are in use, and at least one third of women with ectopic pregnancies can be treated medically. The success of MTX depends on the size/age of the gestation and the initial HCG level. The HCG level should fall at least 15% between days 4 and 7 after the methotrexate injection and at least 15% weekly thereafter.

Benign Gynecologic Lesions Vulva, Vagina, Cervix, Uterus, Oviduct, Ovary, Ultrasound Imaging of Pelvic Structures

Mary Segars Dolan, Cherie Hill, Fidel A. Valea

This chapter reviews benign gynecologic lesions; however, the symptoms and differential diagnoses of these lesions have definite similarity with those of malignant disease. As in many areas of medicine, gynecologic problems do not fall into definitive categories, and those that include malignant disease often overlap with those that include benign disease. When the diagnosis from the history, physical examination, and laboratory tests is clear, management is usually self-evident. When a specific diagnosis is unclear, tissue biopsy may be appropriate. Thus the clinical approach to patient complaints or findings must be broad and not so focused as to prematurely exclude dangerous pathologies within the differential diagnosis.

The discussions in this chapter are arranged anatomically, beginning with the vulva and subsequently covering the vagina, cervix, uterus, oviducts, and ovaries. This chapter does not attempt to be encyclopedic; rather, lesions have been selected based on their clinical importance and prevalence. Therefore extremely rare lesions have been omitted. Because several non-neoplastic abnormalities and lesions present in ways similar to those of benign tumors, this chapter also discusses entities that are not specifically abnormal growths. Clinical problems such as torsion of the ovary, lacerations of the vagina, and hematomas of the vulva are examples of common conditions included in this chapter. Gynecologic infections and associated changes are discussed in [Chapter 23](#).

The successful clinician uses both deductive and inductive reasoning in making a diagnosis. To master both of these techniques, one must be adept at history taking and physical examination skills and be able to form a complete list of possible etiologies that may be related to the patient's complaint. An understanding of the problems discussed in this chapter will be helpful in that endeavor.

VULVA

URETHRAL CARUNCLE AND URETHRAL PROLAPSE

Urethral caruncle and urethral prolapse are conditions that primarily affect postmenopausal women and premenarchal

females. They are thought to occur as a result of decreased estrogen. A urethral caruncle is a small, fleshy mass that occurs at the posterior portion of the urethral meatus of postmenopausal women ([Conces, 2012](#)). The tissue of the caruncle is soft, smooth, friable, and bright red and initially appears as an eversion of the urethra ([Fig. 18.1](#)). Urethral caruncles are generally small, single, and sessile, but they may be pedunculated and grow to be 1 to 2 cm in diameter. Urethral caruncles are believed to arise from an ectropion of the posterior urethral wall associated with retraction and atrophy of the postmenopausal vagina. The growth of the caruncle is secondary to chronic irritation or infection. Histologically, the caruncle is composed of transitional and stratified squamous epithelium with a loose connective tissue. Often the submucosal layer contains relatively large dilated veins. Caruncles are frequently subdivided by their histologic appearance into papillomatous, granulomatous, and angiomatous varieties. They are often secondarily infected, producing ulceration and bleeding. The symptoms associated with urethral caruncles are variable. Many women are asymptomatic, whereas others experience dysuria, frequency, and urgency. Sometimes the caruncle produces point tenderness after contact with undergarments or during intercourse. Ulcerative lesions usually produce spotting on contact more commonly than hematuria. The diagnosis of a urethral caruncle is established by biopsy under local anesthesia, as it can appear like a neoplasm. Initial therapy is oral or topical estrogen and avoidance of irritation. If the caruncle does not regress or is symptomatic, it may be destroyed by cryosurgery, laser therapy, fulguration, or operative excision. Following operative destruction, a Foley catheter is usually left in place for 48 to 72 hours to prevent urinary retention. Follow-up is necessary to ensure that the patient does not develop urethral stenosis. It is not uncommon for the caruncle to recur. Small, asymptomatic urethral caruncles do not need treatment.

Urethral prolapse is predominantly a disease of the premenarcheal female, although it can occur in postmenopausal women ([Fig. 18.2](#)). Patients may have dysuria; however, most are asymptomatic. The annular rosette of friable, edematous, prolapsed mucosa does not have the bright red color of a caruncle and is easily distinguished from a caruncle because it is circumferential

Figure 18.1 Photo of urethral caruncle at the base of the meatus. (From Cundiff GW, Bent AE. *Endoscopic Diagnosis of the Female Lower Urinary Tract*. London: WB Saunders; 1999.)

Figure 18.2 Urethral prolapse found incidentally in a 5-year-old girl on a colposcopic examination for suspected abuse with an edematous red collar of tissue surrounding the urethral meatus. (From Hudson MJ, Swenson AD, Kaplan R, et al. Medical conditions with genital/anal findings that can be confused with sexual abuse. In: Jenny C, ed. *Child Abuse and Neglect: Diagnosis, Treatment and Evidence*. St. Louis: Elsevier; 2011.)

(Tunitsky, 2012). It may be ulcerated with necrosis or grossly edematous. Therapy of a prolapsed urethra is hot sitz baths and antibiotics to reduce inflammation and infection. Topical estrogen cream is sometimes an effective treatment. In rare cases it may be necessary to excise the redundant mucosa.

The differential diagnosis of urethral caruncles includes primary carcinoma of the urethra and prolapse of the urethral mucosa. Malignant lesions are usually hard and irregular in shape and typically are within the urethra itself (Tunitsky, 2012). Urethral carcinoma is primarily a disease of elderly women. The symptoms of a urethral carcinoma include bleeding, urinary frequency, and dysuria. The majority of urethral carcinomas are of squamous cell origin. Most of these rare carcinomas arise from the distal urethra.

The differential diagnosis of a periurethral mass also includes: urethral diverticulum, leiomyoma, vaginal wall inclusion cyst,

Figure 18.3 Skene gland cyst. (From Shah SR, Nitti VW. Benign vaginal wall masses and paraurethral lesions. In: Nitti VW, ed. *Vaginal Surgery for the Urologist*. Philadelphia: Elsevier; 2012.)

Skene gland cyst or abscess, and less commonly Gartner duct cyst and ectopic ureterocele (Tunitsky, 2012). These will be discussed later in this chapter in the Vagina section.

CYSTS

The most common large cyst of the vulva is a cystic dilation of an obstructed Bartholin duct. Bartholin glands open into the vulvar vestibule at about the 5 and 7 o'clock position, distal to the hymenal ring. Bartholin duct cysts and abscesses are fairly common, with a lifetime risk estimated to be 2% (Edwards, 2011). They occur most often during the third decade. Non-inflamed cysts contain sterile, clear, mucinous fluid. They do not require treatment unless large enough to cause discomfort. Inflamed cysts may be treated with oral antibiotics or incision and drainage. A detailed review of the management of these cysts is reported by Wechter (Wechter, 2009). Lesions in the Bartholin gland can occur as carcinomas, a rare tumor that accounts for 2% to 7% of vulvar carcinomas. The median age at diagnosis is 57 years old and the incidence is highest among women in their 60s (Lee, 2015). Chapter 23 covers this topic in more detail.

Occasionally, the ducts of mucous glands of the vestibule become occluded. The resulting small cysts (usually 0.5 to 2 cm) may be clear, yellow, or blue. Similar small mucous cysts occur in the periurethral region. Wolffian duct cysts or mesonephric cysts are rare, but when they do occur, they are found near the clitoris and lateral to the hymeneal ring. These cysts have thin walls and contain clear serous fluid.

Skene duct cysts are rare, usually small, located on the anterior wall of the vagina along the distal urethra, and may present with symptoms of discomfort or be found on routine examination. These cysts arise secondary to infection and scarring of the small ducts (Fig. 18.3). The differential includes urethral diverticula. Clinically, physical compression of the cyst, unlike compression of a urethral diverticula, should not produce fluid from the urethral meatus. Imaging studies such as magnetic resonance imaging (MRI) or ultrasound may also assist in establishing the diagnosis. Asymptomatic cysts in premenopausal women may be

Figure 18.4 Vulvar nevi. **A**, Dome-shaped intradermal nevus. **B**, Compound nevus with irregular pigmentation. (From Fisher BK, Margesson LJ. *Genital Skin Disorders: Diagnosis and Treatment*. St. Louis: Mosby; 1998.)

managed conservatively. Treatment is excision with careful dissection to avoid urethral injury.

The most common small vulvar cysts are epidermal cysts (epidermoid cysts). They are firm, smooth surfaced, white, yellow, slightly pink, or skin colored papules or nodules averaging 0.5 to 2 cm in size (Edwards, 2011). They are most commonly located on the hair-bearing areas. One or several lesions may be present, usually nontender and slow growing. They are firm to shotty in consistency, and their contents are usually under pressure. When noninflamed, they are asymptomatic and no treatment is necessary. If confirmation is needed, incision reveals white, caseous material, like thick cheese. Vulvar epidermal cysts do not have sebaceous cells or sebaceous material identified on microscopic examination but have keratin produced by keratinocytes in the lining of the cyst wall (Edwards, 2011). With rupture or leakage of a cyst, inflammation can occur necessitating treatment with heat applied locally and possibly incision and drainage. Cysts that become recurrently infected or produce pain should be excised when the acute inflammation has subsided. The typical epidermoid cyst develops from embryonic remnants of an anatomically malformed pilosebaceous unit.

An “inclusion cyst” may arise when bits of epithelium are implanted in the skin during surgery or trauma sufficient to break the skin surface. These may be seen at the site of an episiotomy or obstetric laceration. Large epidermal cysts may be confused with fibromas, lipomas, and hidradenomas.

NEVUS

A nevus, commonly referred to as a *mole*, is a localized nest or cluster of melanocytes. These undifferentiated cells arise from the embryonic neural crest and are present from birth. Many nevi are not recognized until they become pigmented at the time of puberty. Approximately one of every 10 women has a pigmented vulvar lesion (Venkatesan, 2010). Vulvar nevi are one of the most common benign neoplasms in females. As with nevi in other parts of the body, they exhibit a wide range in depth of color, from blue to dark brown to black, and some may be amelanotic. The diameter of most common nevi ranges from a 3 to 10 mm. Grossly, a benign nevus may be flat, elevated, or

pedunculated. The borders are sharp, the color even, and the shape is symmetrical. Dysplastic nevi are commonly 6 to 20 mm with one or more atypical features such as speckling of color, diffuse margination, additional red, white, or blue hues, and asymmetry. Other pigmented lesions in the differential diagnosis include hemangiomas, endometriosis, malignant melanoma, vulvar intraepithelial neoplasia, and seborrheic keratosis.

Vulvar nevi are generally asymptomatic. Most women do not closely inspect their vulvar skin; however, during examination, the use of a mirror held by the patient may facilitate teaching self-vulvar exam. Histologically the lesions are subdivided into three major groups: junctional (a symmetric macule), compound, and intradermal nevi (both papules) (Fig. 18.4).

Melanoma is the second most common malignancy arising in the vulva and accounts for 2% to 3% of all of the melanomas occurring in women, even though the vulva contains approximately 1% of the skin surface area of the body. The incidence of vulvar melanoma is stable or slightly decreasing. It is more common in older, white, women with a mean age at diagnosis of 68 years (Sugiyama, 2007). It is estimated that 50% of malignant melanomas arise from a preexisting nevus. Family history of melanoma is one of the strongest risk factors for the disease.

Ideally, all vulvar nevi should be excised and examined histologically. Special emphasis should be directed toward the flat junctional nevus and the dysplastic nevus, for they have the greatest potential for malignant transformation (Fig. 18.5). The lifetime risk of a woman developing melanoma from a congenital junctional nevus that measures greater than 2 cm in diameter is estimated to be approximately 10%. The lifetime risk of a melanoma forming in women with dysplastic nevi is 15 times that of the general population. Removal may be accomplished with local anesthesia or coincidentally with obstetric delivery or gynecologic surgery. Proper excisional biopsy should be three-dimensional and adequate in width and depth. Approximately 5 to 10 mm of normal skin surrounding the nevus should be included, and the biopsy should include the underlying dermis as well. Some patients are reluctant to have a “normal” appearing nevus removed. Nevi that are raised or contain hair rarely undergo malignant change. However, if they are frequently irritated or bleed spontaneously, they should be removed. Recent

Figure 18.5 Suprapubic dysplastic nevus with an irregular shape, reddish hue to the edges, and indistinct margins. (From Fisher BK, Margesson LJ. *Genital Skin Disorders: Diagnosis and Treatment*. St. Louis: Mosby; 1998.)

changes in growth or color, ulceration, bleeding, pain, or the development of satellite lesions mandate biopsy. The characteristic clinical features of an early malignant melanoma may be remembered by thinking ABCD: *asymmetry*, *border* irregularity, *color* variegation, and a *diameter* usually greater than 6 mm.

HEMANGIOMA

Hemangiomas are rare malformations of blood vessels rather than true neoplasms. Vulvar hemangiomas frequently are discovered initially during childhood. They are usually single, 1 to 2 cm in diameter, flat, and soft, and they range in color from brown to red or purple. Histologically, the multiple channels of hemangiomas are predominantly thin-walled capillaries arranged randomly and separated by thin connective tissue septa. These tumors change in size with compression and are not encapsulated. Most hemangiomas are asymptomatic; occasionally they may become ulcerated and bleed.

There are at least five different types of vulvar hemangiomas. The strawberry and cavernous hemangiomas are congenital defects discovered in young children. The strawberry hemangioma is usually bright red to dark red, is elevated, and rarely increases in size after age 2. Approximately 60% of vulvar hemangiomas discovered during the first years of life spontaneously regress in size by the time the child goes to school. Cavernous hemangiomas are usually purple and vary in size, with the larger lesions extending deeply into the subcutaneous tissue. These hemangiomas initially appear during the first few months of life and may increase in size until age 2. Similar to strawberry hemangiomas, spontaneous resolution generally occurs before age 6. Senile or cherry angiomas are common small lesions that arise on the labia majora, usually in postmenopausal women. They are most often less than 3 mm in diameter, multiple, and red-brown to dark blue. Angiokeratomas are approximately twice the

size of cherry angiomas, are purple or dark red, and occur in women between the ages of 30 and 50. They are noted for their rapid growth and tendency to bleed during strenuous exercise. In the differential diagnosis of an angiokeratoma is Kaposi sarcoma and angiosarcoma. Pyogenic granulomas are an overgrowth of inflamed granulation tissue. These lesions grow under the hormonal influence of pregnancy, with similarities to lesions in the oral cavity. Pyogenic granulomas are usually approximately 1 cm in diameter, usually a small nodule that is slightly pedunculated and appears “pinched in” at the base. They may be mistaken clinically for malignant melanomas, basal cell carcinomas, vulvar condylomas, or nevi. Treatment of pyogenic granulomas involves wide and deep excision to prevent recurrence.

The diagnosis is usually established by gross inspection of the vascular lesion. Asymptomatic hemangiomas and hemangiomas in children rarely require therapy. In adults, initial treatment of large symptomatic hemangiomas that are bleeding or infected may require subtotal resection. When the differential diagnosis is questionable, excisional biopsy should be performed. A hemangioma that is associated with troublesome bleeding may be destroyed by cryosurgery, sclerotherapy, or with the use of lasers. Cryosurgical treatment usually involves a single freeze/thaw cycle repeated three times at monthly intervals. Obviously, if the histologic diagnosis is questionable, any bleeding vulvar mass should be treated by excisional biopsy so that the definitive pathologic diagnosis can be established. Surgical removal of a large, cavernous hemangioma may be technically difficult. Lymphangiomas of the vulva do exist but are extremely rare.

Another rare malformation is the vulvar venous malformation. These lesions may become symptomatic at any age and are relatively prone to thrombosis. Venous malformations are different from vulvar varicosities, which are exacerbated with pregnancy and tend to regress postpartum. There are reports of the successful use of sclerotherapy for the treatment of the malformations.

FIBROMA

Fibromas are the most common benign solid tumors of the vulva. They are more frequent than lipomas, the other common benign tumors of mesenchymal origin. Fibromas occur in all age groups and most commonly are found in the labia majora (Fig. 18.6). However, they actually arise from deeper connective tissue. Thus they should be considered as dermatofibromas. They grow slowly and vary from a few centimeters to one gigantic vulvar fibroma reported to weigh more than 250 pounds. Most are between 1 and 10 cm in diameter. The smaller fibromas are discovered as subcutaneous nodules. As they increase in size and weight, they become pedunculated. Smaller fibromas are firm; however, larger tumors often become cystic after undergoing myxomatous degeneration. Sometimes the vulvar skin over a fibroma is compromised by pressure and ulcerates.

Fibromas have a smooth surface and a distinct contour. On cut surface the tissue is gray-white. Fat or muscle cells microscopically may be associated with the interlacing fibroblasts. Fibromas have a low-grade potential for becoming malignant. Smaller fibromas are asymptomatic; larger ones may produce chronic pressure symptoms or acute pain when they degenerate. Treatment is operative removal if the fibromas are symptomatic or continue to grow. Occasionally they are removed for cosmetic reasons.

Figure 18.6 Vulvar fibroma, the most common benign solid tumor of the vulva. (From Friedrich EG, ed. *Vulvar Disease*. 2nd ed. Philadelphia: WB Saunders; 1983.)

Figure 18.7 Skin-colored pedunculated lipoma of labium major observed in a 15-year-old. (From Fisher BK, Margesson LJ. *Genital Skin Disorders: Diagnosis and Treatment*. St. Louis: Mosby; 1998.)

LIPOMA

Lipomas are the second most frequent type of benign vulvar mesenchymal tumor. A common hamartoma of fat, lipomas of the vulva are similar to lipomas of other parts of the body. In the vulva, they are most commonly located periclitally or within the labia majora (Edwards, 2011). When discovered they are softer and usually larger than fibromas (Fig. 18.7).

Figure 18.8 Hidradenoma. (From Shea CH, Stevens A, Dalziel KL, et al. The vulva: cysts, neoplasms, and related lesions. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

The majority of lipomas in the vulvar region are smaller than 3 cm. The largest vulvar lipoma reported in the literature weighed 44 pounds. They are slow growing, and their malignant potential is extremely low.

When a lipoma is cut, the substance is soft, yellow, and lobulated. Histologically, lipomas are usually more homogeneous than fibromas. Prominent areas of connective tissue occasionally are associated with the mature adipose cells of a true lipoma. Unless extremely large, lipomas do not produce symptoms. Computed tomography and MRI may be used to evaluate tumor extensions and anatomic connections with surrounding structures. MRI has been reported to facilitate the differentiation of vulvar lipomas from vulvar liposarcomas (Jayi, 2014). Excision is usually performed to establish the diagnosis, although smaller tumors may be followed conservatively.

HIDRADENOMA (MAMMARY-LIKE GLAND ADENOMA)

The hidradenoma is a rare, small, benign vulvar tumor that is thought to be derived from mammary-like glands located in the anogenital area of women (Fig. 18.8). In a recent review of 46 cases, the tumors occurred only in postpubertal women ages 30 to 90 (Scurry, 2009). Clinically, they are small, smooth-surfaced, medium soft to firm nodules found most commonly on the labia majora or labia minora. They appear cystic and are usually asymptomatic; however, some patients report itching, bleeding, and mild pain. Hidradenomas may be cystic or solid. Approximately 50% of hidradenomas are less than 1 cm in diameter. These tumors have well-defined capsules and arise deep in the dermis. Histologically, because of its hyperplastic, adenomatous pattern, a hidradenoma may be mistaken at first glance for an adenocarcinoma. On close

Figure 18.9 Histology, low-, and high-power micrographs of hidradenoma. (From Clement PB, Young RH. *Atlas of Gynecologic Surgical Pathology*. Philadelphia: WB Saunders; 2000.)

inspection, however, although there is glandular hyperplasia with numerous tubular ducts, there is a paucity of mitotic figures and a lack of significant cellular and nuclear pleomorphism (Fig. 18.9). Excisional biopsy is the treatment of choice.

SYRINGOMA

The syringoma is a benign skin adnexal neoplasm thought to be of eccrine origin. It is common on the face and eyelids but unusual on the vulva. In the vulvar area, these small, asymptomatic papules (usually less than 5 mm in diameter) are located on the labia majora. The papules are skin colored or yellow and may coalesce to form cords of firm tissue. They may be hormonally related, and pregnancy may aggravate associated pruritus. Progesterone receptor positivity has been reported (Heller, 2012). This tumor is usually treated by excisional biopsy. Cryosurgery, or laser therapy. The most common differential diagnosis is Fox-Fordyce disease, a condition of multiple retention cysts of apocrine glands accompanied by inflammation of the skin. The latter disease often produces intense pruritus, whereas syringoma is generally asymptomatic. Fox-Fordyce disease improves with pregnancy and oral contraceptive use and remits after menopause. It is treated with topical steroids, topical tretinoin cream, and oral isotretinoin.

ENDOMETRIOSIS

Endometriosis of the vulva is uncommon. Only 1 in 500 women with endometriosis will present with vulvar lesions. The firm, small nodule or nodules may be cystic or solid and vary from a few millimeters to several centimeters in diameter. The subcutaneous lesions are blue, red, or purple, depending on their size, activity, and closeness to the surface of the skin. The gross and microscopic pathologic picture of vulvar endometriosis is similar to endometriosis of the pelvis (see Chapter 19). Vulvar adenosis may appear similar to endometriosis. The former condition occurs after laser therapy of condylomata acuminata.

Endometriosis of the vulva is usually found at the site of an old, healed obstetric laceration, episiotomy site, an area of operative removal of a Bartholin duct cyst, or along the canal of Nuck. The pathophysiology of development of vulvar endometriosis may be secondary to metaplasia, retrograde lymphatic spread, or potential implantation of endometrial tissue during operation. In one series, 15 cases of vulvar endometriosis believed to be associated with prophylactic postpartum curettage of the uterus to prevent postpartum bleeding, as there was not a single case of vulvar endometriosis in 13,800 deliveries without curettage, but 15 cases of vulvar endometriosis were associated with 2028 deliveries with prophylactic curettage. In general, symptoms do not appear for many months following implantation.

The most common symptoms of endometriosis of the vulva are pain and introital dyspareunia. The classic history is cyclic discomfort and an enlargement of the mass associated with menstrual periods. Treatment of vulvar endometriosis is by wide excision or laser vaporization depending on the size of the mass. Recurrences are common following inadequate operative removal of all the involved area and as a result, most would also recommend medical therapy with continuous oral contraceptives, progestins, or GnRH agonists.

GRANULAR CELL MYOBLASTOMA

Granular cell myoblastoma is a rare, slow-growing, solid vulvar tumor. The tumor originates from neural sheath (Schwann) cells and is sometimes called a *schwannoma*. These tumors are found in connective tissues throughout the body, most commonly in the tongue, and occur in any age group. Approximately 7% of solitary granular cell myoblastomas are found in the subcutaneous tissue of the vulva. Twenty percent of multiple granular cell myoblastomas are located in the vulva. The tumors are usually located in the labia majora but occasionally involve the clitoris.

These tumors are subcutaneous nodules, usually 1 to 5 cm in diameter. They are benign but characteristically infiltrate the surrounding local tissue. The tumors are slow growing, but as they grow, they may cause ulcerations in the skin. The overlying skin often has hyperplastic changes that may look similar to invasive squamous cell carcinoma. Grossly, these tumors are not encapsulated. The cut surface of the tumor is yellow. Histologically, there are irregularly arranged bundles of large, round cells with indistinct borders and pink-staining cytoplasm. Initially the cell of origin was believed to be striated muscle; however, electron microscopic studies have demonstrated that this tumor is from cells of the neural sheath.

The tumor nodules are painless. Treatment involves wide excision to remove the filamentous projections into the surrounding tissue. If the initial excisional biopsy is not adequate and aggressive enough, these benign tumors tend to recur. Recurrence occurs in approximately one in five of these vulvar tumors. The appropriate therapy is a second operation with wider margins, as these tumors are not radiosensitive.

VON RECKLINGHAUSEN DISEASE

The vulva is sometimes involved with the benign neural sheath tumors of von Recklinghausen disease (generalized neurofibromatous and café-au-lait spots). The vulvar lesions of this disease are fleshy, brownish red, polypoid tumors. Approximately 18% of women with von Recklinghausen disease have vulvar involvement. Excision is the treatment of choice for symptomatic tumors.

OTHER ABNORMAL TISSUES PRESENTING AS VULVAR MASSES

The differential diagnosis of vulvar masses includes a large array of rare lesions and aberrant tissues, including leiomyomas, squamous papillomas, sebaceous adenomas, dermoids, accessory breast tissue and Müllerian or wolffian duct remnants, epidermal inclusion cysts, sebaceous cysts, mucous cysts, and skin diseases such as seborrheic keratosis, condylomata acuminata, and molluscum contagiosum. Some of these diseases are discussed in this chapter, others in [Chapter 23](#).

HEMATOMAS

Hematomas of the vulva are usually secondary to blunt trauma such as a straddle injury from a fall, an automobile accident, or a physical assault. Traumatic injuries producing vulvar hematomas have been reported secondary to a wide range of recreational activities, including bicycle, motorcycle, and go-cart riding; sledging; water skiing; cross-country skiing; and amusement park rides ([Fig. 18.10](#)). Spontaneous hematomas are rare and usually occur from rupture of a varicose vein during pregnancy or the postpartum period.

The management of nonobstetric vulvar hematomas is usually conservative unless the hematoma is greater than 10 cm in diameter or is rapidly expanding. The bleeding that produces a vulvar hematoma is usually venous in origin. Therefore it may be controlled by direct pressure. Compression and application of an ice pack to the area are appropriate therapy. If the hematoma continues to expand, operative therapy is indicated in an attempt to identify and ligate the damaged vessel. Often identification of the “key responsible vein” is a futile operative procedure. However, obvious bleeding vessels are ligated, and a pack is placed to promote hemostasis. During the operation, careful inspection and, if needed, endoscopy is performed to rule out injury to the urinary bladder and rectosigmoid.

The majority of small hematomas regress with time. However, a “chronic expanding hematoma” may become particularly problematic. The most familiar clinical example of this type of problem is the chronic subdural hematoma, but a similar situation may accompany vulvar hematomas. The underlying pathophysiology is the repetitive episodes of bleeding from capillaries

Figure 18.10 Vulva hematoma from straddle injury that produced urethral obstruction. (From Naumann RO, Droegemueller W. Unusual etiology of vulvar hematomas. *Am J Obstet Gynecol.* 1982;142[3]:357-358.)

in the granulation tissue of the hematoma, which result in a chronic, slowly expanding vulvar mass. Treatment of a chronic expanding hematoma is drainage and débridement.

DERMATOLOGIC DISEASES

The skin of the vulva is similar to the skin over any surface of the body and is therefore susceptible to any generalized skin disease or involvement by systemic disease. The most common skin diseases involving the vulva include contact dermatitis, neurodermatitis, psoriasis, seborrheic dermatitis, cutaneous candidiasis, and lichen planus. The majority of vulvar skin problems are red, scalelike rashes, and the woman's primary complaint is of pruritus. The diagnosis and treatment of these lesions are often obscured or modified by the environment of the vulva. The combination of moisture and heat of the intertriginous areas may produce irritation; maceration; and a wet, weeping surface. Patients will commonly apply ointments and lotions, which may produce secondary irritation. Therefore it is important that the gynecologist examine the skin of the entire body, because the patient may have more classic lesions of the dermatologic disease in another location. The skin of the vulva is susceptible to acute infections produced by *Streptococcus* or *Staphylococcus*, such as folliculitis, furunculitis, impetigo, and a special chronic infection, hidradenitis suppurativa.

The nonspecific symptom complex of vulvar pruritus and burning is presented next as an introduction to the discussion of dermatologic diseases of the vulva.

PRURITUS

Pruritus is the single most common gynecologic problem; it is a symptom of intense itching with an associated desire to scratch and rub the affected area. Not uncommonly, secondary vulvar pain develops in association or subsequent to pruritus. In some women pruritus becomes an almost unrelenting symptom, with the development of repetitive “itch-scratch” cycles. The itch-scratch cycle is a complex of itching leading to scratching, producing excoriation and then healing. The healing skin itches, leading to further scratching. Pruritus is a nonspecific symptom. The differential diagnosis includes a wide range of vulvar diseases, including skin infections, sexually transmitted diseases, specific dermatosis, vulvar dystrophies, lichen sclerosus, premalignant and malignant disease, contact dermatitis, neurodermatitis, atrophy, diabetes, drug allergies, vitamin deficiencies, pediculosis, scabies, psychological causes, and systemic diseases such as leukemia and uremia.

The management of pruritus involves establishing a diagnosis, treating the offending cause, and improving local hygiene. For successful treatment the itch-scratch cycle must be interrupted before the condition becomes chronic, resulting in lichenification of the skin, lichen simplex chronicus. Lichenification clinically is recognized by palpably thickened skin, exaggerated skin markings, and lichen-type scale. The resulting dry, scaly skin frequently cracks, forms fissures, and becomes secondarily infected, thus complicating the treatment. (See [Chapter 30](#).)

CONTACT DERMATITIS

The vulvar skin, especially the intertriginous areas, is a frequent site of contact dermatitis. The vulvar skin is more reactive to exposure by irritants than other skin areas such as the extremities. Contact dermatitis is usually caused by one of two basic pathophysiologic processes: a primary irritant (nonimmunologic) or a definite allergic (immunologic) origin. In adult women, 50% of cases of chronic vulvovaginal pruritus is due to allergic and irritant contact dermatitis ([Lambert, 2014](#)). Substances that are irritants produce immediate symptoms such as a stinging and burning sensation when applied to the vulvar skin. The symptoms and signs secondary to an irritant disappear within 12 hours of discontinuing the offending substance. In contrast, allergic contact dermatitis requires 36 to 48 hours to manifest its symptoms and signs. Allergic contact dermatitis is a cell-mediated delayed-type (type IV) hypersensitivity reaction. There is development of antigen-specific T cells that may return to the skin at the next contact with the allergen. Often the signs of allergic contact dermatitis persist for several days despite removal of the allergen. Rarely, some women will be allergic to latex or semen. These reactions are type 1, IgE-mediated, immediate reactions. Angioedema and urticarial plaques and papules arise within minutes of contact. This may result in anaphylaxis. Excessive cleansing of the vulvar skin, and urinary or fecal incontinence, may precipitate an irritant dermatitis. The majority of chemicals that produce hypersensitivity of the vulvar skin are cosmetic or therapeutic agents, including vaginal contraceptives, lubricants, sprays, perfumes, douches, fabric dyes, fabric softeners, synthetic fibers, bleaches, soaps, chlorine, dyes in toilet tissues, and local anesthetic creams ([Fig. 18.11](#)). External chemicals that trigger the disease process must be avoided. Some of

Figure 18.11 Acute contact dermatitis to chlorhexidine. Edema and erythema are present in areas where the antiseptic chlorhexidine solution was applied. (From Stevens A, Dalziel KL. Vulvar dermatoses. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

the most severe cases of contact dermatitis involve lesions of the vulvar skin secondary to poison ivy or poison oak. Women with a history of atopy or eczema are more prone to contact dermatitis and tend to be more sensitive to skin irritations.

Acute contact dermatitis results in a red, edematous, inflamed skin. The skin may become weeping and eczematoid. The most severe skin reactions form vesicles, and at any stage may become secondarily infected. The common symptoms of contact dermatitis include superficial vulvar tenderness, burning, and pruritus. Chronic untreated contact dermatitis can evolve into a syndrome of lichenification, with the skin developing a leathery appearance and texture, *lichen simplex chronicus* ([Fig. 18.12](#)).

The foundation of treatment of contact dermatitis is to withdraw the offending substance. Sometimes the distribution of the vulvar erythema helps to delineate the irritant. For example, localized erythema of the introitus often results from vaginal medication, whereas generalized erythema of the vulva is secondary to an allergen in clothing. It is possible to use a vulvar chemical innocuously for many months or years before the topical vulvar “allergy” develops.

Initial treatment of severe lesions is removal of all irritants or potential allergens and application of topical steroids until the skin returns to normal ([Lambert, 2014](#)). The vulvar skin should be kept clean and dry. Use of a barrier product such as zinc oxide ointment or vitamin A and D ointment may be needed to keep urine and feces away from the skin in patients with incontinence. The pain and burning can be treated with tepid water bath soaks several times a day for the first few days. Use of a lubricating agent such as petroleum jelly or Eucerin cream will reduce the pruritus by rehydrating the skin and should be applied after the

Figure 18.12 **A**, Lichen simplex chronicus manifesting of the right labium majus. There is thickening and accentuation of skin markings, with surface excoriation caused by recent scratching. **B**, Lichen simplex chronicus. The epidermis shows thickening of rete ridges, thickening of the granular layer, and overlying hyperkeratosis. (From Stevens A, Dalziel KL. Vulvar dermatoses. In Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

soaks. Cotton undergarments that allow the vulvar skin to aerate should be worn, and constrictive, occlusive, or tight-fitting clothing such as pantyhose should be avoided. Use of a non-medicated cornstarch baby powder may facilitate vulvar dryness. Hydrocortisone (0.5% to 1%) and fluorinated corticosteroids (Valisone, 0.1%, or Synalar, 0.01%) as lotions or creams may be rubbed into the skin two to three times a day for a few days to control symptoms. Synthetic systemic corticosteroids (prednisone, starting with 50 mg/day for 7 to 10 days in a decreasing dose) are sometimes necessary for treatment of poison ivy and

poison oak or severe reactions. Antipruritic medications, such as antihistamines, are not of great therapeutic benefit except as soporific agents. Women often experience pruritus after steroid therapy for vulvar dermatitis. This is not necessarily a recurrence but rather represents a type of withdrawal reaction. This rebound pruritus is seen most commonly with prolonged and higher doses of steroids. After examination, the optimal treatment is a step-down to a short course of a low-potency topical steroid such as 1% hydrocortisone. Topical steroids should be continued for a month or more after clinical improvement as microscopic evidence of inflammation remains for a considerable period of time (Edwards, 2011).

PSORIASIS

Psoriasis is a common, generalized skin disease of unknown origin. Generally, women develop psoriasis during their teenage years, with approximately 3% of adult women being affected. Approximately 20% of these have involvement of vulvar skin. The disease is chronic and relapsing, with an extremely variable and unpredictable course marked by spontaneous remissions and exacerbations. Twenty-five percent of women have a family history of the disease. Genetic susceptibility to develop psoriasis is believed to be multifactorial. Common areas of involvement are the scalp and fingernails. When psoriasis involves the vulvar skin, it produces both anxiety and embarrassment. Similar to candidiasis, psoriasis may be the first clinical manifestation of HIV infection.

Vulvar psoriasis usually affects intertriginous areas and is manifested by red to red-yellow papules. These papules tend to enlarge, becoming well-circumscribed, dull-red plaques (Fig. 18.13). Though the presence of classic silver scales and bleeding on gentle scraping of the plaques may help to establish the diagnosis, the scales are less common in the vulva than on other areas of the body.

With psoriasis on the vulvar region, the number of scales is extremely variable and frequently they are absent. Under the influence of the moisture and heat of the vulva, vulvar psoriasis may resemble candidiasis. Importantly for the diagnosis, psoriasis does not involve the vagina. Sometimes dermatologists treat refractory cases of psoriasis with oral retinoids. The margins of psoriasis are more well defined than the common skin conditions in the differential diagnosis, including candidiasis, seborrheic dermatitis, and eczema. Initial treatment for mild disease is 1% hydrocortisone cream. If the patient has pain secondary to chronic fissures, more moderate disease, a 4-week course of a fluorinated corticosteroid cream should be given. If this treatment is not successful, a dermatologist should be consulted. Several newer antipsoriatic treatments may benefit this condition, especially when it becomes moderate to severe including vitamin D analogs, topical retinoids, calcineurin inhibitors, salicylic acid, coal tar cyclosporine, and drugs that alter the immune system (biologics). Systemic steroids often produce a rebound flare-up of the disease.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a common chronic skin disease of unknown origin that classically affects the face, scalp, sternum, and the area behind the ears. Rarely, the mons pubis and vulvar areas may be involved. Vulvar lesions are pale to yellow-red,

Figure 18.13 **A**, Psoriasis of perineum and vulva. Flexural psoriasis often lacks the typical parakeratotic scale of psoriasis on other body sites. Painful erosion of the natal cleft is common. **B**, Psoriasis. There is psoriasiform hyperplasia of rete ridges with papillary dermal edema and telangiectasia. The parakeratotic scale on the skin surface is not prominent in vulvar psoriasis. (From Stevens A, Dalziel KL. Vulvar dermatoses. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

erythematous, and edematous, and they are covered by a fine, nonadherent scale that is usually oily. Excessive sweating and emotional tension precipitate attacks. Although the cause is unknown, an abnormal reaction in the skin to a commensal yeast, *Pityrosporum ovale*, has been implicated in the pathogenesis. Treatment with topical and oral antifungal agents causes improvement; however, they are not as effective as topical steroids (Edwards, 2011). Approximately 2% to 4% of women have some form of the disease. The pruritus associated with seborrheic dermatitis varies from mild to severe. Treatment is similar to that for contact dermatitis, with hydrocortisone cream being the most effective medication. The differential diagnosis of seborrheic dermatitis includes psoriasis, cutaneous candidiasis, and contact dermatitis. Often it is difficult to differentiate between the cutaneous manifestations of psoriasis and seborrheic dermatitis. Clinically and pragmatically, the exact diagnosis is only of academic interest because the treatment is similar.

LICHEN PLANUS

Lichen planus is an uncommon vulvovaginal dermatosis. Women complain of soreness, burning, itching, and dyspareunia. The disease presents most commonly as a hypertrophic, coalesced plaque similar to lichen sclerosis. Lichen sclerosis, though, does not involve the vagina, whereas lichen planus can. Three types of vulvar lichen planus have been described: erosive, classical, and hypertrophic. Erosive lichen planus is the most common variant occurring in 85% of the cases (Lambert, 2014). Erosive lichen planus is characterized by erosions around the introitus, clitoris, and labia majora and minora (Fig. 18.14). A lacy white

edge is commonly seen. Vaginal involvement is common and patients may also present with contact bleeding, erythema, and scarring with synechiae. Many patients may also report mouth pain and have gingival lesions that appear erosive and desquamative. The classical type presents with small purple, polygonal papules, with sometimes a reticulate lace pattern. Hyperkeratotic lichen planus presents as single or multiple white-hyperkeratotic papules and plaques. Lichen planus is an inflammatory condition with unknown etiology; however, evidence suggests it to be an autoimmune disease of cellular immunity (Edwards, 2011). The autoimmune phenomenon, can be triggered by certain drugs, including beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, and other medications. It may also arise spontaneously. The correct diagnosis is confirmed by a small punch biopsy of the vagina or vulva. Histologic findings (Fig. 18.15) include degeneration of the basal layers, a lymphocytic infiltrate of the dermis, as well as epidermal acanthosis.

This chronic disease tends to have spontaneous remissions and exacerbations that last for weeks to months. Treatment of local lesions is by use of a potent topical steroid ointment such as clobetasol applied twice daily. Steroid suppositories may be inserted intravaginally at night. If the patient is intensely symptomatic, oral steroids may be necessary. In postmenopausal women, topical or systemic estrogen replacement can also be crucial to avoid additional mucosal thinning. Other treatments for resistant cases include methotrexate, oral retinoids, oral griseofulvin, dapson, azathioprine, cyclophosphamide, and topical cyclosporine. Surgery may be necessary to separate vaginal adhesions or uncover a buried clitoris. Postoperatively, the use of vaginal dilators can prevent scar reformation. Women with this condition should be

monitored at periodic intervals because of an associated increased risk of developing vulvar squamous cell carcinoma.

BEHÇET DISEASE

Behçet disease is a rare disorder initially described as a triad of oral aphthous ulcers, genital aphthous ulcers, and uveitis. It is now known to be a multisystem disease with potential

development of problems in many organ systems: skin, joints, cardiovascular, central nervous system, and gastrointestinal tract. The prevalence is high in the Mediterranean, Middle East, and Japan. Turkey has the highest prevalence with a rate of 100 to 400/100,000 individuals (Edwards, 2011). The diagnosis is made after exclusion of herpetic lesions and other ulcerative diseases. The symptoms respond to topical anesthetics. Severe disease may require antineoplastic therapy including methotrexate, steroids, or other medications.

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa is a chronic, unrelenting, refractory infection of skin and subcutaneous tissue that contains apocrine glands. The apocrine glands are found mainly in the axilla and the anogenital region. The disease is rare before puberty; 98% of cases are found in reproductive-age women, and most all disease regresses after menopause. As the infection progresses over time, deep scars and pits are formed (Fig. 18.16). The patient undergoes great emotional distress as this condition is both painful and is associated with a foul-smelling discharge. Current theories of the cause of this condition favor an inflammation beginning in the hair follicles (Fig. 18.17). Thus the term sometimes used synonymously is *acne inversa*. The lesions involve the mons pubis, the genitocrural folds, and the buttocks. The differential diagnosis of hidradenitis suppurativa includes simple folliculitis, Crohn disease of the vulva, pilonidal cysts, and granulomatous sexually transmitted diseases. The differentiation from Crohn disease is usually made by history with an absence of gastrointestinal (GI)

Figure 18.16 Hidradenitis suppurativa: multiple vulvar abscesses with edema of the mons pubis and labia majora. Notice the “pitting” and “scars” from chronic infection. (From Amankwah Y, Haefner H. Vulvar edema. *Dermatol Clin*. 2010;28[4]:765-777.)

Figure 18.17 Hidradenitis suppurativa. Biopsy with follicular plugging and connection to dilated apocrine duct. (From Kelly P. Folliculitis and the follicular occlusion tetrad. In Bologna JL, Jorizzo JL, Rapini RP, eds. *Dermatology*. Edinburgh: Mosby; 2003.)

involvement. The early phase of the disease involves infection of the follicular epithelium, with what first appears as a boil. Erythema, involvement of multiple follicles, chronic infections that burrow and form cysts that break open and track through subcutaneous tissue, creating odiferous and painful sinuses and fistula in the vulva. The chronic scarring, fibrosis, and hyperpigmentation with foul-smelling discharge and soiling of underclothes lead to a socially debilitating condition. The diagnosis should be confirmed by biopsy.

Early on in the disease process there are small furuncles and folliculitis, for which topical and oral clindamycin is usually effective in the short term, usually requiring a 3-month course of antibiotics. Unfortunately, relapse is common; if treatment with long-term antibiotic therapy and topical steroids is unsuccessful, other medical therapies have included antiandrogens, isotretinoin, and cyclosporine. The treatment of refractory cases is aggressive, wide operative excision of the infected skin.

EDEMA

Edema of the vulva may be a symptom of either local or generalized disease. Two of the most common causes of edema of the vulva are secondary reactions to inflammation or to lymphatic blockage. Vulvar edema is often recognized before edema in other areas of the female body is noted. The loose connective tissue of the vulva and its dependent position predispose to early development of pitting edema. Systemic causes of vulvar edema include circulatory and renal failure, ascites, and cirrhosis. Vulvar edema also may occur after intraperitoneal fluid is instilled to prevent adhesions or for dialysis. Local causes of vulvar edema include allergy, neurodermatitis, inflammation, trauma, and lymphatic obstruction caused by carcinoma or infection. Infectious diseases that are associated with vulvar edema include necrotizing fasciitis, tuberculosis, syphilis, filariasis, and lymphogranuloma venereum.

Vulvar Pain Syndromes: Vulvar Vestibulitis, Vestibulodynia, and Dysesthetic Vulvodynia

Vulvar pain, vulvodynia, is one of the most common gynecologic problems, reported by up to 16% of women in the general population (Stockdale, 2014). Vulvodynia has been defined by the International Society for the Study of Vulvovaginal Disease as vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific clinically identifiable, neurologic disorder (Moyal-Barracco, 2004). It is not caused by infection, inflammation, neoplasia, or a neurologic disorder. The disease has a wide spectrum of symptomatology and response to treatment; therefore causation is most likely multifactorial. The diagnosis is made after excluding other treatable causes. A complete history identifying the onset of pain, other associated symptoms, duration of pain, medical and sexual history, treatments tried, allergies, and triggers for pain should be taken. Examination using cotton swab testing to identify areas of pain as well as pain intensity as described in The Vulvodynia Guideline (Haefner, 2005) is helpful to follow patients and response to treatment over time. Large population-based studies have noted that symptoms wax and wane, with many women having spontaneous remission. Reed and colleagues noted a 10% remission over a 2-year evaluation period. Interestingly, in the control group, approximately 2% of women developed symptoms (Reed, 2008).

The terms *vulvar pain syndrome*, *vulvodynia*, and *vulvar vestibulitis* are often used interchangeably. Vulvar vestibulitis is somewhat of a misnomer, because it is not inflammation. Vulvar pain syndrome is further subdivided into two categories: vestibulodynia and dysesthetic vulvodynia. The two conditions have a significant amount of overlap, although different etiologies and clinical course. In general, vestibulodynia is found in younger women, most commonly white, with onset shortly after puberty through the mid-20s. Dysesthetic vulvodynia is most common in peri- and postmenopausal women who have rarely if ever had previous vulvar pain.

The differential diagnosis of vulvar pain includes neurologic diseases, herpes simplex infection, chronic infections, abuse, pain syndromes, neoplasia, contact dermatitis, and psychogenic causes. Chronic pain is considered to be part of the vulvodynia spectrum, once the diagnoses of infection, invasive disease, and inflammation have been excluded. Severe chronic pain can be socially debilitating, and these patients have a wide spectrum of associated affective symptomatology as well. Women with vulvodynia have greater psychologic distress than women who have other vulvar problems. Importantly, these psychologic concerns must be addressed as part of the therapeutic management.

Vestibulodynia involves the symptom of allodynia, which is hyperesthesia, a pain that is related to nonpainful stimuli. The pain is not present without stimulation. The diagnostic maneuver to establish the presence of allodynia is to lightly touch the vulvar vestibule with a cotton-tipped applicator. The vulvar areas most likely to be affected are from the 4 to 8 o'clock positions along the vulvar-vaginal borders. Erythema is not always present, but when present it is confined to the vulvar vestibule (Fig. 18.18). Additionally, patients with

vestibulodynia experience intolerance to pressure in the vulvar region. This pain is neurogenic in origin. The intolerance to pressure may be caused by tampon use, sexual activity, or tight clothing. The pain is described as raw and burning. It is not a spontaneous pain; it is invoked. However, it is severe in nature. Some authors have suggested that symptoms be present for at least 6 months prior to establishing the diagnosis. The symptoms may appear around the time of first intercourse, or within the next 5 to 15 years. Studies of women with vulvar vestibulodynia have found no increased incidence of sexual abuse compared with controls. However, many women are found to have erotophobia. Some even noted an increased nerve density and normal estrogen receptors compared with controls. In contrast, other investigators have noted an increase in alpha-estrogen receptors. Theories regarding the etiology cite potential immunologic, and infectious factors, though no theory has been proved to date. Oral contraceptive use in younger women and hormone replacement in older women have no association with vestibulodynia.

Vulvar dysesthesia, vulvodynia, is a non-localized pain that is constant (not provoked by touch), mimicking a neuralgia. Allodynia is rarely noted, and erythema is also much less common than in vulvar vestibulodynia. Women with vulvodynia are more often perimenopausal or postmenopausal. Dyspareunia is currently present but has usually not been present prior to the development of dysesthesia. Similar to women with vulvar vestibulodynia, there is not an increased history of sexual abuse compared with controls. Women with dysesthesia also have an increased incidence of chronic interstitial cystitis. In general, both groups of women have an increased incidence of atopy. In some, a history of inflammation from topical agents may be elicited. These agents have usually either been

Figure 18.18 Vulvar vestibulitis. **A**, Redness localized to the right Bartholin duct opening and, below it, vulvar vestibulitis. **B**, Discrete localized periglandular erythema in vulvar vestibulitis in a 60-year-old woman. (From Fisher BK, Margesson LJ. *Genital Skin Disorders: Diagnosis and Treatment*. St. Louis: Mosby; 1998.)

self-prescribed or prescribed by a professional to treat initially what seems to be infection. Patients are often depressed and anxious, but this is thought to be a secondary reaction to the chronic pain. An outline for evaluating these patients is presented in [Box 18.1](#). Prior to the diagnosis, one should exclude infection from atypical *Candida* (which may not be obvious on inspection and should be diagnosed by culture), as well as exclusion of infection by group B streptococcus. Some would recommend that prior to extensive treatment a punch biopsy should be obtained to rule out dermatitis presenting atypically, including lichen sclerosis.

The therapeutic approach for these two conditions emphasizes a sensitivity to the debilitating social aspects of the problem. Similar to other chronic pain syndromes, tricyclic antidepressants or gabapentin have been found to be successful in several series. Doses of gabapentin range from 300 to 3600 mg, usually given with increasing doses every week. Most authors start at 300 mg daily, increase to 300 mg twice daily, then three times a day, then 600 mg three times per day to 900 three times per day and so on; the average affective dose is approximately 1800 mg a day. Approximately 66% to 75% of women have a response to treatment with gabapentin. When the medication is discontinued, it should be tapered. Biofeedback and behavior modification therapy have also produced relief. Zolnoun and coworkers reported on 61 women treated successfully for vulvar vestibulitis with 5% lidocaine ointment nightly for a period of 6 to 8 weeks ([Zolnoun, 2003](#)). In the past, women with refractory vulvar vestibulitis have been treated with surgical removal of the vulvar vestibule and reapproximation of tissue. The surgery is difficult, with a significant complication rate, but results are generally good. In one series of 126 women with vulvar vestibulitis, the complication rate was 39%; 89% of women felt that the surgery improved their condition enough to recommend it to other women. Importantly, 30% of women will have spontaneous relief of their symptoms without any treatment. Reports of multilevel nerve block given simultaneously for refractory cases have shown some response. Botulinum neurotoxin is also effective in some women, particularly for those with concurrent vaginismus and levator ani spasm. Series of treatments and combinations of treatments are often used.

For women with vestibulodynia unresponsive to other therapies, surgery is usually recommended. Vestibulectomy and modified vestibulectomy (partial or limited from 3 to 9 o'clock) have

shown resolution in 60% to 90% compared with 40% to 80% for nonsurgical interventions ([Stockdale, 2014](#)). Surgery was noted to be most effective in younger women. Some advocate for partial vestibulectomy, because most pain and painful skin occurs in the lower half of the vestibule. Complications from vestibulectomy include occlusion of the Bartholin gland leading to development of cysts. This problem requires surgical “unroofing” of the duct.

VAGINA

URETHRAL DIVERTICULUM

A urethral diverticulum is a permanent, epithelialized, saclike projection that arises from the posterior urethra. Most are thought to be acquired and present in women between 30 and 60 years of age ([Lee, 2005](#)). They often present as a mass of the anterior vaginal wall and represent approximately 84% of periurethral masses ([Table 18.1](#)). It is a common problem, being discovered in approximately 1% to 3% of women. Most urogynecologists have noted a decline in the prevalence of this condition since the early 1990s. The majority of cases are initially diagnosed in reproductive-age females, with the peak incidence in the fourth decade of life. The symptoms of a urethral diverticulum are nonspecific and are identical to the symptoms of a lower urinary tract infection. To diagnose this elusive condition, one should suspect urethral diverticulum in any woman with chronic or recurrent lower urinary tract symptoms. The urologic aspects of this condition are discussed in [Chapter 21](#). Histologically the diverticulum is lined by epithelium; however, there is a lack of muscle in the saclike pocket.

Urethral diverticula may be congenital or acquired. Few urethral diverticula are present in children; therefore it is assumed that most diverticula are not congenital. The anatomy of the urethra has been described as a tree with many stunted branches that represent the periurethral ducts and glands. It is assumed that the majority of urethral diverticula result from repetitive or chronic infections of the periurethral glands. The suburethral infection may cause obstruction of the ducts and glands, with subsequent production of cystic enlargement and retention cysts. These cysts may rupture into the urethral lumen and produce a suburethral diverticulum. Persistent inflammation and stasis can lead to stone formation (10%). Malignancy has been reported in 6% to 9% of cases, mostly adenocarcinoma ([Foley, 2011](#)). Urethral diverticula are small, from 3 mm to 3 cm in diameter. The majority of urethral diverticula open

Box 18.1 Evaluation of Patients with Vulvar Pain

Examination of vulva for abnormal redness, erosions, crusting, ulceration, hypopigmentation
Cotton swab test to identify areas of pain on pressure (e.g., vestibule)
Sensory neurologic examination for allodynia and symmetric sensation
Examination for vaginal redness, erosions, pallor, dryness
Biopsy of specific skin findings for evaluation by dermatopathologist
Microscopic evaluation of vaginal secretions for yeast, pH, increased white blood cells
Culture for *Candida* (exclusive of *C. albicans*) and bacteria (especially group B *Streptococcus*)
Evaluation for depression and impact on quality of life
Classification of vulvar vestibulitis syndrome or dysesthetic vulvodynia

Table 18.1 Final Diagnosis of Periurethral Mass and Frequency

Diagnosis	N (%)	95% Confidence Interval (%)
Urethral diverticulum	66 (84)	73-91
Diverticulum with malignancy	4 (6)	2-14.8
Vaginal cyst	6 (7)	3-15
Leiomyoma	4 (5)	1-12
Vaginal squamous cell carcinoma	2 (2.5)	0.03-8.8
Etopic ureter	2 (2.5)	0.03-8.8
Granuloma	1 (1)	0.03-6.8

From Blaivas JG, Flisser AJ, Bleustein CB, Panagopoulos G. Periurethral masses: diagnosis in a large series of women. *Obstet Gynecol.* 2004;103(5 Pt 1):842-847.

into the midportion of the urethra (Table 18.2). Occasionally, multiple suburethral diverticula occur in the same woman.

Classically, the symptoms associated with the urethral diverticulum are extremely chronic in nature and they have not resolved with multiple courses of oral antibiotic therapy. The most common symptoms associated with urethral diverticula are urinary urgency, frequency, and dysuria occurring about 90% of the time as the presenting symptom. Approximately 15% of women with urethral diverticula experience hematuria. Other authors have stressed the three *Ds* associated with a diverticulum: *dysuria*, *dyspareunia*, and *dribbling* of the urine. Although for years, postvoiding dribbling has been termed a classic symptom of urethral diverticulum, it is reported by fewer than 10% of women with this condition. In Lee's series a palpable, tender mass was discovered in 56 of 108 patients (Lee, 2005). It is interesting that in most large series, approximately 20% of the women are asymptomatic. A classic sign of a suburethral diverticulum is the expression of purulent material from the urethra after compressing the suburethral area during a pelvic examination. Although the sign of producing a discharge by manual expression is specific, its sensitivity is poor.

The foundation of diagnosing urethral diverticulum is the physician's awareness of the possibility of this defect occurring in women with chronic symptoms of lower urinary tract infection. Historically, the two most common methods of diagnosing urethral diverticulum have been the voiding cystourethrography and cystourethroscopy. Approximately 70% of urethral diverticula will be filled by contrast material on a postvoiding radiograph with a lateral view. Cystourethroscopy will demonstrate the urethral opening of the urethral diverticulum in approximately 6 of 10 cases. Other diagnostic tests used to identify urethral diverticula include urethral pressure profile recordings, transvaginal ultrasound, computed tomography (CT) scans, magnetic resonance imaging (MRI), and positive-pressure urethrography. For diagnosis of urethral diverticulum, MRI sensitivity is 100% as the resolution is excellent (Tunitsky, 2012). Ultrasonography, done translabially (or introitally) may assist in the assessment of the mass being cystic or solid. Positive-pressure urethrography is done with a special double-balloon urethral catheter (Davis catheter) (Fig. 18.19). Classically, the recordings of the pressure profile of the urethra demonstrate a biphasic curve in a woman with a urethral diverticulum. If a woman has a urethral diverticulum and urinary incontinence, performing a stress urethral pressure profile will help to differentiate the etiology. The differential diagnosis includes the Gartner duct cyst, an ectopic ureter that empties into the urethra, and Skene glands cysts.

Table 18.2 Location of the Ostium in 108 Female Patients with Diverticulum of the Urethra

Site	Number of Patients

From Lee RA. Diverticulum of the urethra: clinical presentation, diagnosis, and management. *Clin Obstet Gynecol*. 1984;27:490-498.

Several different operations can correct urethral diverticula. Excisional surgery should be scheduled when the diverticulum is not acutely infected. Operative techniques can be divided into transurethral and transvaginal approaches, with most gynecologists preferring the transvaginal approach as described by Lee (Lee, 2005). The majority of diverticula enter into the posterior aspect of the urethra. Diverticula of the distal one third may be treated by simple marsupialization. Following operations, approximately 80% of patients obtain complete relief from symptoms. Some diverticula have multiple openings into the urethra. Complete excision of this network of fistulous connections is important. The recurrence rate varies between 10% and 20%, and many failures are due to incomplete surgical resection. The most serious consequences of surgical repair of urethral diverticula are urinary incontinence and urethrovaginal fistula. Postoperative incontinence usually follows operative repairs of large diverticula that are near the bladder neck. This incontinence may be secondary to damage to the urethral sphincter. The incidence of each of these complications is approximately 1% to 2%.

INCLUSION CYSTS

Inclusion cysts are the most common cystic structures of the vagina. In a series of 64 women with cystic masses of the vagina, 34 had inclusion cysts. The cysts are usually discovered in the posterior or lateral walls of the lower third of the vagina. Inclusion cysts vary from 1 mm to 3 cm in diameter. Similar to inclusion cysts of the vulva, inclusion cysts of the vagina are more common in parous women. Inclusion cysts usually result from birth trauma or gynecologic surgery. Often they are discovered in the site of a previous episiotomy or at the apex of the vagina following hysterectomy.

Histologically, inclusion cysts are lined by stratified squamous epithelium. These cysts contain a thick, pale yellow substance that is oily and formed by degenerating epithelial cells. Often these cysts are erroneously called sebaceous cysts in the misbelief

Figure 18.19 Double-balloon catheter in use for positive-pressure urethrography.

that the central material is sebaceous. Similar to vulvar inclusion cysts, the cause is either a small tag of vaginal epithelium buried beneath the surface following a gynecologic or obstetric procedure or a misplaced island of embryonic remnant that was destined to form epithelium.

The majority of inclusion cysts are asymptomatic. If the cyst produces dyspareunia or pain, the treatment is excisional biopsy.

DYSONTOGENETIC CYSTS

Dysontogenetic cysts of the vagina are thin-walled, soft cysts of embryonic origin. Whether the cysts arise from the mesonephros (Gartner duct cyst), the paramesonephricum (Müllerian cyst), or the urogenital sinus (vestibular cyst) is predominantly of academic rather than clinical importance. The cysts may be differentiated histologically by the epithelial lining (Fig. 18.20). Most mesonephric cysts have cuboidal, nonciliated epithelium. Most perimesonephric cysts have columnar, endocervical-like epithelium. Occasionally pressure produced by the cystic fluid produces flattening of the epithelium, which makes histologic diagnosis less reliable. Although most commonly single, dysontogenetic cysts may be multiple. The cysts are usually 1 to 5 cm in diameter and are usually discovered in the upper half of the vagina (Fig. 18.21). Sometimes multiple small cysts may present like a string of large, soft beads. A large cyst presenting at the introitus may be mistaken for a cystocele, anterior enterocoele, or obstructed aberrant ureter. Approximately 1 in 200 females develop these cysts.

Figure 18.20 Histology of vaginal cyst. Gartner duct cyst from the lateral vaginal wall. The cyst is lined by nonciliated cells. (From Clement PB, Young RH. *Atlas of Gynecologic Surgical Pathology*. Philadelphia: WB Saunders; 2000.)

Embryonic cysts of the vagina, especially those discovered on the anterior lateral wall, are usually Gartner duct cysts. In the embryo the distal portion of the mesonephric duct runs parallel with the vagina. It is assumed that a segment of this embryonic structure fails to regress, and the obstructed vestigial remnant becomes cystic. These cysts are most commonly found in the lower one third of the vagina.

Most of these benign cysts are asymptomatic, sausage-shaped tumors that are discovered only incidentally during pelvic examination. Small asymptomatic Gartner duct cysts may be followed conservatively. In a series of 25 women undergoing operations for symptomatic dysontogenetic cysts, a wide range of symptoms were reported, including dyspareunia, vaginal pain, urinary symptoms, and a palpable mass. Sometimes large cysts interfere with the use of tampons. MRI can be useful in delineating the course and anatomic arrangement of vaginal cysts (Wai, 2004).

Operative excision is indicated for chronic symptoms. Rarely, one of these cysts becomes infected, and if operated on during the acute phase, marsupialization of the cyst is preferred. Excision of the vaginal cyst may be a much more formidable operation than anticipated. The cystic structure may extend up into the broad ligament and anatomically be in proximity to the distal course of the ureter.

Rare tumors of the vagina include fibromas, angiomyxomas, and hemangiomas. All are usually found by the patient and require surgical excision.

TAMPON PROBLEMS

The vaginal tampon has achieved immense popularity and ubiquitous use. It is not surprising that there are rare associated risks with tampon usage: vaginal ulcers, the “forgotten” tampon, and toxic shock syndrome. The latter, related to toxins elaborated by *Staphylococcus aureus*, is discussed in Chapter 23.

Wearing tampons for a few days has been associated with microscopic epithelial changes. The majority of women develop epithelial dehydration and epithelial layering, and some will develop microscopic ulcers. These minor changes take between 48 hours and 7 days to heal. In a study of colposcopic changes related to the tampon, Friedrich found serial changes of epithelial drying, peeling, layering, and ultimately microulceration (Friedrich, 1981). In his study, 15% of women wearing tampons only during the time of normal menstruation developed microulcerations. No clinical symptoms were associated with these microscopic changes. Theoretically, these microulcerations are a potential portal of entry for the HIV virus.

Large macroscopic ulcers of the vaginal fornix have been described in women using vaginal tampons for prolonged lengths of time for persistent vaginal discharge or spotting. The ulcers have a base of clean granulation tissue with smooth, rolled edges. One can even find tampon fibers in the biopsies of these ulcers. The pathophysiology of the ulcer is believed to be secondary to drying and pressure necrosis induced by the tampon. Obviously, many of these young women use tampons for the identical symptoms that are associated with a vaginal ulcer—that is, spotting and vaginal discharge. Often the intermenstrual spotting is believed to be breakthrough bleeding from oral contraceptives, and the possibility of a vaginal ulcer from chronic tampon usage is overlooked.

Vaginal ulcers are not uncommon secondary to several types of foreign objects, including diaphragms, pessaries, and medicated silicon rings. Management is conservative, because the ulcers heal spontaneously when the foreign object is removed. Any persistent ulcer should be biopsied to establish the cause.

A woman with a “lost” or “forgotten” tampon presents with a classic foul vaginal discharge and occasionally spotting. The tampon is usually found high in the vagina. The odor from a forgotten tampon is overwhelming. The tampon is removed using a “double glove technique” where two gloves are donned on the removal hand and, upon grasping the tampon, the outer glove is pulled over the tampon and tied as the tampon is removed. The woman should be treated with an antibiotic vaginal cream or gel (such as MetroGel or clindamycin) for the next 5 to 7 days.

LOCAL TRAUMA

The most frequent cause of trauma to the lower genital tract of adult females is coitus. Approximately 80% of vaginal lacerations occur secondary to sexual intercourse. Other causes of vaginal trauma are straddle injuries, penetration injuries by foreign

objects, sexual assault, vaginismus, and water-skiing accidents. The management of vulvar and vaginal trauma in children is discussed in [Chapters 11 and 12](#).

The predisposing factors believed to be related to coital injury include virginity, the state of the postpartum and postmenopausal vaginal epithelium, pregnancy, intercourse after a prolonged period of abstinence, hysterectomy, and inebriation. In one series of 19 injuries from normal coitus, 12 of the women were between the ages of 16 and 25 and 5 were older than 45. The most common injury is a transverse tear of the posterior fornix. Similar linear lacerations often occur in the right or left vaginal fornices. The location of the coital injury is believed to be related to the poor support of the upper vagina, which is supported only by a thin layer of connective tissue. The most prominent symptom of a coital vaginal laceration is profuse or prolonged vaginal bleeding. Many women experienced sharp pain during intercourse, and 25% noted persistent abdominal pain. The most troublesome but extremely rare complication of vaginal laceration is vaginal evisceration. Coital injury to the vagina should be considered in any woman with profuse or prolonged abnormal vaginal bleeding. Sensitive but thorough history regarding abuse is always appropriate.

Figure 18.21 **A**, Normal mesonephric duct. On cross section it is a single duct in the submucosa surrounded by clusters of smooth muscle bands. **B**, Mesonephric duct. The mother duct, located deep in the wall of the vagina, is surrounded by smaller arborized offshoots. **C**, Elongated mesonephric duct. (From Robboy SJ, Anderson MC, Russell P, et al. *The vagina*. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

Management of coital lacerations involves prompt suturing under adequate anesthesia. Secondary injury to the urinary and gastrointestinal tracts should be ruled out.

CERVIX

ENDOCERVICAL AND CERVICAL POLYPS

Endocervical and cervical polyps are the most common benign neoplastic growths of the cervix, reported in 4% of gynecologic patients. Endocervical polyps are most common in multiparous women in their 40s and 50s. Cervical polyps usually present as a single polyp, but multiple polyps do occur occasionally. The majority are smooth, soft, reddish purple to cherry red, and fragile. They readily bleed when touched. Endocervical polyps may be single or multiple and are a few millimeters to 4 cm in diameter. The stalk of the polyp is of variable length and width (Fig. 18.22). Polyps may arise from either the endocervical canal (endocervical polyp) or ectocervix (cervical polyp). Endocervical polyps are more common than are cervical polyps. Often the terms *endocervical* and *cervical* polyps are used to describe the same abnormality. Polyps whose base is in the endocervix usually have a narrow, long pedicle and occur during the reproductive years, whereas polyps that arise from the ectocervix have a short, broad base and usually occur in postmenopausal women.

The hypothesis of the origin of endocervical polyps is that they are usually secondary to inflammation or abnormal focal responsiveness to hormonal stimulation. Focal hyperplasia and localized proliferation are the response of the cervix to local inflammation. The color of the polyp depends in part on its origin, with most endocervical polyps being cherry red and most cervical polyps grayish white.

The classic symptom of an endocervical polyp is intermenstrual bleeding, especially following contact such as coitus or a pelvic examination. Sometimes an associated leukorrhea emanates from the infected cervix. Many endocervical polyps are asymptomatic and recognized for the first time during a routine

speculum examination. Often the polyp seen on inspection is difficult to palpate because of its soft consistency.

Histologically the surface epithelium of the polyp is columnar or squamous epithelium, depending on the site of origin and the degree of squamous metaplasia (Fig. 18.23). The stalk is composed of an edematous, inflamed, loose, and richly vascular connective tissue. Six different histologic subtypes have been described: adenomatous, cystic, fibrous, vascular, inflammatory, and fibromyomatous. Greater than 80% are of the adenomatous type. During pregnancy, focal areas of decidual changes may develop in the stroma. Often there is ulceration of the stalk's most dependent portion, which explains the symptom of contact bleeding. Malignant degeneration of an endocervical polyp is extremely rare. The reported incidence is less than 1 in 200. Considerations in the differential diagnosis include endometrial polyps, small prolapsed myomas, retained products of conception, squamous papilloma, sarcoma, and cervical malignancy. Microglandular endocervical hyperplasia sometimes presents as a 1- to 2-cm polyp. This is an exaggerated histologic response, usually to oral contraceptives.

Most endocervical polyps may be managed in the office by grasping the base of the polyp with an appropriately sized clamp. The polyp is avulsed with a twisting motion and sent to the pathology laboratory for microscopic evaluation. The polyp is usually friable. If the base is broad or bleeding ensues, the base may be treated with chemical cautery, electrocautery, or cryocautery. After the polyp is removed, the endometrium should be evaluated in women older than 40 who have presented with abnormal bleeding, to rule out coexisting pathology, as significant endometrial pathology is found in approximately 5% of asymptomatic women with endocervical polyps.

NABOTHIAN CYSTS

Nabothian cysts are retention cysts of endocervical columnar cells occurring where a tunnel or cleft has been covered by squamous metaplasia. These cysts are so common that they are considered a normal feature of the adult cervix. Many women have

Figure 18.22 Cervical polyp. A large polyp protrudes from the external cervical os. The surface is red and rough, covered by endocervical epithelium. (From Anderson MC, Robboy SJ, Russell P, et al. The cervix—benign and non-neoplastic conditions. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

Figure 18.23 Cervical polyp. The stroma is fibromuscular and the base contains thick-walled blood vessels. Endocervical crypts, some dilated, are present within the polyp. (From Anderson MC, Robboy SJ, Russell P, et al. The cervix—benign and non-neoplastic conditions. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

multiple cysts. Grossly, these cysts may be translucent or opaque whitish or yellow in color. Nabothian cysts vary from microscopic to macroscopic size, with the majority between 3 mm and 3 cm in diameter. Rarely, a woman with several large nabothian cysts may develop gross enlargement of the cervix. These mucous retention cysts are produced by the spontaneous healing process of the cervix. The area of the transformation zone of the cervix is in an almost constant process of repair, and squamous metaplasia and inflammation may block the cleft of a gland orifice. The endocervical columnar cells continue to secrete, and thus a mucous retention cyst is formed. Nabothian cysts are asymptomatic, and no treatment is necessary.

LACERATIONS

Cervical lacerations may occur during obstetric deliveries. Obstetric lacerations vary from minor superficial tears to extensive full-thickness lacerations at 3 and 9 o'clock, respectively, which may extend into the broad ligament. Lacerations may occur in nonpregnant women with mechanical dilation of the cervix. The atrophic cervix of the postmenopausal woman increases the risk of cervical laceration when the cervix is mechanically dilated for dilation and curettage or hysteroscopy.

Acute cervical lacerations bleed and should be sutured. Cervical lacerations that are not repaired may give the external os of the cervix a fish-mouthed appearance; however, they are usually asymptomatic. The use of laminaria tents to slowly soften and dilate the cervix before mechanical instrumentation of the endometrial cavity has reduced the magnitude of iatrogenic cervical lacerations. Furthermore, the practice of routine inspection of the cervix following every second- or third-trimester delivery has enabled physicians to discover and repair extensive cervical lacerations. Extensive cervical lacerations, especially those involving the endocervical stroma, may lead to incompetence of the cervix during a subsequent pregnancy.

CERVICAL MYOMAS

Cervical myomas are smooth, firm masses that are similar to myomas of the fundus (Figs. 18.24 and 18.25). A cervical myoma is usually a solitary growth in contrast to uterine myomas, which in general, are multiple. Depending on the series, 3% to 8% of myomas are categorized as cervical myomas. Because of the relative paucity of smooth muscle fibers in the cervical stroma, the majority of myomas that appear to be cervical actually arise from the isthmus of the uterus.

Most cervical myomas are small and asymptomatic. When symptoms do occur, they are dependent on the direction in which the enlarging myoma expands. The expanding myoma produces symptoms secondary to mechanical pressure on adjacent organs. Cervical myomas may produce dysuria, urgency, urethral or ureteral obstruction, dyspareunia, or obstruction of the cervix. Occasionally a cervical myoma may become pedunculated and protrude through the external os of the cervix. These prolapsed myomas are often ulcerated and infected. A very large cervical myoma may produce distortion of the cervical canal and upper vagina. Rarely, a cervical myoma causes dystocia during childbirth.

The diagnosis of a cervical myoma is by inspection and palpation. Grossly and histologically, cervical myomas are identical to and indistinguishable from myomas of the corpus of the uterus.

Figure 18.24 Large fibroid originating from the lateral wall of the cervix and growing into the broad ligament. (Courtesy of Fidel A. Valea, MD.)

Figure 18.25 Posterior view of the uterus with a large fibroid that is prolapsing through a very dilated cervix and completely distorts the anatomy of the lower uterine segment. (Courtesy of Fidel A. Valea, MD.)

Occasionally the histologic picture of cervical myomas will demonstrate many hyalinized, thick-walled blood vessels that are postulated to be the source of the neoplastic smooth muscle tumor. This latter subtype of cervical myoma is termed a *vascular leiomyoma*. Management is similar to that of uterine myomas.

in that asymptomatic, small myomas may be observed for rate of growth. The occurrence and persistence of symptoms from a cervical myoma are an indication for medical therapy with gonadotropin-releasing hormone (GnRH) agonists or myomectomy or hysterectomy, depending on the patient's age and future reproductive plans. Treatment of cervical myomas that grow laterally may become a challenge if myomectomy is the operation of choice, because of both a complex blood supply and involvement with the distal course of the ureter. Cervical myomas may be treated by radiologic catheter embolization. Prolapsed uterine myomas are discussed later in this chapter.

CERVICAL STENOSIS

Cervical stenosis most often occurs in the region of the internal os. Cervical stenosis may be divided into congenital or acquired types. The causes of acquired cervical stenosis are operative, radiation, infection, neoplasia, or atrophic changes. Loop electrocautery excision procedure (LEEP), cone biopsy, and cautery of the cervix (either electrocautery or cryocoagulation) are the operations that most commonly associated with cervical stenosis. The volume of tissue removed and repeat excision procedures have been reported to increase the risk for cervical stenosis (Suh-Burgmann, 2000). The symptoms of cervical stenosis depend on whether the patient is premenopausal or postmenopausal and whether the obstruction is complete or partial. Common symptoms in premenopausal women include dysmenorrhea, pelvic pain, abnormal bleeding, amenorrhea, and infertility. The infertility is usually associated with endometriosis, which is commonly found in reproductive-age women with cervical stenosis. Postmenopausal women are usually asymptomatic for a long time. Slowly they develop a hematometra (blood), hydrometra (clear fluid), or pyometra (exudate).

The diagnosis is established by inability to introduce a 1- to 2-mm dilator into the uterine cavity. If the obstruction is complete, a soft, slightly tender, enlarged uterus is appreciated as a midline mass, and ultrasound examination demonstrating fluid within the uterine cavity. Management of cervical stenosis is dilation of the cervix with dilators under ultrasound guidance. If stenosis recurs, monthly laminaria tents may be used. Similarly, office follow-up and sounding of the cervix of women who have had a cone biopsy or cautery of the cervix is important to establish patency of the endocervical canal. Postmenopausal women with pyometra usually do not need antibiotics. After the acute infection has subsided, endometrial carcinoma and endocervical carcinoma should be ruled out by appropriate diagnostic biopsies. After cervical dilation, it is often useful to leave a T tube or latex nasopharyngeal airway as a stent in the cervical canal for a few days to maintain patency.

UTERUS

ULTRASOUND

Ultrasound, primarily endovaginal, is the most common and most efficient imaging technique for pelvic structures. For endovaginal ultrasound, transducers are configured on vaginal probes and placed in a sterile sheath, usually a glove or condom, prior to an examination. During the examination the woman is in a dorsal lithotomy position and has an empty bladder. Because

the transducer is closer to the pelvic organs than when a transabdominal approach is employed, endovaginal resolution is usually superior. However, if the pelvic structures to be studied have expanded and extend into the patient's abdomen, the organs are difficult to visualize with an endovaginal probe. Most ultrasound machines are equipped with both types of transducers.

For transabdominal gynecologic examinations, a sector scanner is preferable. It provides greater resolution of the pelvis and an easier examination than the linear array. During abdominal pelvic ultrasound examination, it is helpful for the patient to have a full bladder. This serves as an acoustic window for the high-frequency sound waves. Ultrasound is more than 90% accurate in recognizing the presence of a pelvic mass, but it does not establish a tissue diagnosis.

Ultrasonography employs an acoustic pulse echo technique. The transducer of the ultrasound machine is made up of piezoelectric crystals that vibrate and emit acoustic pulses. Acoustic echoes return from the tissues being scanned and cause the crystals to vibrate again and release an electric charge. A computer within the ultrasound machine then integrates the electric charges to form the image. Present equipment provides resolution of less than 0.2 mm.

Doppler ultrasound techniques assess the frequency of returning echoes to determine the velocity of moving structures. Measurement of diastolic and systolic velocities provides indirect indices of vascular resistance. Muscular arteries have high resistance. Newly developed vessels, such as those arising in malignancies, have little vascular wall musculature and thus have low resistance. Three-dimensional ultrasound is a computer technique in which multiple two-dimensional images are compiled to render either a surface- or volume-based image that appears to occupy space, as opposed to being flat. Three-dimensional ultrasound has of yet not been shown to have a specific diagnostic advantage in gynecology compared with other modalities.

A disadvantage of ultrasound is its poor penetration of bone and air; thus the pubic symphysis and air-filled intestines and rectum often inhibit visualization. Advantages of ultrasound include the real-time nature of the image, the absence of radiation, the ability to perform the procedure in the office before, during, or immediately after a pelvic examination, and the ability to describe the findings to the patient while she is watching. One of the most reassuring aspects of sonography is the absence of adverse clinical effects from the energy levels used in diagnostic studies.

Sonographic evaluation of endometrial pathology involves measurement of the endometrial thickness or stripe. The normal endometrial thickness is 4 mm or less in a postmenopausal woman not taking hormones. The thickness varies in premenopausal women at different times of the menstrual cycle and in women taking hormone replacement (Fig. 18.26); making endometrial thickness measurements less reliable in that setting. The endometrial thickness is measured in the longitudinal plane, from outer margin to outer margin, at the widest part of the endometrium. Ultrasound is not a screening tool in asymptomatic women. However, several studies of postmenopausal women with vaginal bleeding have documented that malignancy is extremely rare in women with an endometrial thickness of 4 mm or less. Systematic reviews have noted that ultrasound may be reliably used to predict 96% to 99% of endometrial cancers in women with postmenopausal bleeding. The flip side of the coin is that 1% to 4% of malignancies will be missed using a cutoff of less than 4 mm (Tabor, 2002). In addition, papillary-serous adenocarcinomas of

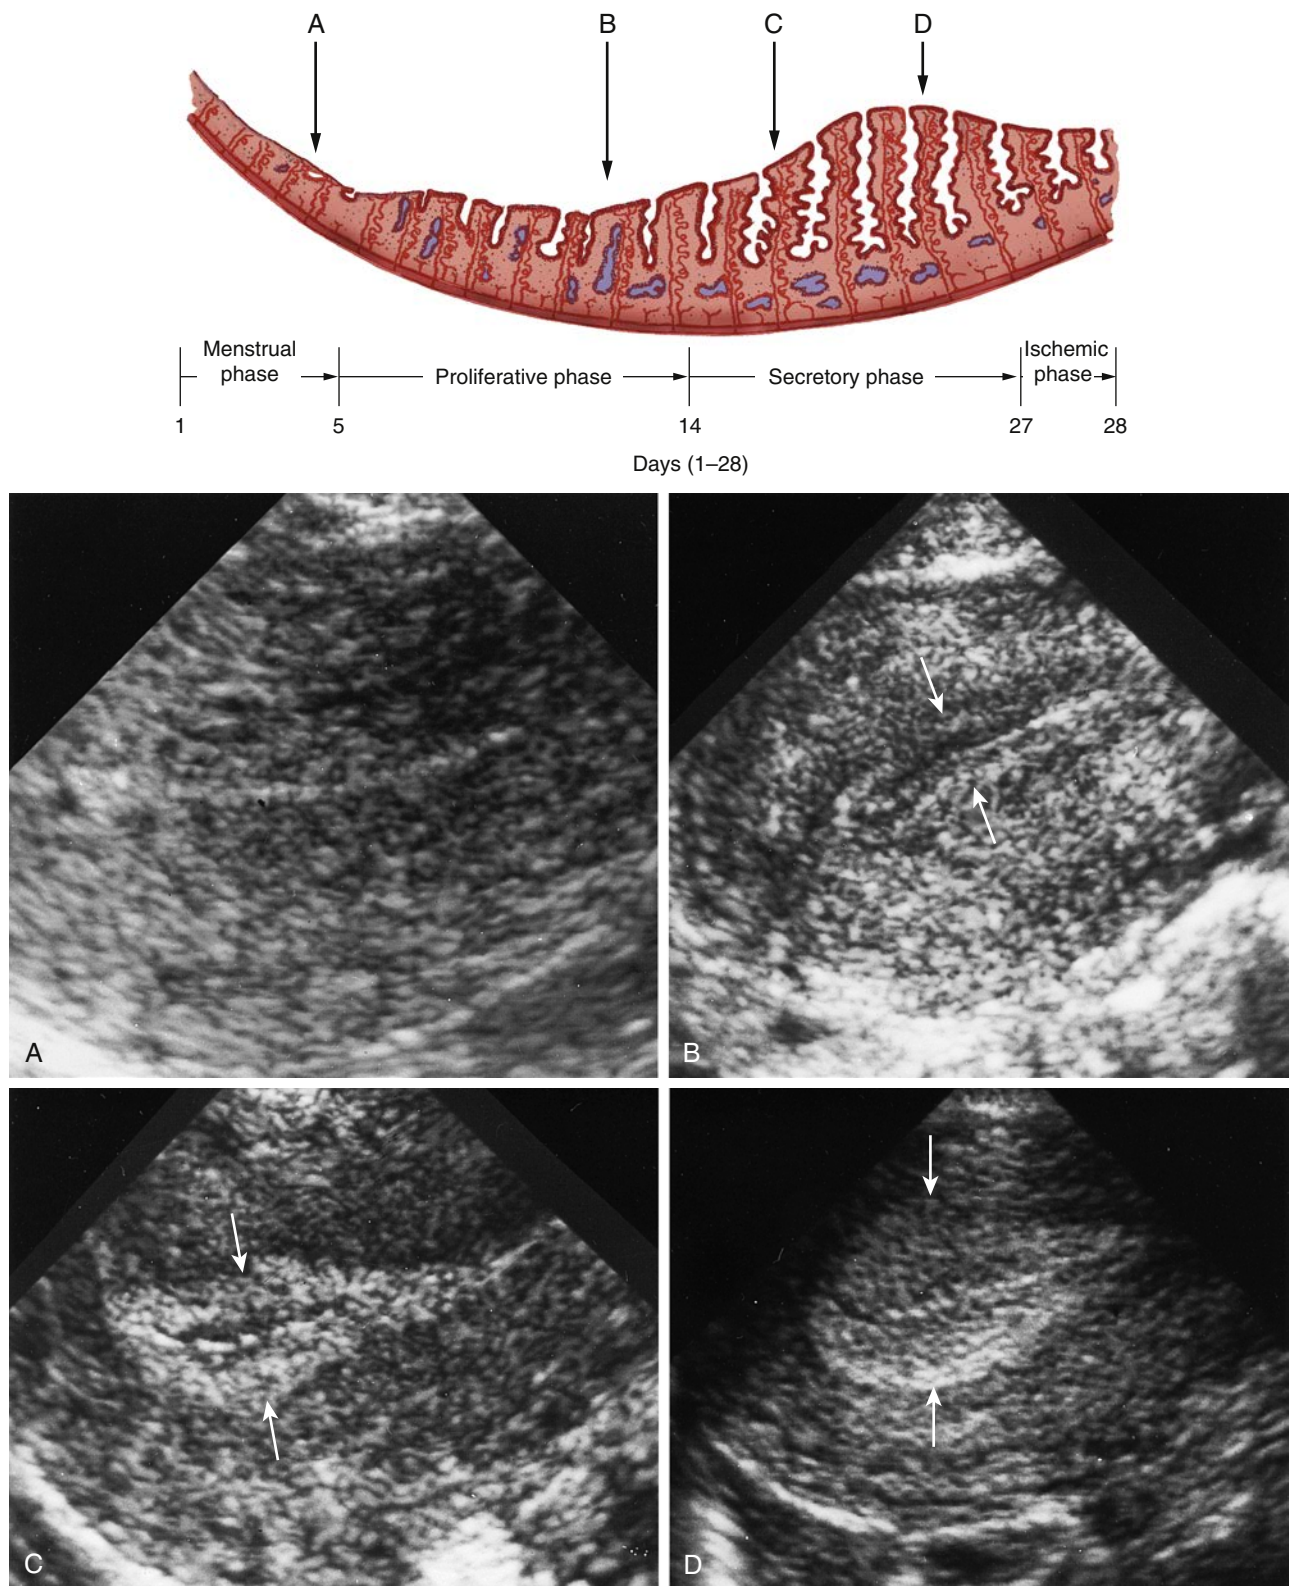

Figure 18.26 Variation in endometrium during menstrual cycle. **A**, Early proliferative phase. **B**, Late proliferative phase. **C**, Periovulatory phase. **D**, Late secretory phase. Note increase in endometrial thickness throughout the menstrual cycle. Also note multilayered appearance in the late proliferative phase. (From Fleischer AC, Kepple DM. Benign conditions of the uterus, cervix, and endometrium. In: Nyberg DA, Hill LM, Bohm-Velez M, et al, eds. *Transvaginal Ultrasound*. St. Louis: Mosby-Year Book; 1992.)

the endometrium do not always develop the same endometrial stripe thickness as endometrioid cancer. Two caveats for using ultrasound in screening of postmenopausal bleeding are (1) ultrasound does not provide a diagnosis—a tissue specimen is necessary for a diagnosis, and (2) all women with bleeding, no matter the endometrial thickness, should have a tissue biopsy. If an endometrial biopsy obtains inadequate tissue and the endometrial thickness is 5 mm or greater, a repeat biopsy, hysteroscopically directed biopsy, or curettage should be performed.

Sonohysterography is an easily accomplished and validated technique for evaluating the endometrial cavity. The technique involves instilling saline into the uterine cavity. Sonohysterography is an alternative to office hysteroscopy. In this procedure, a

thin balloon-tipped catheter or intrauterine insemination catheter is inserted through the cervical os, and 5 to 30 mL of warmed saline is slowly injected into the uterine cavity. Meta-analyses of sonohysterography have found the procedure to be successful in obtaining information in 95% of women, with minimal complications. Contraindications are active cervical or uterine infection. Some clinicians will have patients take a dose of ibuprofen prior to the procedure. Preferably, sonohysterography is performed in the proliferative phase of the cycle when the endometrial lining is at its lowest level. Sonohysterography has also been helpful in the evaluation of polyps, filling defects, submucous myomas, and uterine septae (Fig. 18.27). Importantly, sonohysterography, as with all types of ultrasound, does not make a tissue diagnosis.

Figure 18.27 Sonohysterograms. **A**, Well-defined, round echogenic polyp. **B**, Carpet of small polyps. **C**, Polyp on a stalk. **D**, Polyp with cystic areas. **E**, Small polyp. **F**, Small polyp. **G**, Hypoechoic submucosal fibroid. **H**, Hypoechoic attenuating submucosal fibroid. **I**, Endometrial adhesions. Note bridging bands of tissue within fluid-filled endometrial canal. (From Salem S. The uterus and adnexa. In Rumack CM, Wilson SR, Charboneau JW, eds. *Diagnostic Ultrasound*, 2nd ed. St. Louis: Mosby; 1998:538.)

Sonography is the method of choice to locate a “missing” intrauterine device (IUD). It will help in diagnosing perforation of the uterus or unrecognized expulsion of the device. Endovaginal ultrasound transducers equipped with needle guides are frequently used for oocyte aspiration as part of in vitro fertilization.

In summary, ultrasound has become an extremely valuable adjunct to the bimanual examination. In many patients, particularly obese patients, it is superior to perform bimanual examination alone. An endovaginal ultrasound of an early pregnancy has become a mainstay in the evaluation of the pregnant woman with first-trimester vaginal bleeding.

ENDOMETRIAL POLYPS

Endometrial polyps are localized overgrowths of endometrial glands and stroma that project beyond the surface of the endometrium. They are soft, pliable, and may be single or multiple. Most polyps arise from the fundus of the uterus. *Polypoid hyperplasia* is a benign condition in which numerous small polyps are discovered throughout the endometrial cavity. Endometrial polyps vary from a few millimeters to several centimeters in diameter, and it is possible for a single large polyp to fill the endometrial cavity. Endometrial polyps may have a broad base (sessile) or be attached by a slender pedicle (pedunculated). They occur in all age groups but have a peak incidence between the ages of 40 and 49. The prevalence of endometrial polyps in reproductive-age women is 20% to 25%. Endometrial polyps are noted in approximately 10% of women when the uterus is examined at autopsy. The cause of endometrial polyps is unknown. Because polyps are often associated with endometrial hyperplasia, unopposed estrogen has been implicated as a possible etiology.

The majority of endometrial polyps are asymptomatic. Those that are symptomatic are associated with a wide range of abnormal bleeding patterns. No single abnormal bleeding pattern is diagnostic for polyps; however, menorrhagia, premenstrual and postmenstrual staining, and scanty postmenstrual spotting are the most common. Occasionally a pedunculated endometrial polyp with a long pedicle may protrude from the external cervical os. Sometimes large endometrial polyps may contribute to infertility.

Polyps are succulent and velvety, with a large central vascular core. The color is usually gray or tan but may occasionally be red or brown. Histologically, an endometrial polyp has three components: endometrial glands, endometrial stroma, and central vascular channels (Figs. 18.27 and 18.28). Epithelium must be identified on three sides, like a peninsula. Approximately two of three polyps consist of an immature endometrium that does not respond to cyclic changes in circulating progesterone. This immature endometrium differs from surrounding endometrium and often appears as a “Swiss cheese” cystic hyperplasia during all phases of the menstrual cycle (Fig. 18.29). The other one third of endometrial polyps consist of functional endometria that will undergo cyclic histologic changes. The tip of a prolapsed polyp often undergoes squamous metaplasia, infection, or ulceration. The clinician cannot distinguish whether the abnormal bleeding originates from the polyp or is secondary to the frequently coexisting endometrial hyperplasia. Approximately one in four reproductive-age women with abnormal bleeding will have endometrial polyps discovered in her uterine cavity.

Figure 18.28 Endometrial polyp. **A**, Note cystic glands in the polyp. **B**, The fibrous stroma of the polyp contrasts with the cellular stroma of the adjacent endometrium. (From Anderson MC, Robboy SJ, Russell P, et al. Endometritis, metaplasias, polyps, and miscellaneous changes. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

Malignancy in an endometrial polyp is related to patient's age and is most often of a low stage and grade. In one series of 67 women from the UK with endometrial polyps, 86% were benign, 13% hyperplastic, and 3% malignant. Another series of 61 women with polyps found 88% were benign and 5% were malignant. A recent review and meta-analysis of the oncogenic potential of endometrial polyps reported among women found to have endometrial polyps; the prevalence of premalignant or malignant polyps was 5.42% in postmenopausal women compared with 1.7% in reproductive aged women. Furthermore, the prevalence of endometrial neoplasia within polyps in women with symptomatic bleeding was 4.15% compared with 2.16% for those without bleeding. Among symptomatic postmenopausal women with endometrial polyps, 4.47% had a malignant polyp compared with 1.51% in asymptomatic postmenopausal women (Lee, 2010). The question of an association with endometrial polyps and endometrial carcinoma is still debated.

Endometritis, metaplasias, polyps and miscellaneous changes. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

Figure 18.30 Endocervical polyp was seen at hysteroscopy. (From Goldberg JM, Falcone T. *Atlas of Endoscopic Techniques in Gynecology*. London: WB Saunders; 2000.)

A population-based, case-control study from Sweden estimated that the increased risk of subsequent endometrial carcinoma in women with endometrial polyps is only twofold. It is interesting that benign polyps have been found in approximately 20% of uteri removed for endometrial carcinoma.

Unusual polyps have been described in association with chronic administration of the nonsteroidal antiestrogen tamoxifen. The endometrial abnormalities associated with chronic tamoxifen therapy include polyps, 20% to 35%; endometrial hyperplasia, 2% to 4%; endometrial carcinoma, 1% to 2%; and often with multiple irregular sonolucencies suggesting the presence of cysts.

Most endometrial polyps are asymptomatic, and the diagnosis is not usually established until the uterus is opened following hysterectomy for other reasons. Endometrial polyps may be discovered by vaginal ultrasound, with or without hydrosalpingography, hysteroscopy, or hysterosalpingography during the diagnostic workup of a woman with a refractory case of abnormal uterine bleeding or pelvic

mass. Endometrial polyps are frequently confused with endocervical polyps (Fig. 18.30). A well-defined, uniformly hyperechoic mass that is less than 2 cm in diameter, identified by vaginal ultrasound within the endometrial cavity, is usually a benign endometrial polyp (see Fig. 18.27, A-C). Most endometrial polyps usually resolve after a few years, although new polyps can form.

The optimal management of endometrial polyps is removal by hysteroscopy with D&C. Because of the frequent association of endometrial polyps and other endometrial pathology, it is important to examine histologically both the polyp and the associated endometrial lining. Polyps, because of their mobility, often tend to elude the curette. Postcurettage hysteroscopic studies have demonstrated that routine use of a long, narrow polyp forceps at the time of curettage at best results in discovery and removal of only approximately one in four endometrial polyps. The differential diagnosis of endometrial polyps includes submucous leiomyomas, adenomyomas, retained products of conception, endometrial hyperplasia, carcinoma, and uterine sarcomas.

HEMATOMETRA

A hematometra is a uterus distended with blood and is secondary to gynatresia, which is partial or complete obstruction of any portion of the lower genital tract. Obstruction of the isthmus of the uterus, cervix, or vagina may be congenital or acquired. The two most common congenital causes of hematometra are an imperforate hymen and a transverse vaginal septum. Among the leading causes of acquired lower tract stenosis are senile atrophy of the endocervical canal and endometrium, scarring of the isthmus by synechiae, cervical stenosis associated with surgery, radiation therapy, cryocautery or electrocautery, endometrial ablation, and malignant disease of the endocervical canal.

The symptoms of hematometra depend on the age of the patient, her menstrual history and the rapidity of the accumulation of blood in the uterine cavity, and the possibility of secondary infection producing pyometra. Thus common symptoms of hematometra include primary or secondary amenorrhea and possibly cyclic lower abdominal pain. During the early teenage years, the combination of primary amenorrhea and cyclic, episodic cramping lower abdominal pains suggests the possibility of a developing hematometra. Occasionally the obstruction is incomplete, and there is associated spotting of dark brown blood. Hematometra in postmenopausal women may be entirely asymptomatic. On pelvic examination a mildly tender, globular uterus is usually palpated. Ultrasound may be used to confirm the diagnosis.

The diagnosis of hematometra is generally suspected by the history of amenorrhea and cyclic abdominal pain. The diagnosis is usually confirmed by vaginal ultrasound or probing the cervix with a narrow metal dilator, with release of dark brownish black blood from the endocervical canal. Sometimes the blood retained inside the uterus becomes secondarily infected and has a foul odor.

Management of hematometra depends on operative relief of the lower tract obstruction. Treatment of congenital obstruction is discussed in Chapter 11. Appropriate biopsy specimens of the endocervical canal and endometrium should be obtained to rule out malignancy when the cause of hematometra is not obvious. If the uterus is significantly enlarged or if there is any suspicion that the retained fluid is infected, drainage should be accomplished first. Biopsy should be postponed for approximately 2 weeks to diminish the chances of infection or uterine

perforation. Hematometra following operations or cryocautery usually resolves with cervical dilation. Rarely, a hematometra may form following a first-trimester abortion. This is treated by repeat suction aspiration of the products of conception that are blocking the internal os.

LEIOMYOMAS

Leiomyomas, also called *myomas*, are benign tumors of muscle cell origin. These tumors are often referred to by their popular names, *fibroids* or *fibromyomas*, but such terms are semantic misnomers if one is referring to the cell of origin. Most leiomyomas contain varying amounts of fibrous tissue, which is believed to be secondary to degeneration of some of the smooth muscle cells.

Leiomyomas are the most common benign neoplasms of the uterus. The lifetime prevalence of leiomyomas is greater than 80% among African-American women and approaches 70% among white women (Baird, 2003). In general, a third of myomas will become symptomatic causing abnormal and excessive uterine bleeding, pelvic pain, pelvic pressure, bowel and bladder dysfunction, infertility, recurrent miscarriage, and abdominal protrusion. Leiomyomas are a tremendous public health burden and the most frequent indication for hysterectomy in the United States. There are significant health disparities for African-American women with fibroids (Eltoukhi, 2014). Approximately 42 per 1000 women are hospitalized annually because of fibroids, but African-American women have higher rates of hospitalization, myomectomies, and hysterectomies compared with white women (relative risk [RR] of 3.5, 6.8, and 2.4, respectively) (Wechter, 2011). In black women, vitamin D deficiency has been linked with increased fibroid risk (Baird, 2013). Why some women develop myomas while others do not is unknown. Therefore effective treatment is limited by the poor understanding of their pathogenesis.

Risk factors associated with the development of myomata include increasing age, early menarche, low parity, tamoxifen use, obesity, and in some studies a high-fat diet. Smoking has been found to be associated with a decreased incidence of myomata. African-American women have the highest incidence, whereas Hispanic and Asian women have similar rates to white women. There appears to be a familial tendency to develop myoma. Studies of twins have noted that when identical and fraternal twins are compared, a significant proportion of myoma tend to have an inherited basis. Rare genetic conditions such as hereditary leiomyomatosis and renal cell cancer (Launond, 2001) and Alport syndrome (Uliana, 2011) feature development of myomas. The growth of myomas is dependent on gonadal steroids, and there are increased numbers of steroid receptors in myomas compared with normal myometrium. They are diagnosed only after menarche and tend to regress after menopause (Okolo, 2008). They have a limited malignant potential with less than 1% transformation into malignancy. Cytogenetically, the most fibroids are chromosomally normal and arise from a single cell (are clonal). However, the remainder share similar tumor-specific chromosomal rearrangements that are associated with tumor growth (Levy, 2012). Although fibroids are clonal in nature, heterogeneity exists and they may vary greatly in size, location, and appearance within the same

Figure 18.31 Image of large fibroid uterus prior to hysterectomy. (Courtesy of Fidel A. Valea, MD.)

uterus. There is accumulating evidence that suggests hypoxia is implicated in early cellular events that lead to the myometrial smooth muscle cell to transform into leiomyoma (Tal, 2014). Angiogenesis and vascularization are factors that control the growth of tumors. Tal and Segars reviewed the molecular regulation of the growth factors involved in angiogenesis of fibroids and described the potential implications for future therapy (Tal, 2014).

Although leiomyomas arise throughout the body in any structure containing smooth muscle, in the pelvis the majority are found in the corpus of the uterus. Occasionally, leiomyomas may be found in the fallopian tube or the round ligament, and approximately 5% of uterine myomas originate from the cervix. Rarely, myomas will arise in the retroperitoneum and produce symptoms secondary to “mass effects” on adjacent organs.

Myomas may be single but most often are multiple. They vary greatly in size from microscopic to multinodular uterine tumors that may weigh more than 50 pounds and literally fill the patient's abdomen (Fig. 18.31). Initially most myomas develop from the myometrium, beginning as intramural myomas. As they grow, they remain attached to the myometrium with a pedicle of varying width and thickness. Small myomas are round, firm, solid tumors. With continued growth, the myometrium at the edge of the tumor is compressed and forms a pseudocapsule. Although myomas do not have a true capsule, this pseudocapsule is a valuable surgical plane during a myomectomy.

Myomas are classed into subgroups by their relative anatomic relationship and position to the layers of the uterus (Fig. 18.32). The three most common types of myomas are intramural, subserous, and submucous, with special nomenclature for broad ligament and parasitic myomas (Fig. 18.33). Continued growth in one direction determines which myomas will be located just below the endometrium (submucosal) and which will be found just

Figure 18.32 Drawing of cut surface of uterus showing characteristic whorl-like appearance and varying locations of leiomyomas. (From Novak ER, Woodruff JD, eds. *Novak's Gynecologic and Obstetric Pathology*. 6th ed. Philadelphia: WB Saunders; 1967:215.)

Figure 18.33 Multiple leiomyomas. These are predominantly intramural. The bulging cut surfaces are clearly shown. (From Anderson MC, Robboy SJ, Russell P. Uterine smooth muscle tumors. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

beneath the serosa (subserosal) (Fig. 18.34). Although only 5% to 10% of myomas become submucosal, they usually are the most troublesome clinically (Fig. 18.35). These submucosal tumors may be associated with abnormal vaginal bleeding or distortion of the uterine cavity that may produce infertility or miscarriage. Rarely, a submucosal myoma enlarges and becomes pedunculated. The uterus will try to expel it, and the prolapsed myoma may protrude through the external cervical os (see Fig. 18.25).

Subserosal myomas give the uterus its knobby contour during pelvic examination. Further growth of a subserosal myoma may lead to a pedunculated myoma wandering into the peritoneal cavity. This myoma may outgrow its uterine blood supply and obtain a secondary blood supply from another organ, such as the omentum, and become a parasitic myoma. Growth of a myoma in a lateral direction from the uterus may result in a broad ligament myoma (see Fig. 18.24). The clinical significance of broad ligament myomas is that they are difficult to differentiate on pelvic examination from a solid ovarian tumor. Large, broad ligament myomas may produce a hydronephrosis as they enlarge.

Though the origin of uterine leiomyomas is incompletely understood, cytogenetic studies have yielded some clues to how and why myomas develop. Each tumor develops from a single muscle cell a progenitor myocyte, thus each myoma is monoclonal. Cytogenetic analysis has demonstrated that myomas have

Figure 18.34 A, Large subserosal myoma. B, Hysterectomy specimen of myomatous uterus. (Courtesy of Vern L. Katz and William Droegemueller.)

multiple chromosomal abnormalities. (Each myoma would have cells with the same abnormality.) Sixty percent are normal, 46XX. The larger the myoma, the more an abnormal karyotype will be detected. Interestingly, the chromosomal anomalies of myomata have a remarkable clustering of changes. Twenty percent of abnormalities involve translocations between chromosomes 12 and 14. Seventeen percent involve a deletion of chromosome 7. Twelve percent involve a deletion of chromosome 12, and some

Figure 18.35 Uterus with multiple myomata. Note the large central submucosal myoma. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

are trisomy 12. The affected regions on chromosome 12 are also abnormal in many other types of solid tumors. The regions of chromosome 12 and 7 involve genes that may regulate growth-inducing proteins and cytokines, including transforming growth factor β (TGF- β), epidermal growth factor (EGF), insulin-like growth factors (IGF) 1 and 2, and platelet-derived growth factor (PDGF) (Fig. 18.36). Many of these cytokines have been found in significantly higher concentrations in myomas than in the surrounding myometrium. Current theory holds that the neoplastic transformation from normal myometrium to leiomyomata is the result of a somatic mutation in the single progenitor cell. The mutation then affects cytokines that affect cell growth. The growth may also be influenced by the relative levels of estrogen or progesterone. Both estrogen and progesterone receptors are found in higher concentrations in uterine myomas, as are other genomic changes that potentiate cellular proliferation. There also appear to be similarities between fibroids and keloid formation. Interestingly, Ishikawa and colleagues noted that myoma cells have an increased expression of aromatase, which further potentiates more local estrogen. Interestingly, African-American women had the highest levels of aromatase in myoma cells (Ishikawa, 2009).

Myomas are rare before menarche, and most myomas diminish in size following menopause with the reduction of a significant amount of circulating estrogen. Myomas often enlarge during pregnancy and occasionally enlarge secondary to oral contraceptive therapy. Medically induced hypoestrogenic states produce reductions in the size of myomas. Women who smoke cigarettes and are thus relatively estrogen-deficient have a lower

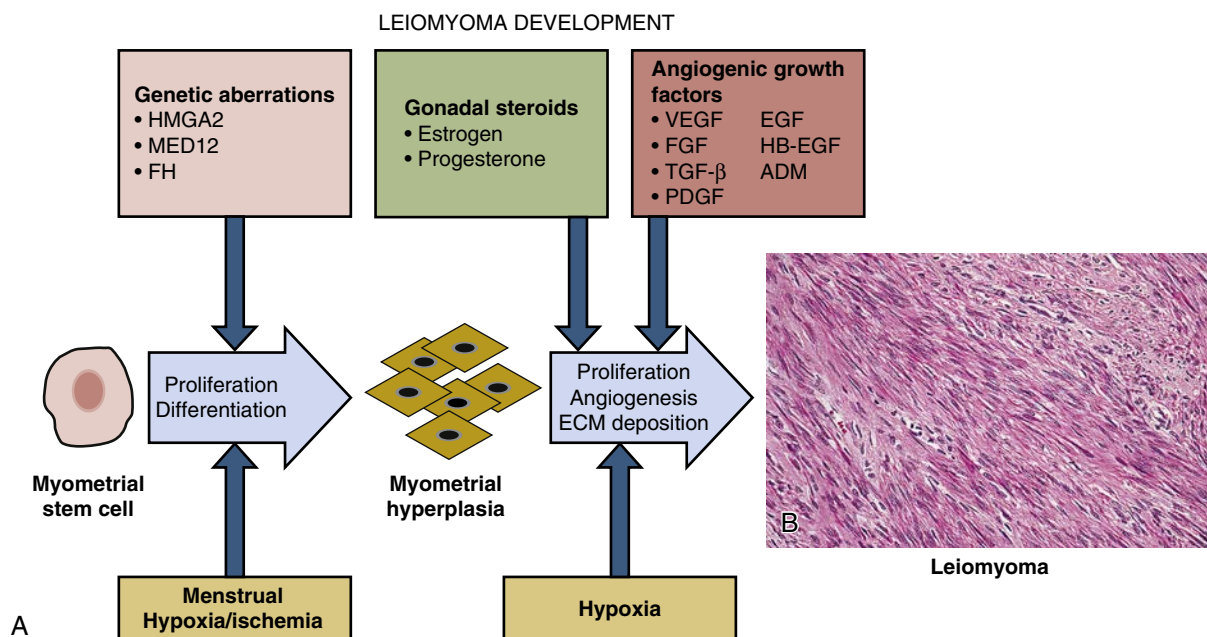

Figure 18.36 **A**, Leiomyoma development. **B**, Leiomyoma. The smooth muscle cells are markedly elongated and have eosinophilic cytoplasm and elongated, cigar-shaped nuclei. The nuclei are uniform and mitotic figures absent or sparse. (**A**, Modified from Tal R, Segars JH. The role of angiogenic factors in fibroid pathogenesis: potential implications for future therapy. *Hum Reprod Update*. 2014; 20[2]:194-216. **B**, From Anderson MC, Robboy SJ, Russell P. Uterine smooth muscle tumors. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

incidence of myomas. Many women, though, have small myomas that do not grow under the influence of high circulating estrogen levels. Thus the relationship between estrogen and progesterone levels and myoma growth is complex.

Grossly, a myoma has a lighter color than the normal myometrium. On a cut surface, the tumor has a glistening, pearl-white appearance, with the smooth muscle arranged in a trabeculated or whorled configuration. Histologically there is a proliferation of mature smooth muscle cells. The nonstriated muscle fibers are arranged in interlacing bundles. Between bundles of smooth muscle cells are variable amounts of fibrous connective tissue, especially toward the center of any large tumor (see Fig. 18.36). The amount of fibrous tissue is proportional to the extent of atrophy and degeneration that has occurred over time. The intracellular structure of myoma cells is different from the surrounding normal myometrium. The abnormal cells contain more

collagen and what has been described as a “stiffer” cytoskeleton secondary to the intracellular pressure generated by the densely packed surrounding myoma. Less than 5% of myomas exhibit hypercellularity, and these are termed *cellular leiomyomata*. Cellular leiomyomata tend to be larger in size and solitary. There is less accompanying adenomyosis or other uterine pathology. The clinical presentation of cellular leiomyoma is more similar to that of a sarcoma (leiomyosarcoma). Other authors have noted a genomic expression that is similar, as well, to leiomyosarcomas. However, cellular leiomyomata are not precursors to sarcoma and have a benign prognosis.

The eventual fate of some myomas is determined by their relatively poor vascular supply. This supply is found in one or two major arteries at the base or pedicle of the myoma. The arterial supply of myomas is significantly less than that of a similarly sized area of normal myometrium. Thus with continued growth, degeneration occurs because the tumor outgrows its blood supply. The severity of the discrepancy between the myoma's growth and its blood supply determines the extent of degeneration: hyaline, myxomatous, calcific, cystic, fatty, or red degeneration and necrosis. The mildest form of degeneration of a myoma is hyaline degeneration (Fig. 18.37). Grossly, in this condition the surface of the myoma is homogeneous with loss of the whorled pattern. Histologically, with hyaline degeneration, cellular detail is lost as the smooth muscle cells are replaced by fibrous connective tissue. Huang and colleagues, using transvaginal color Doppler ultrasound, documented that the intratumoral blood flow correlated with reduced tumor size and tumor volume but did not correlate with angiogenesis or cell proliferation (Huang, 1996).

The most acute form of degeneration is red, or carneous, infarction (Fig. 18.38). This acute muscular infarction causes severe pain and localized peritoneal irritation. This form of degeneration occurs during pregnancy in approximately 5% to 10% of gravid women with myomas. The condition is best treated with nonsteroidal anti-inflammatory agents for 72 hours, as long as the woman is less than 32 weeks' gestation. The ultrasound appearance of painful myomas is one of mixed echodense and echolucent areas. Serial ultrasound examinations have also

Figure 18.37 Hyaline degeneration is a leiomyoma. There is an eosinophilic ground-glass appearance. (From Anderson MC, Robboy SJ, Russell P. Uterine smooth muscle tumors. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

Figure 18.38 **A**, Gross view of an infarcted leiomyoma. **B**, Red degeneration; the ghosts of the muscle cells and their nuclei remain. (**A**, From Anderson MC, Robboy SJ, Russell P. Uterine smooth muscle tumors. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002. **B**, From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

demonstrated that most (80%) myomas do not change size during pregnancy; if a change in size does occur, it is usually not associated with painful symptomatology. During pregnancy this complication should be treated medically, for attempts at operative removal may result in profuse blood loss. If the patient is not pregnant, acute degeneration is not a contraindication to myomectomy. The more advanced forms of degenerating myomas may become secondarily infected, especially when large necrotic areas exist. The histologic changes of degeneration are found more commonly in larger myomas. However, two thirds of all myomas show some degree of degeneration, with the three most common types being hyaline degeneration (65%), myxomatous degeneration (15%), and calcific degeneration (10%).

The literature emphasizes that the incidence of malignant degeneration is estimated to be between 0.3% and 0.7%. The term *malignant degeneration* is incorrect. It is unknown as to whether myomas degenerate into sarcomas. Given the very high prevalence of myomas, most investigators believe that sarcomas arise spontaneously in myomatous uteri. A meta-analysis of the prevalence of occult leiomyosarcoma found at surgery for presumed uterine fibroids estimated the rate of leiomyosarcoma to be 0.51 per 1000 procedures (confidence interval [CI] = 0.16 to 0.98) or approximately 1 in 2000. If only the prospective studies were included (64 studies), there was a substantially lower estimate of 0.12 leiomyosarcomas per 1000 procedures (CI = 0.01 to 0.75) or 1 in 8300 surgeries (Pritts, 2015). The possibility of a uterine tumor being a leiomyoma sarcoma is 10 times greater in a woman in her 60s than in a woman in her 40s.

The most common symptoms related to myomas are pressure from an enlarging pelvic mass, pain including dysmenorrhea, and abnormal uterine bleeding. The severity of symptoms is usually related to the number, location, and size of the myomas. However, over two thirds of women with uterine myomas are asymptomatic.

One of three women with myomas experiences pelvic pain or pressure. Acquired dysmenorrhea is one of the most frequent complaints. Various forms of vascular compromise, either acute degeneration or torsion of the pedicle, produce severe pelvic pain. Mild pelvic discomfort is described as pelvic heaviness or a dull, aching sensation that may be secondary to edematous swelling in the myoma. An enlarged myoma or myomas often produce pressure symptoms similar to those of an enlarging pregnant uterus. Sometimes a woman will notice that her abdominal girth is increasing without appreciable change in weight. Alternatively, an anterior myoma pressing on the bladder may produce urinary frequency and urgency. In general, urinary symptoms are more common than rectal symptoms. Extremely large myomas and broad ligament myomas may produce a unilateral or bilateral hydronephrosis.

Abnormal bleeding is experienced by 30% of women with myomas. The most common symptom is menorrhagia, but intermenstrual spotting and disruption of a normal pattern are other frequent complaints. Wegienka and colleagues evaluated the bleeding pattern of 596 women with myomas. Compared with a control group, bleeding was more frequently described as gushing. Menses were longer in duration and heavier. In this study, symptoms of bleeding were related to the size of myomas. Interestingly, the location of the myomas, submucous versus intramural, was not related to bleeding symptoms (Wegienka, 2003). The exact cause-and-effect relationship between myomas

and abnormal bleeding is difficult to determine and is poorly understood. The explanation is straightforward when there are areas of ulceration over submucous myomas. However, ulceration is a rare finding. The most popular theory is that myomas result in an abnormal microvascular growth pattern and function of the vessels in the adjacent endometrium. The older theory that the amount of menorrhagia is directly related to an increase of endometrial surface area has been disproved. One of three women with abnormal bleeding and submucous myomas also has endometrial hyperplasia, which may be the cause of the symptom.

Occasionally, myomas are the only identifiable abnormality after a detailed infertility investigation. Because the data relating myomas to infertility are weak, myomectomy is indicated only in long-standing infertility and recurrent abortion after all other potential factors have been investigated and treated. Studies suggest that submucous myomas that distort the uterine cavity are the myomas that may affect reproduction. Successful full-term pregnancy rates of 40% to 50% have been reported following a myomectomy. The success of an operation is most dependent on the age of the patient, the size of the myomas, and the number of compounding factors that affect the couple's fertility. A Cochrane review of the surgical treatment of fibroids for subfertility noted "insufficient evidence from randomized controlled trials to evaluate the role of myomectomy to improve fertility" (Metwally, 2012).

Rapid growth of a uterine myoma after menopause is a disturbing symptom. This is the classic symptom of a leiomyosarcoma; however, fibroids can have growth spurts, and most guidelines (but not all) suggest rapid growth is not necessarily an indication for treatment (Stewart, 2015). Rarely, a secondary polycythemia is noted in women with uterine myomas. This syndrome is related to elevated levels of erythropoietin. The polycythemia diminishes following removal of the uterus.

Clinically, the diagnosis of uterine myomas is usually confirmed by physical examination. Upon palpation, an enlarged, firm, irregular uterus may be felt. The three conditions that commonly enter into the differential diagnosis are pregnancy, adenomyosis, and an ovarian neoplasm. The discrimination between large ovarian tumors and myomatous uteri may be difficult on physical examination, because the extension of myomas laterally may make palpation of normal ovaries impossible during the pelvic examination. The mobility of the pelvic mass and whether the mass moves independently or as part of the uterus may be helpful diagnostically. Ultrasound is diagnostic; it can easily differentiate fibroids from a pregnant uterus or adnexal mass (Stewart, 2015). Submucosal myomas may be diagnosed by vaginal ultrasound, sonohysterography, hysteroscopy, or as a filling defect on hysterosalpingography. Occasionally, an abdominal pelvic radiograph will note concentric calcifications. Several reports promote CT and MRI studies of uterine myomas. However, these imaging techniques are more expensive than ultrasound. Until CT and MRI can distinguish between benign and malignant myomas, they will rarely be ordered in routine clinical management of myomas. MRI is helpful in differentiating adenomyosis or an adenomyoma from a single, solitary myoma, especially in a woman desiring preservation of her fertility. MRI with gadolinium contrast can also provide information on vascularized (degenerated) fibroids and more detail on the location of fibroids with respect to endometrial, intramural, or serosal

(Stewart, 2015). Serial ultrasound examinations have been used to evaluate progression in the size of myomas or response to therapy, although there is a strong correlation between pelvic exam and ultrasound, in determining the size of myomas.

The management of small, asymptomatic myomas is judicious observation. When the tumor is first discovered, it is appropriate to perform a pelvic examination at 6-month intervals to determine the rate of growth. The majority of women will not need surgery, especially those women in the perimenopausal period, where the condition usually improves with diminishing levels of circulating estrogens.

Cases of abnormal bleeding and leiomyomas should be investigated thoroughly for concurrent problems such as endometrial hyperplasia. If symptoms do not improve with conservative management, operative therapy may be considered. The choice between a myomectomy and hysterectomy is usually determined by the patient's age, parity, and, most important, future reproductive plans. Myomectomy is associated with longer hospital stays and more pelvic adhesions than hysterectomy. Studies suggest that myomectomy results in approximately 80% resolution of symptoms. Hysterectomy is associated with a greater than 90% patient satisfaction rate, though hysterectomy has a higher rate of urinary tract injuries, particularly abdominal hysterectomy. When myomectomies are performed to preserve fertility, care must be taken to avoid adhesions, which may compromise the goal of the operation. In the past, full-thickness myomectomies (surgeries that entered the endometrial cavity) were considered an indication for cesarean delivery prior to labor. Currently, most clinicians recommend strong consideration for cesarean section for all degrees of myomectomy other than removal of a pedunculated leiomyomata or small hysteroscopic resection.

Classic indications for a myomectomy include persistent abnormal bleeding, pain or pressure, or enlargement of an asymptomatic myoma to more than 8 cm in a woman who has not completed childbearing. The causal relationship of myomas and adverse reproductive outcomes is poorly understood. Long-standing infertility or repetitive abortion directly related to myomas is rare. Contraindications to a myomectomy include pregnancy, advanced adnexal disease, malignancy, and the situation in which enucleation of the myoma would severely reduce endometrial surface so that the uterus would not be functional. The choice between the two operations is not always an easy one.

Within 20 years of the myomectomy operation, one in four women subsequently has a hysterectomy performed, the majority for recurrent leiomyomas. Myomectomy may be performed in selected women using laparoscopic techniques. Hurst and associates have emphasized careful, multilayer closure and the use of antiadhesive barriers (Hurst, 2005). Some centers excise uterine myomas vaginally using an anterior or posterior colpotomy. They believe that vaginal myomectomy is an alternative surgical plan even in women with moderately enlarged tumors. Submucous myomas may be resected via the cervical canal using the hysteroscope. Although preliminary studies using laser surgery have been reported, most investigators advocate using an operative resectoscope. Three out of four women have long-term relief of their menorrhagia secondary to uterine myomas following hysteroscopic resection of the myomas.

The indications for hysterectomy for myomas are similar to indications for myomectomy, with a few additions. Some gynecologists selectively perform a hysterectomy for asymptomatic

myomas when the uterus has reached the size of a 14- to 16-week gestation. The hypothesis is that most myomas of this size will eventually produce symptoms. However, it is impossible to predict which individual woman will develop symptoms. Rapid growth of a myoma after menopause warrants investigation and consideration for surgery. Prolapse of a myoma through the cervix is optimally treated by vaginal removal and ligation of the base of the myoma, with antibiotic coverage. Hysteroscopic resection aids the transvaginal removal of a prolapsed myoma.

There has been much controversy regarding the prevalence of undiagnosed uterine cancers among women with presumed benign fibroids at the time of hysterectomy. Morcellation is the process by which a large portion of tissue is divided into smaller pieces. The benefit of morcellation is the ability to perform a hysterectomy or myomectomy in a minimally invasive fashion, avoiding an open abdominal incision and the associated longer recovery time and higher mortality rate (Lawrence, 2014). This can be accomplished manually (i.e., with a scalpel or scissors) or via a rapidly rotating blade known as a *power morcellator*. The use of power morcellation may spread unsuspected cancer during surgery for treatment of symptomatic fibroids. There is no evidence that manual morcellation vaginally or abdominally eliminates this risk (ACOG, 2014). Wright reported that among women undergoing minimally invasive hysterectomy with morcellation, the risk of uterine cancer was 1 in 300 in women younger than 40 years of age and 1 in 1500 in women 40 to 44 years old (Wright, 2014). The Food and Drug Administration (FDA) recommends against the use of laparoscopic power morcellators in the majority of women undergoing myomectomy or hysterectomy for treatment of fibroids, thereby significantly limiting the use of morcellation to hysterectomy in premenopausal women who are not candidates for en bloc resection, and only after counseling women about the risks of power morcellation and the potential spread of cancer and offering alternatives such as morcellation in a bag that some centers are performing (USFDA, 2014). The use of an intraperitoneal bag for morcellation has been proposed to reduce tissue dissemination. Unfortunately, the current intraperitoneal bags are not designed for concurrent use with a power morcellator (ACOG, 2014).

For women undergoing minimally invasive surgery for symptomatic fibroids, preoperative considerations must be made regarding age, menopausal status, hereditary factors, uterine size, rapid uterine growth, endometrial sampling, cervical cytology, and pelvic imaging. Informed consent for these procedures should include a discussion of the risks and benefits of power morcellation. If after careful review malignancy is strongly suspected or known, then power morcellation must be avoided. After the FDA statement was released, a systematic review and meta-analysis were performed investigating survival outcomes of patients with unexpected uterine leiomyosarcoma. The pooled analysis showed a threefold increased risk of overall recurrence and fourfold increased risk of intraabdominal recurrence of leiomyosarcoma in patients undergoing uterine morcellation, whereas no increased risk of extraabdominal recurrence was demonstrated (Bogani, 2015). The data sampled were limited due to small sample size and the retrospective nature of the studies, thus more research is needed to determine the true impact of morcellation on unsuspected cancer and disease prognosis. Nonetheless, the impact of the FDA warning on clinical practice

has become quickly evident. A survey of American Association of Gynecologic Laparoscopists (AAGL) and American College of Obstetricians and Gynecologists (ACOG) members showed nearly half of the respondents had increased their rate of laparotomy and nearly three quarters stopped using power morcellation during hysterectomy and myomectomy primarily due to hospital mandate, although they did not believe it resulted in improved patient outcomes (Lum, 2016).

It is possible to treat leiomyomas medically by reducing the circulating level of estrogen and progesterone. GnRH agonists, medroxyprogesterone acetate (Depo-Provera), danazol, aromatase inhibitors, and the antiprogesterone RU 486 have undergone clinical trials. Randomized controlled trials of 5 and 10 mg of mifepristone (RU486) have shown significant reduction in size, bleeding, and improvement in quality of life. Mifepristone acts through inhibition of progesterone receptors. Daily administration of 5 mg and 10 mg has shown uterine volume reductions of 48% and 52% after 1 year for both doses. Amenorrhea occurred in 65% of the women in 6 months and in 705 within a year. However, long-term use is controversial due to the potential of inducing endometrial pathology (Eisinger, 2005). The use of GnRH agonists, sometimes with add-back hormonal therapy, has also been successful in treating myomas. A Cochrane review on add-back therapy with GnRH analogues for uterine fibroids concluded there was low or moderate evidence that tibolone, raloxifene, estriol, and ipriflavone help preserve bone density and medroxyprogesterone acetate (MPA) and tibolone may reduce vasomotor symptoms. The studies included assessed only short-term (within 12 months) effectiveness and safety. Larger uterine volume was an adverse effect associated with some of the therapies (MPA, tibolone, and conjugated estrogens) (Moroni, 2015). Reductions in mean uterine volume and myoma size by 40% to 50% have been documented. However, individual responses vary greatly. With medical treatments, most of the size reductions occur within the first 3 months. After cessation of therapy, myomas gradually resume their pretreatment size. By 6 months after treatment, most myomas will have returned to their original size. During treatment, Doppler flow studies have demonstrated increased resistance in the uterine arteries and in the smaller arteries feeding the myoma. Also during treatment, the proliferative activity of the myoma and the binding of epidermal growth factor are reduced. The use of medical suppressive therapies such as GnRH agonists for women with large myomas and those with anemia may reduce blood loss at the time of hysterectomy or myomectomy. However, one study found that tourniquets at the time of myomectomy were as effective as pretreatment with GnRH agonists in decreasing blood loss.

Therapies for Heavy Menstrual Bleeding

In women who have heavy menstrual bleeding as the primary symptom, limited data support the effectiveness of medical therapies including tranexamic acid and the levonorgestrel-releasing intrauterine device (Stewart, 2015). Tranexamic acid is an oral fibrinolytic agent that may decrease bleeding when taken only during heavy menstrual bleeding. As its mechanism of action is concerning for increased thrombotic risk, it should not be taken concomitantly with oral contraceptives. The levonorgestrel-releasing intrauterine device decreased menstrual bleeding while providing contraception; however, the rate of expulsion among women with submucosal fibroids

may be as high as 12% (Stewart, 2015). Oral progestogens have not been demonstrated to reduce fibroid size or fibroid-related symptoms (Sangkomkamhang, 2013). Oral contraceptives reduce menstrual bleeding in women with fibroids according to observational data. In addition, nonsteroidal anti-inflammatory drugs decrease heavy menstrual bleeding and menstrual pain.

Future Options for Medical Treatment

Currently, no validated medical treatment is able to eliminate fibroids; therefore surgery is the most effective treatment for symptomatic fibroids. However, there are emerging medical treatments that may be a good option for women who wish to avoid surgery, or before surgery, to reduce the invasiveness of the operation. In women with planned surgical treatment, oral ulipristal acetate controls symptoms, reduces tumor size, and improves quality of life compared with placebo and is not inferior to leuprolide acetate when used for 3 months (Perez-Lopez, 2015).

Ulipristal acetate is a selective progesterone receptor modulator that on binding to the progesterone receptor in target tissues displays antagonist and partial agonist effects (McKeage, 2011). The efficacy of ulipristal acetate has been demonstrated in three European phase III studies evaluating PGL4001 (Ulipristal Acetate) Efficacy Assessment in Reduction of Symptoms Due to Uterine Leiomyomata (PEARL I, II, and III) (Donnez 2012a, 2012b, 2014). Ulipristal acetate was approved for medical treatment for fibroids in Canada in 2013 (Singh, 2015). It is also licensed in Europe for the same indication (Trefoux, 2015). It is not FDA approved for treatment of fibroids in the United States.

Aromatase inhibitors block the synthesis of estrogen. They have been shown to reduce uterine fibroid size (up to 71% in 2 months) and ameliorate uterine fibroid symptoms, including a reduction in menstrual volume and duration of menstruation, and urinary retention (Shozu, 2003). Table 18.3 summarizes the medical options for the management of patients with uterine leiomyomas.

Uterine Artery Embolization

Uterine myomas may also be treated with uterine artery embolization (UAE) (Fig. 18.39). Multiple embolic materials have been used including gelatin sponge (Gelfoam) silicone spheres, gelatin microspheres, metal coils, and most commonly polyvinyl alcohol (PVA) particles of various diameters. Postprocedural abdominal and pelvic pain is common for the first 24 hours and may last up to 2 weeks. Most patients remain overnight in the hospital for pain relief and observation; however, some women will go home a few hours after treatment. Large trials, including the EMMY trial (Uterine Artery Embolization for Treatment of Symptomatic Uterine Fibroid Tumors), have consistently documented shorter hospitalizations and shorter recoveries, with a similar complication rate to hysterectomy. Reviews of the large trials and reports find that the need for reoperation within the first few years after embolization is 20% to 30%, with an overall failure rate of 40%, *failure rate* being defined as a return of symptoms and decrement in quality of life measures. The 5-year failure rate from the EMMY trial as reported by van der Kooij and associates included a 28.4% subsequent hysterectomy rate (van der Kooij, 2010). Risk factors for failure with UAE included younger age at embolization, bleeding as an indication for therapy, multiple myomas, and the finding at the time of imaging of collateral ovarian vessels feeding the myoma. Thus the procedure

Table 18.3 Summary of the Medical Management Options for Patients with Uterine Leiomyomas

Drug Class	Action	Benefits	Risks	Side Effects (%)	Authors*
COC	Inhibits ovulation; inhibits sex steroid secretion	17% decrease in the risk of leiomyoma growth; decreases bleeding and increases hematocrit	Thromboembolic events; hepatocellular adenoma (rare)	Spotting; mastalgia; headache; gastrointestinal upset	Qin et al; Orsini et al
Progestogens	May inhibit ovulation and sex steroid synthesis; decidualizes endometrium, inducing a "pseudopregnancy" state	Improves bleeding in up to 70%; amenorrhea in up to 30%; may decrease uterine volume in up to 50%	Loss of bone mass (prolonged use of depot MPA)	Irregular bleeding/spotting; ovarian follicular cysts	Venkatachalam et al; Ichigo et al
LNG-IUS	Endometrial atrophy	Reduces bleeding intensity in up to 99%; decreases uterine volume in about 40%	Device expulsion	Ovarian cysts; acne	Kriplani et al; Sayed et al
GnRH-a	Hypoestrogenism due to gonadotrophin secretion inhibition	Uterine volume decrease in up to 50%; high rates of amenorrhea	Loss of bone mass with prolonged use	Hot flashes (>90%); vaginal atrophy; headache; mood disorders	Friedman et al; Tummon et al; Dawood et al
SPRM	Inhibits ovulation; inhibits progesterone action on fibroid tissue	Improves bleeding in up to 98% of patients; decreases fibroid volume in up to 53%	Long term endometrial safety is unknown	Benign endometrial changes after short-term use	Donnez et al; Williams et al

In Mauro MA, Murphy KPJ, Thomson KR, et al, eds. *Image-Guided Interventions*. 2nd ed. Philadelphia: Elsevier; 2014:542-546.)

itself, though a valuable alternative to hysterectomy, is not for all women, with a significant proportion of women needing follow-up procedures.

Fertility after arterial embolization is difficult to quantify. Higher than expected rates of intrauterine growth restriction, preterm delivery, and miscarriage have been reported. In general, women choosing a conservative approach to preserve fertility should have a surgical myomectomy rather than UAE.

Complications of UAE affect about 5% of patients and include postembolization fever; sepsis from infarction of the necrotic myometrium, which may occur several weeks to a few months post procedure; and ovarian failure, affecting up to 3% of cases in women younger than 45 and 15% in women older than 45. This is thought to occur from spread of emboli material into the ovarian circulation. There is, in general, a decreased ovarian reserve found in older women after embolization. Amenorrhea

Figure 18.40 Intravenous leiomyomatosis. **A**, Tumor masses are present within distended blood vessels. **B**, This example shows hyaline degeneration of the intravascular element. (From Anderson MC, Robboy SJ, Russell P. Uterine smooth muscle tumors. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

may occur secondary to an endometrial hypoxic injury, as well. Rarely, necrosis of surrounding tissues may present as a complication of embolization.

Another complication of UAE is shedding of necrotic myomata or portions of myomata into the intrauterine cavity. Shedding may lead to infection or abdominal pain as the uterus tries to pass the material. This may require either a uterine curettage or hysteroscopic removal, although some authors have reported removing the necrotic material in the office. Because shedding of necrotic material is a relatively common complication, several authors have recommended that submucous myomata be removed hysteroscopically rather than attempted through UAE because these types of myomata are more prone to be shed into the uterine cavity. Intraabdominal adhesions, particularly after embolization of larger myomata, are also an uncommon but not rare complication.

Other Minimally Invasive Interventions

Endometrial ablation is used mainly to manage heavy uterine bleeding. It is limited to women with a normal-size uterus and uterine fibroids less than 3 cm in diameter. Compared with hysterectomy, endometrial ablation has a shorter intraoperative time, faster recovery, and fewer adverse events; however, it has inferior reduction in menstrual bleeding and lower patient satisfaction (Lethaby, 2000). Pregnancy following endometrial ablation is not recommended due to the high risk of miscarriage, ectopic pregnancy, and invasive placental disorders that may occur after this procedure.

Myolysis (the destruction of uterine fibroids or their blood supply via ultrasound, laser, cryotherapy, or other methods) has been studied as a conservative alternative for women who want to preserve their uterus but not fertility. Candidates are women with small fibroids (typically less than or equal to 5 cm) or the largest fibroid being less than 10 cm in diameter. Cheung reviewed the literature on sonographically guided high-intensity focused ultrasound for the management of fibroids, a procedure commonly used in China (Cheung, 2013). Magnetic resonance guided focused ultrasound surgery appears to be the most effective and least aggressive; however, this technique is limited by the

Figure 18.41 Photograph of leiomyomatosis peritonealis disseminate. (Courtesy of William Droegemueller and Vern L. Katz.)

need for costly equipment and limited data of efficacy and safety (Marret, 2012).

Two associated but rare diseases should be noted: intravenous leiomyomatosis and leiomyomatosis peritonealis disseminata. *Intravenous leiomyomatosis* is a rare condition in which benign smooth muscle fibers invade and slowly grow into the venous channels of the pelvis (Fig. 18.40). The tumor grows by direct extension and grossly appears like a “spaghetti” tumor. Only 25% of tumors extend beyond the broad ligament. However, case series and reports document tumor growth into the vena cava and right heart. The tumors may present with cardiac symptomatology and usually require surgical resection. Series from Zhang and colleagues and Worley and colleagues noted good results with single staged surgeries. Most authors recommend antiestrogen therapy with aromatase inhibitors after resection of leiomyomatosis of any degree (Worley, 2009; Zhang, 2010).

Leiomyomatosis peritonealis disseminata (LPD) is a benign disease with multiple small nodules over the surface of the pelvis and abdominal peritoneum. Grossly, LPD mimics disseminated carcinoma (Fig. 18.41). However, histologic examination

Figure 18.42 Peritoneal leiomyomatosis. Multiple tiny nodules of smooth muscle are scattered throughout the omentum. (From Anderson MC, Robboy SJ, Russell P. Uterine smooth muscle tumors. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

demonstrates benign-appearing myomas (Fig. 18.42). This disorder is often associated with a recent pregnancy. Also, the use of power morcellation increases the risk of LPD, due to intraperitoneal spread of uterine tissue (Kumar, 2008). Therapies with progestogens, selective estrogen receptor modulators (SERMS), or aromatase inhibitors have all been used in management. A rare autosomal syndrome of uterine and cutaneous leiomyomata and renal cell carcinoma also exists. Consideration should be given to renal evaluation in families with this history and with cutaneous leiomyomas.

In summary, leiomyomas are the most common tumor in women, and certainly one of the most common problems facing the gynecologist. Symptoms will present in 30% to 50% of women with myomata. Management is individualized to fit the patient's symptoms and reproductive desires.

ADENOMYOSIS

Adenomyosis has often been referred to as *endometriosis interna*. This term is misleading because endometriosis and adenomyosis are discovered in the same patient in less than 20% of women. More important, endometriosis and adenomyosis are clinically different diseases. The only common feature is the presence of ectopic endometrial glands and stroma. Adenomyosis is derived from aberrant glands of the basalis layer of the endometrium. Therefore these glands do not usually undergo the traditional proliferative and secretory changes that are associated with cyclic ovarian hormone production. The disease is common and may be found in up to 60% of hysterectomy specimens in women in the late reproductive years. Most studies have documented an incidence closer to 30%, with greater than 50% of these women being relatively asymptomatic. The symptoms of menorrhagia and dysmenorrhea form a spectrum and are subjective, thus delineating an incidence of associated symptomatology with adenomyosis is problematic.

Adenomyosis is usually diagnosed incidentally by the pathologist examining histologic sections of surgical specimens. The frequency of the histologic diagnosis is directly related to how

Figure 18.43 Adenomyosis. The myometrial wall is distorted and thickened by poorly circumscribed trabeculae that contain pinpoint hemorrhagic cysts. (From Anderson MC, Robboy SJ, Russell P. Uterine smooth muscle tumors. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

meticulously the pathologist searches for the disease. Adenomyosis is also a common incidental finding during autopsy. Serial histologic slides confirm the continuity of benign growth of the basalis layer of the endometrium into the myometrium. Thus the histogenesis of adenomyosis is direct extension from the endometrial lining.

The disease is associated with increased parity, particularly uterine surgeries and traumas. The pathogenesis of adenomyosis is unknown but is theorized to be associated with disruption of the barrier between the endometrium and myometrium as one series noted a 1.7 RR (1.1 to 2.6) of a dilation and curettage with an SAB in women with adenomyosis versus control subjects. Other studies have found a higher rate of induced abortion with presumed curettage in women with adenomyosis versus controls. Panganamamula and associates noted the history of any prior uterine surgery to be a significant risk factor in a set of 412 women with adenomyosis, 1.37 RR (1.05 to 1.79) (Panganamamula, 2004). These studies and experimental work in animals strongly support the theory that trauma to the endometrial-myometrial interface is a significant factor in the etiology of this condition. However, because adenomyosis was described well before uterine curettage and may occur (though uncommonly) in nulliparous women, the full pathogenesis is yet to be determined.

PATHOLOGY

There are two distinct pathologic presentations of adenomyosis. The most common is a diffuse involvement of both anterior and posterior walls of the uterus. The posterior wall is usually involved more than the anterior wall (Fig. 18.43). The individual areas of adenomyosis are not encapsulated. The second presentation is a focal area or adenomyoma. This results in an asymmetrical uterus, and this special area of adenomyosis may have a pseudocapsule. Diffuse adenomyosis is found in two thirds of cases.

In the more common, diffuse type of adenomyosis the uterus is uniformly enlarged, usually two to three times normal size. It is often difficult to distinguish on physical examination from uterine leiomyomas. However, the ultrasound appearance of leiomyomata helps to distinguish the two. Similarly on visual

Figure 18.44 Adenomyosis, histologic appearance. **A**, Endometrial tissue infiltrates into the myometrium. **B**, The infiltrating islands of endometrium consist of both glands and stroma. The glands are inactive and of basal pattern. (From Anderson MC, Robboy SJ, Russell P. Uterine smooth muscle tumors. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

inspection the two entities are quite different. When a knife transects the myometrium, the cut surface protrudes convexly and has a spongy appearance. The cut surface of a uterus with adenomyosis is darker than the white surface of a myoma. Sometimes there are discrete areas of adenomyosis that are not densely encapsulated and contain small, dark cystic spaces. There is not a distinct cleavage plane around focal adenomyomas as there is with uterine myomas.

Histologic examination will note benign endometrial glands and stroma are within the myometrium. These glands rarely undergo the same cyclic changes as the normal uterine endometrium. Studies have demonstrated both estrogen and progesterone receptors in tissue samples from adenomyosis.

The standard criterion used in diagnosis of adenomyosis is the finding of endometrial glands and stroma more than one low-powered field (2.5 mm) from the basalis layer of the endometrium. The small areas of adenomyosis have the same general appearance as the basalis layers of the endometrium. Histologically the glands exhibit an inactive or proliferative pattern. Rarely, one can also see cystic hyperplasia or a pseudodecidual pattern. In general, there is a lack of inflammatory cells surrounding the fossae of adenomyosis. Although the areas do not undergo full menstrual-type changes, bleeding may occur in these ectopic areas, as evidenced by both gross and microscopic findings. It is not unusual to see histologic variability in several different areas deep in the walls of the myometrium from the same uterus. Some fossae of adenomyosis undergo decidual changes either during pregnancy or during estrogen-progestin therapy for endometriosis. The reaction of the myometrium to the ectopic endometrium is hyperplasia and hypertrophy of

Figure 18.45 Hysterectomy with adenomyosis. The uterine corpus is thickened and shows prominent trabeculation of the myometrium with multiple small foci of hemorrhage. (From Oliva E. Endometrial stromal tumors, mixed müllerian tumors, adenomyosis, adenomyomas and rare sarcomas. In: Mutter GL, Prat J, eds. *Robboy's Pathology of the Female Reproductive Tract*. 3rd ed. Philadelphia: Elsevier; 2014:425-458.)

individual muscle fibers (Figs. 18.43 and 18.44). Surrounding most foci of glands and stroma are localized areas of hyperplasia of the smooth muscle of the uterus. This change in the myometrium produces the globular enlargement of the uterus (Fig. 18.45).

CLINICAL DIAGNOSIS

Over 50% of women with adenomyosis are asymptomatic or have minor symptoms that do not annoy them enough to seek medical care. They attribute the increase in dysmenorrhea or menstrual bleeding to the aging process and tolerate the symptoms. Symptomatic adenomyosis usually presents in women between the ages of 35 and 50. The severity of pelvic symptoms increases proportionally to the depth of penetration and the total volume of disease in the myometrium.

The classic symptoms of adenomyosis are secondary dysmenorrhea and menorrhagia. The acquired dysmenorrhea becomes increasingly more severe as the disease progresses. Occasionally the patient complains of dyspareunia, which is midline in location and deep in the pelvis. On pelvic examination the uterus is diffusely enlarged, usually two to three times normal size. It is most unusual for the uterine enlargement associated with adenomyosis to be greater than a 14-week-size gestation unless the patient also has uterine myomas. The uterus is globular and tender immediately before and during menstruation (see Fig. 18.45). LevGur and colleagues evaluated the gynecologic histories of women with diffuse adenomyosis compared with women without such a history (LevGur, 2000). In their series, the symptoms of dysmenorrhea and menorrhagia correlated with the amount of adenomyosis and the depth of myometrial invasion.

The diagnosis of adenomyosis is usually confirmed following histologic examination of the hysterectomy specimen. Frequently the clinical diagnosis is inaccurately assigned to the patient who has chronic pelvic pain. Traditionally the patient will have endometrial sampling to rule out other organic causes of abnormal bleeding. Many times adenomyosis is diagnosed retrospectively following a hysterectomy for other indications. Attempts have been made to establish the diagnosis preoperatively by transcervical needle biopsy of the myometrium. However, even with multiple needle biopsies, the sensitivity of the test is too low to be of practical clinical value. Adenomyosis may coexist with both endometrial hyperplasia and endometrial carcinoma. Approximately two of three women with adenomyosis have coexistent pelvic pathology, most commonly myomas but also endometriosis, endometrial hyperplasia, and salpingitis isthmica nodosa.

Ultrasound and MRI are both useful to help differentiate between adenomyosis and uterine myomas in a young woman desiring future childbearing. Diagnosing adenomyosis by transvaginal ultrasonography has a reported sensitivity between 53% and 89% and a specificity of 50% to 89%. In some series, MRI is more sensitive, ranging between 88% and 93%, and has a higher specificity (66% to 91%) than ultrasonography in the diagnosis of adenomyosis. Verma and associates reported the addition of sonohysterography with vaginal ultrasound, with an increase in sensitivity and specificity comparable with MRI. T2-weighted images are superior in making the diagnosis and documenting widened junctional zones (Verma, 2009). Studies indicate that three-dimensional transvaginal ultrasound is superior to two-dimensional transvaginal ultrasound and may allow for the diagnosis of early stage disease (Struble, 2016). Findings of poorly defined junctional zone markings in the endometrial-myometrial interface help confirm the diagnosis. Ascher and coworkers described high signal intensity striations emanating from the endometrium and trailing into the myometrium as

helpful findings (Ascher, 2003). These bands most likely represent the glands and hypertrophied muscle of adenomyosis. MRI is clinically useful in differentiating adenomyosis from uterine leiomyoma, especially preoperatively in women who desire future fertility or who may choose uterine artery embolization for treatment of myomata. The success of uterine artery embolization for adenomyosis is unproved.

MANAGEMENT

There is no satisfactory proved medical treatment for adenomyosis. Patients with adenomyosis have been treated with GnRH agonists, progestogens, and progesterone-containing IUDs, cyclic hormones, or prostaglandin synthetase inhibitors for their abnormal bleeding and pain. Hysterectomy is the definitive treatment if this therapy is appropriate for the woman's age, parity, and plans for future reproduction. Size of the uterus, degree of prolapse, and presence of associated pelvic pathology determine the choice of surgical approach. Women who become pregnant with adenomyosis are at increased risk of pregnancy complications such as premature labor and delivery, low birthweight, and preterm premature rupture of membranes.

OVIDUCT

LEIOMYOMAS

Both benign and malignant tumors of the oviduct are uncommon compared with other gynecologic neoplasms. Although these tumors are underreported, fewer than 100 women with myomas or leiomyomas of the oviduct are described in the literature. Tubal leiomyomas may be single or multiple and usually are discovered in the interstitial portion of the tubes. They usually coexist with the more common uterine leiomyomas. Myomas may originate from muscle cells in the walls of the tube or blood vessels or from smooth muscle in the broad ligament.

Leiomyomas of the tube present as smooth, firm, mobile, usually nontender masses that may be palpated during the bimanual examination. Similar to uterine myomas, they may be subserosal, interstitial, or submucosal. During laparoscopy the myomas appear as a spherical mass that protrudes from beneath the peritoneal surface. They vary from a few millimeters to 15 cm in diameter. Histologically they are identical to uterine leiomyomas.

The majority of the myomas of the oviduct are asymptomatic. Rarely, they may undergo acute degeneration or be associated with unilateral tubal obstruction or torsion. Treatment of a symptomatic tubal leiomyoma is excision.

ADENOMATOID TUMORS

The most prevalent benign tumor of the oviduct is the *angio-myoma* or *adenomatoid tumor* (Fig. 18.46). They are small, gray-white, circumscribed nodules, 1 to 2 cm in diameter. These tumors are usually unilateral and present as small nodules just under the tubal serosa. These small nodules do not produce pelvic symptoms or signs. These benign tumors also are found below the serosa of the fundus of the uterus and the broad ligament. Microscopically, they are composed of small tubules lined by a low cuboidal or flat epithelium. Histologic studies have

Figure 18.46 Adenomatoid tumor. (From Anderson MC, Robboy SJ, Russell P. The fallopian tube. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

Figure 18.47 Adenomatoid tumor arising in the fallopian tube. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

established that the thin-walled channels that comprise these tumors are of mesothelial origin (Fig. 18.47). These tumors do not become malignant; however, they may be mistaken for a low-grade neoplasm when initially viewed during a frozen-section evaluation.

PARATUBAL CYSTS

Paratubal cysts are frequently incidental discoveries during gynecologic operations for other abnormalities. They are often multiple and may vary from 0.5 cm to more than 20 cm in diameter. Most cysts are small, asymptomatic, and slow growing and are discovered during the third and fourth decades of life. When paratubal cysts are *pedunculated* and near the fimbrial end of the oviduct, they are called hydatid cysts of Morgagni (Figs. 18.48 and 18.49). Cysts near the oviduct may be of mesonephric,

Figure 18.48 Broad ligament cyst. This parovarian, or paratubal cyst, is thin walled and contains clear watery fluid. (From Anderson MC, Robboy SJ, Russell P. The fallopian tube. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

Figure 18.49 A nonneoplastic cyst with the broad ligament abuts the normal ovary. (From Clement PB, Young RH. *Atlas of Gynecologic Surgical Pathology*. Philadelphia: Saunders; 2000.)

mesothelial, or paramesonephric origin. Sometimes the histologic differentiation is difficult because of mechanically produced changes in the cells that line the cyst. These cysts are translucent and contain a clear or pale yellow fluid.

The histogenesis of the majority of paratubal cysts had been believed to be from the mesonephric duct, with the cysts arising from the main duct or accessory tubules. These latter cysts often develop between the leaves of the broad ligament in the mesosalpinx, with the ovary being separate. However, a histologic study of 79 paratubal cysts documented that 60 of the cysts were of tubal origin. Thus the majority of grossly identified “paratubal cysts” are in reality accessory lumina of the fallopian tubes. The remaining 19 cysts were of mesothelial origin. Paratubal cysts are thin walled and smooth and contain clear fluid. Often there are multiple small cysts. Occasionally there is a papillomatous proliferation on the internal wall of these cysts. Inflammatory cysts of the peritoneum may be found anywhere in the pelvis.

The majority of paratubal cysts are asymptomatic and are usually discovered incidentally during ultrasound or during gynecologic operations. When paratubal cysts are symptomatic, they generally produce a dull pain. During a pelvic examination it is difficult to distinguish a paratubal cyst from an ovarian mass. At operation the oviduct is often found stretched over a large paratubal cyst. The oviduct should not be removed in these cases because it will return to normal size after the paratubal cyst is excised. In one retrospective 10-year review of 168 women with parovarian tumors, three low-grade malignant neoplasms were found. These malignancies were in women of reproductive age who had cysts greater than 5 cm in diameter with internal papillary projections. The authors cautioned that the differentiation between benign and malignant parovarian masses cannot be made by external examination of the cyst. The practice of aspirating cysts via the laparoscope should be limited to cysts that are completely simple and associated with normal cancer antigen-125 (CA-125) levels. More recent theories of epithelial ovarian carcinogenesis suggest that serous, endometrioid, and clear cell carcinomas are derived from the fallopian tube and the endometrium rather than the ovarian surface epithelium (Erickson, 2013). The American College of Obstetricians and Gynecologists supports the view that prophylactic salpingectomy may offer clinicians the opportunity to prevent ovarian cancer in their patients, and the surgeon should discuss the potential benefits of the removal of the fallopian tubes during hysterectomy in women at population risk for ovarian cancer (ACOG, 2015).

Paratubal cysts may grow rapidly during pregnancy, and most of the cases of torsion of these cysts have been reported during pregnancy or the puerperium. Treatment is simple excision.

TORSION

Acute torsion of the oviduct is a rare event; however, it has been reported with both normal and pathologic fallopian tubes. Pregnancy predisposes to this problem. Tubal torsion usually accompanies torsion of the ovary, as they have a common vascular pedicle. (See the discussion of ovarian torsion presented later in this chapter.) Torsion of the fallopian tube is secondary to an ovarian mass in approximately 50% to 60% of patients. The right tube is involved more frequently than is the left (Fig. 18.50). The degree of tubal torsion varies from less than one turn to four complete rotations. Torsion of the oviduct is usually seen in women of reproductive age. However, it occurs also in preadolescent children, especially when part of the tube is enclosed in the sac of a femoral or inguinal hernia.

Tubal torsion may be divided into intrinsic and extrinsic causes. Prominent intrinsic causes include congenital abnormalities, such as increased tortuosity caused by excessive length of the tube, and pathologic processes, such as hydrosalpinx, hematosalpinx, tubal neoplasms, and previous operation, especially tubal ligation. Torsion of the fallopian tube following tubal ligation is usually of the distal end. Extrinsic causes of tubal torsion are ovarian and peritubal tumors, adhesions, trauma, and pregnancy.

The most important symptom of tubal torsion is acute lower abdominal and pelvic pain. The onset of this pain is usually sudden, but it may also be gradual, and the pain is usually located in the iliac fossa, with radiation to the thigh and flank. The duration of pain is generally less than 48 hours, and it is associated with nausea and vomiting in two thirds of the cases. Usually, the pelvic pain,

Figure 18.50 Hematosalpinx with torsion. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

secondary to hypoxia, is so intense that it is difficult to perform an adequate pelvic exam. Unless there is associated torsion of the ovary, a specific mass is usually not palpable on pelvic examination.

The preoperative diagnosis of tubal torsion is made in less than 20% of reported cases. However, the number of cases diagnosed preoperatively has increased dramatically with the use of vaginal ultrasonography. Because of the severity of the pain, a wide differential diagnosis of abdominal and pelvic pathology must be considered. The differential diagnosis includes acute appendicitis, ectopic pregnancy, pelvic inflammatory disease, and rupture or torsion of an ovarian cyst.

Exploratory operation determines the extent of hypoxia and the choice of operative techniques. With tubal torsion, usually the tubes are gangrenous and must be excised. The twisted tube is usually filled with a bloody or serous fluid. It may be possible to restore normal circulation to the tube by manually untwisting it. The tube is usually sutured into a secure position to prevent recurrence.

OVARY

Ovarian masses are a frequent finding on pelvic examination and pelvic imaging. The task of the clinician is to determine whether the mass should be removed or may be managed expectantly. The general factors used to consider removal include the symptoms produced by the mass, the chances that the mass is malignant, and the likelihood of spontaneous resolution.

FUNCTIONAL CYSTS

Follicular Cysts

Follicular cysts are by far the most frequent cystic structures in normal ovaries. They may be found as early as 20 weeks, gestation in female fetuses and throughout a woman's reproductive life. Follicular cysts are frequently multiple and may vary from a few millimeters to as large as 15 cm in diameter. A normal follicle may develop into a physiologic cyst. A minimum diameter to be considered as a cyst is generally considered to be between 2.5 and 3 cm. Follicular cysts are not neoplastic and are believed to be dependent on gonadotropins for growth. They arise from a temporary variation of a normal physiologic process. Clinically they may present with the signs and symptoms of ovarian enlargement and therefore must be differentiated from a true

ovarian neoplasm. Functional cysts may be solitary or multiple. These cysts are found most commonly in young, menstruating women. Solitary cysts may occur during the fetal and neonatal periods and rarely during childhood, but there is an increase in frequency during the perimenarcheal period. Wolf and coworkers studied 149 postmenopausal women and found simple cysts ranging in size from 0.4 to 4.7 cm in 15% of them (Wolf, 1991). Large solitary follicular cysts in which the lining is luteinized are occasionally discovered during pregnancy and the puerperium. CA-125 may be used to evaluate such cysts in pregnancy. The values for CA-125 should be within the normal range past 12 weeks' gestation. Multiple follicular cysts in which the lining is luteinized are associated with either intrinsic or extrinsic elevated levels of gonadotropins. Interestingly, reproductive-age women with cystic fibrosis appear to have an increased propensity for developing individual follicular cysts.

Follicular cysts are translucent, thin-walled, and are filled with a watery, clear to straw-colored fluid. If a small opening in the capsule of the cyst suddenly develops, the cyst fluid under pressure will squirt out. These cysts are situated in the ovarian cortex, and sometimes they appear as translucent domes on the surface of the ovary. Histologically the lining of the cyst is usually composed of a closely packed layer of round, plump granulosa cells, with the spindle-shaped cells of the theca interna deeper in the stroma. In many cysts the lining of granulosa cells is difficult to distinguish, having undergone pressure atrophy. All that remains is a hyalinized connective tissue lining. The temporary disturbance in follicular function that produces the clinical picture of a follicular cyst is poorly understood. Follicular cysts may result from either the dominant mature follicle's failing to rupture (persistent follicle) or an immature follicle's failing to undergo the normal process of atresia. In the latter circumstance, the incompletely developed follicle fails to reabsorb follicular fluid. Some follicular cysts lose their ability to produce estrogen, and in others the granulosa cells remain productive, with prolonged secretion of estrogens. Occasionally, follicular cysts are better termed *follicular hematomas*, because blood from the vascular theca zone fills the cavity of the cyst.

Most follicular cysts are asymptomatic and are discovered during ultrasound imaging of the pelvis or a routine pelvic examination. Ultrasound cannot reliably differentiate a benign from a malignant process. However, several characteristics of ovarian masses correlate with malignancy, including internal papillations (echogenic structures protruding into the mass), loculations, solid lesions or cystic lesions with solid components, thick septations, and smaller cysts adjacent to or part of the wall of the larger cyst—daughter cysts (Fig. 18.51).

These cysts may rupture during examination, because of their thin walls. The patient may experience tenesmus, a transient pelvic tenderness, deep dyspareunia, or no pain whatsoever. Rarely is significant intraperitoneal bleeding associated with the rupture of a follicular cyst. However, women who are chronically anticoagulated or those with von Willebrand disease may bleed. Occasionally, menstrual irregularities and abnormal uterine bleeding may be associated with follicular cysts, which produce elevated blood estrogen levels. The syndrome associated with such follicular cysts consists of a regular cycle with a prolonged intermenstrual interval, followed by episodes of menorrhagia. Some women with larger follicular cysts notice a vague, dull sensation or heaviness in the pelvis.

The initial management of a suspected follicular cyst is conservative observation. The majority of follicular cysts disappear spontaneously by either reabsorption of the cyst fluid or silent rupture within 4 to 8 weeks of initial diagnosis. However, a persistent ovarian mass necessitates operative intervention to differentiate a physiologic cyst from a true neoplasm of the ovary. There is no way to make the differentiation on the basis of signs, symptoms, or the initial growth pattern during early development of either process. Endovaginal ultrasound examination is helpful in differentiating simple from complex cysts and is also helpful during conservative management by providing dimensions to determine if the cyst is increasing in size. When the diameter of the cyst remains stable for greater than 10 weeks or enlarges, a neoplasia should be ruled out. Oral contraceptives may be prescribed for 4 to 6 weeks for young women with adnexal masses. This therapy removes any influence that pituitary gonadotropins may have on the persistence of the ovarian cyst. It also allows for several weeks of observation. In one series, 80% of cystic masses 4 to 6 cm in size disappeared during the time the patient was taking oral contraceptives. However, randomized prospective trials found no difference in the rate of disappearance of functional ovarian cysts between the group that received oral contraceptives and the control group, perhaps because so many cysts will resolve spontaneously.

The evaluation of an asymptomatic cyst, found incidentally, is based on the principle that the cyst should be removed if there is any suspicion of malignancy. Suspicion may develop because of history, including family history, patient age, and other nongynecologic signs and symptoms. The size and physical characteristics of the cyst are as important as are other laboratory parameters. CA-125 is helpful in evaluating the adnexal mass in postmenopausal women. In premenopausal women, CA-125 is rarely helpful unless the mass is extremely suggestive of malignancy. As discussed earlier, measurement of diastolic and systolic velocities provide indirect indices of vascular resistance. Muscular arteries have high resistance. Newly developed vessels, such as those arising in malignancies, have little vascular wall musculature and thus have low resistance. When a color flow Doppler scan demonstrates vascularity, the vascular resistance can be calculated. Low resistance is associated with malignancy, and high resistance usually is associated with normal tissue or benign disease. Although color flow Doppler has been shown to be sensitive in evaluating ovarian neoplasms, it is neither sensitive nor specific enough to be used as a determining study. In most cases, simple small cysts may be observed. In general, complex cysts or persistent simple cysts larger than 10 cm should be evaluated. In women with cysts in pregnancy, if the cyst is simple with a normal CA-125, conservative management is acceptable. (CA-125 is generally not obtained in pregnant women with cysts less than 5 cm if they are simple.)

A cyst in a perimenopausal or postmenopausal woman should be removed if it is anything other than a simple cyst, if the CA-125 is abnormal (>35), or if the cyst is persistent or large (>10 cm), although observation may be reasonable in select cases. A small simple cyst in a perimenopausal or postmenopausal woman (<5 cm) with a normal CA-125 may be observed with follow-up ultrasound and CA125 testing every 6 months for 2 years. If unchanged at that point routine monitoring can be stopped. Several studies, including the large prospective series from Greenlee and colleagues, examined the issue of simple cysts

in postmenopausal women with simple cysts. These studies have noted that expectant management is safe and reasonable. In the series by Greenlee, the Prostate, Lung, Colorectal, and Ovarian cancer Screening Trial, women were followed for 4 years with transvaginal ultrasound. Of 15,735 women, 2217 (14%) had at least one simple cyst. Cysts were more common in women in the 50- to 59-year-old age group and women with hysterectomies prior to age 40. Cysts were less common among smokers and older women. In all, 54% of cysts were present on scans 1 year later; 8% of women had more than one cyst. Only 0.4% of the entire population developed ovarian cancer, and half of the women who developed cancer did not have cysts. The 14% incidence of cysts in postmenopausal women is similar to rates of simple cysts in other large series. Thus women with simple cysts who are asymptomatic and with negative CA-125 may be reassured and if desired, followed expectantly (Greenlee, 2010). Management of cysts between 5 and 10 cm that are otherwise

not suggestive should be individualized. Ekerhovd and coworkers reported on 927 premenopausal women and 377 postmenopausal women with ovarian cysts. Of these women, 660 had unilocular simple cysts, 3 were borderline, and 4 were malignant (total of 1%). All of the borderline and malignant tumors were found in cysts greater than 7.5 cm. In women with cysts that had echodensity and papulations (644 women), 24 (3.7%) turned out to be borderline or malignant. Cysts that were multiseptate were not included in the study. All cysts with internal structures were excised and had a much higher rate of malignancy. The authors, as well as others, have confirmed the recommendation that unilocular cysts less than 5 cm may be followed if there is no family history, a normal CA-125, or other significant findings (Ekerhovd, 2001).

In premenopausal women, operative management of nonmalignant cysts is cystectomy, not oophorectomy. Many clinicians will manage simple cysts laparoscopically. Because this procedure

Figure 18.51 Serous cystadenocarcinoma, varying appearances. **A**, Transvaginal scan shows large cystic mass containing multiple low-level internal echoes and solid echogenic components (arrows). **B**, Transabdominal scan shows large cystic mass with irregular solid echogenic mural nodules (arrows) and low-level internal echoes. **C**, Mucinous cystadenoma. Transabdominal scan shows large cystic mass with multiple thin septations (arrows) and fine low-level internal echoes. **D**, Gross pathologic specimen shows multiple cystic loculations. (From Salem S. The uterus and adnexa. In: Rumack CM, Wilson SR, Charboneau JW, eds. *Diagnostic Ultrasound*. St. Louis: Mosby; 1998:555-556.)

has an accompanying risk of spilling malignant cells into the peritoneal cavity if the cyst is an early carcinoma, strict preoperative criteria should be fulfilled before laparoscopy is attempted. These include the woman's age; size of the mass; and ultrasound characteristics, such as nonadherent, smooth, and thin-walled cysts, without papillae or internal echoes (simple). DeWilde and associates, reporting on a series of follicular cysts averaging 6 cm in diameter, found that the recurrence rate following laparoscopic fenestration was approximately 2% (DeWilde, 1989). Higher rates of recurrence, up to 40%, have been reported for simple drainage of multiple types of benign cysts, the point being that drainage or fenestration is effective for follicular cysts and poorly effective for other cysts. When cysts are drained, it is essential to remember that cytologic examination of cyst fluid has poor predictive value and poor sensitivity in differentiating benign from malignant cysts. One report of fine-needle aspiration of ovarian cysts found sensitivity of 25%, specificity of 90%, a false-positive rate of 73%, and a false-negative rate of 12% (Higgins, 1999). If there is any suspicion of malignancy, the cyst should be removed as carefully as possible and a histopathologic evaluation obtained. The size of the cyst is not a necessary reason to avoid laparoscopy. Most simple cysts, even those larger than 10 cm, can be managed through the laparoscope.

Corpus Luteum Cysts

Corpus luteum cysts are less common than follicular cysts, but clinically they are more important. This discussion collectively combines corpus luteum cysts and persistently functioning mature corpora lutea (Fig. 18.52). Pathologists are sometimes able to distinguish between a hemorrhagic cystic corpus luteum and a corpus luteum cyst, but at other times this difference cannot be established. All corpora lutea are cystic with gradual reabsorption of a limited amount of hemorrhage, which may form a cavity. Clinically, corpora lutea are not termed *corpus luteum cysts* unless they are a minimum of 3 cm in diameter. Corpus luteum cysts may be associated with either normal endocrine function or prolonged secretion of progesterone. The associated menstrual pattern may be normal, delayed menstruation, or amenorrhea.

Corpora lutea develop from mature graafian follicles. Intra-follicular bleeding does not occur during ovulation. However, 2 to 4 days later, during the stage of vascularization, thin-walled

Figure 18.52 Hemorrhagic corpus luteum with an outer yellow rim and central hemorrhage. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

capillaries invade the granulosa cells from the theca interna. Spontaneous but limited bleeding fills the central cavity of the maturing corpus luteum with blood. Subsequently this blood is absorbed, forming a small cystic space. When the hemorrhage is excessive, the cystic space enlarges. If the hemorrhage into the central cavity is brisk, intracystic pressure increases and rupture of the corpus luteum is a possibility. If rupture does not occur, the size of the resulting corpus luteum cyst usually varies between 3 and 10 cm. Occasionally a cyst may be 11 to 15 cm in diameter. If a cystic central cavity persists, blood is replaced by clear fluid, and the result is a hormonally inactive corpus albicans cyst (Fig. 18.53). A corpus luteum of pregnancy is normally 3 to 5 cm in diameter with a central cystic structure, occupying at least 50% of the ovarian mass.

Most corpus luteum cysts are small, the average diameter being 4 cm. Grossly, they have a smooth surface and, depending on whether the cyst represents acute or chronic hemorrhage, are purplish red to brown. When a corpus luteum is cut, the convoluted lining is yellowish orange, and the center contains an organizing blood clot. Both the granulosa and the theca cells undergo luteinization. In chronic corpus luteum cysts, the wall becomes gray-white, and the polygonal luteinized cells usually undergo pressure atrophy. Hallatt and colleagues reviewed 173 ruptured corpora lutea with hemoperitoneum. In their institution the frequency of serious bleeding from a corpus luteum cyst compared with ectopic pregnancy was one in four (Hallatt, 1984).

Corpus luteum cysts vary from being asymptomatic masses to those causing catastrophic and massive intraperitoneal bleeding associated with rupture. Many corpus luteum cysts produce dull, unilateral, lower abdominal and pelvic pain. The enlarged ovary is moderately tender on pelvic examination. Depending on the amount of progesterone secretion associated with cysts, the menstrual bleeding may be normal or delayed several days to weeks with subsequent menorrhagia. Halban, in 1915, described

Figure 18.53 Corpus albicans cyst. Lining of cyst is composed of hyalinized connective tissue. (From Blaustein A. *Nonneoplastic cysts of the ovary*. In: Blaustein A, ed. *Pathology of the Female Genital Tract*. New York: Springer-Verlag; 1977:396.)

a syndrome of a persistently functioning corpus luteum cyst that has clinical features similar to an unruptured ectopic pregnancy. Halban's classic triad was a delay in a normal period followed by spotting; unilateral pelvic pain; and a small, tender, adnexal mass. This triad of symptomatology is similar to the triad of an anomalous period or delay in a normal period, spotting, and unilateral pelvic pain that are exhibited by the classic ectopic pregnancy. The differential diagnosis between these two conditions without a sensitive pregnancy test is difficult.

Corpus luteum cysts may cause intraperitoneal bleeding. The amount of bleeding varies from slight to clinically significant hemorrhage, necessitating blood transfusion. Internal bleeding often follows coitus, exercise, trauma, or a pelvic examination. However, episodes of bleeding usually do not recur, which differs from an ectopic pregnancy. Women with a bleeding diathesis or those undergoing chronic warfarin (Coumadin) therapy are especially prone to developing ovarian hemorrhage from a corpus luteum cyst. Bleeding occurs usually between days 20 and 26 of their cycle, and these women have a 31% chance for subsequent hemorrhage from a recurrent corpus luteum cyst. Oral contraceptives are sometimes used to suppress ovulation and avoid recurrent hemorrhage.

Hallatt and colleagues reported that sudden, severe, lower abdominal pain was a prominent symptom in women with hemoperitoneum caused by a ruptured corpus luteum cyst (Table 18.4). One of three women also noted unilateral cramping and lower abdominal pain for 1 to 2 weeks before overt rupture. The right ovary was the source of hemorrhage in 66% of their series (Hallatt, 1984). Tang and coworkers have also reported a right-sided predominance in the incidence of hemorrhage from corpus luteum cysts. They postulated that the difference is related to a higher intraluminal pressure on the right side because of the differences in ovarian vein architecture (Tang, 1985). Most ruptures occur between days 20 and 26 of the cycle, although in the series of Hallatt and colleagues, 28% of the women had a delay in menses not explained by pregnancy (Table 18.5).

The differential diagnosis of a woman with acute pain and suspected ruptured corpus luteum cyst includes ectopic pregnancy, a ruptured endometrioma, and adnexal torsion. A sensitive serum or urinary assay for human chorionic gonadotropin (HCG) will help to differentiate a bleeding corpus luteum from ectopic pregnancy (see Chapter 17). Vaginal ultrasound is useful

in establishing a preoperative diagnosis. Culdocentesis has been used in the past to establish the severity of the hemorrhage, but it is rarely used today. If the hematocrit of the fluid obtained from the posterior cul-de-sac is greater than 15%, operative therapy is recommended. Cystectomy is the operative treatment of choice, with preservation of the remaining portion of the ovary. In the series by DeWilde and associates reporting on persistent corpus luteum cysts treated by fenestration via the laparoscope, 6 of 44 (14%) recurred. Obviously, it was impossible for the authors to distinguish between a recurrent corpus luteum cyst and the development of a new corpus luteum (DeWilde, 1989). Unruptured corpus luteum cysts may be followed conservatively. Raziel and coworkers reported on a series of 70 women with ruptured corpora lutea. Ultrasonic evidence of large amounts of peritoneal fluid and severe pain were indications for operative intervention. In 12 of 70 patients with small amounts of intraperitoneal fluid and mild to moderate pain, observation alone was associated with resolution of symptoms (Raziel, 1993).

Theca Lutein Cysts

Theca lutein cysts are by far the least common of the three types of physiologic ovarian cysts (Fig. 18.54). Unlike corpus luteum cysts, theca lutein cysts are almost always bilateral and produce moderate to massive enlargement of the ovaries. The individual cysts vary in size from 1 cm to 10 cm or more in diameter. These cysts arise from either prolonged or excessive stimulation of the ovaries by endogenous or exogenous gonadotropins or increased ovarian sensitivity to gonadotropins. The condition of ovarian enlargement secondary to the development of multiple luteinized follicular cysts is termed *hyperreactio luteinialis*. Approximately 50% of molar pregnancies and 10% of choriocarcinomas have associated bilateral theca lutein cysts (Chapter 35). In these patients the HCG from the trophoblast produces luteinization of the cells in immature, mature, and atretic follicles. The cysts are also discovered in the latter months of pregnancies, often with conditions that produce a large placenta, such as twins, diabetes, and Rh sensitization. It is not uncommon to iatrogenically produce theca lutein cysts in women receiving medications to induce ovulation. Theca lutein cysts are occasionally discovered in association with normal pregnancy, as well as in newborn infants secondary to transplacental effects of maternal gonadotropins. Rarely, these cysts are found in young girls with juvenile hypothyroidism.

Table 18.4 Symptoms of 173 Women with Ruptured Corpus Luteum

Location	Number	Percentage
Right ovary	114	66
Left ovary	56	32
Unknown	3	2
Abdominal pain	173	100
Right ovary	21	72
Left ovary	8	28
Duration		
Less than 24 hours	94	54
1 to 7 days	40	23
Over 7 days	14	8
Unknown	25	15
Nausea or vomiting or diarrhea	60	35

Figure 18.54 Bilateral theca lutein cysts. (Courtesy of Daniel R. Mishell, Jr., MD.)

Grossly the total ovarian size may be voluminous, 20 to 30 cm in diameter, with multiple theca lutein cysts. Bilateral ovarian enlargement is produced by multiple gray to bluish-tinged cysts. The bilateral enlargement is secondary to hundreds of thin-walled locules or cysts, producing a honeycombed appearance. Grossly the external surface of the ovary appears lobulated. The small cysts contain a clear to straw-colored or hemorrhagic fluid. Histologically the lining of the cyst is composed of theca lutein cells (paralutein cells), believed to originate from ovarian connective tissue. Occasionally there is also luteinization of granulosa cells. These voluminous and congested ovaries are slow growing. The majority of women with smaller cysts are asymptomatic. Generally only the larger cysts produce vague symptoms, such as a sense of pressure in the pelvis. Ascites and increasing abdominal girth have been reported with hyperstimulation from exogenous gonadotropins. Rarely, associated adnexal torsion or bleeding may occur less than 1% of the time. Some theca lutein cysts persist for weeks after HCG levels normalize.

The presence of theca lutein cysts is established by palpation and often confirmed by ultrasound examination. Treatment is conservative because these cysts gradually regress. If these cysts are discovered incidentally at cesarean delivery, they should be handled delicately. No attempt should be made to drain or puncture the multiple cysts because of the possibility of hemorrhage. Bleeding is difficult to control in these cases because of the thin walls that constitute the cysts.

A condition related to theca lutein cysts is the luteoma of pregnancy. The condition is rare and not a true neoplasm but rather a specific, benign, hyperplastic reaction of ovarian theca lutein cells (Figs. 18.55 and 18.56). These nodules do not arise from the corpus luteum of pregnancy. Fifty percent of luteomas are multiple, and approximately 30% of those reported have bilateral nodules. In appearance they are discrete and brown to reddish brown and may be solid or cystic.

The majority of patients with luteomas are asymptomatic. The solid, fleshy, often hemorrhagic nodules are discovered incidentally at cesarean delivery or postpartum tubal ligation. Most cases have been reported in multiparous African-American women. Masculinization of the mother occurs in 30% of cases,

Figure 18.55 Luteoma of pregnancy with numerous solid brown nodules. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

Figure 18.56 Luteoma with multiple reddish nodules. (From Clement PB, Young RH. *Atlas of Gynecologic Surgical Pathology*. Philadelphia: WB Saunders; 2000.)

and masculinization of the external genitalia of the female fetus may sometimes occur. These tumors regress spontaneously following completion of the pregnancy.

BENIGN NEOPLASMS OF THE OVARY

Benign Cystic Teratoma (Dermoid Cyst, Mature Teratoma)

Benign ovarian teratomas are usually cystic structures that on histologic examination contain elements from all three germ cell layers. The word *teratoma* was first advanced by Virchow and translated literally means “monstrous growth.” Teratomas of the ovary may be benign or malignant. Although *dermoid* is a misnomer, it is the most common term used to describe the benign cystic tumor, composed of mature cells, whereas the malignant variety is composed of immature cells (immature teratoma). *Dermoid* is a descriptive term in that it emphasizes the preponderance of ectodermal tissue with some mesodermal and rare

Figure 18.57 Age distribution of cystic teratomas. (From Lakkis WG, Martin MC, Gelfand MM. Benign cystic teratoma of the ovary: a 6-year review. Originally published in *Can J Surg*. 1985;28:444.)

endodermal derivatives. Malignant teratomas that are immature are usually solid with some cystic areas and histologically contain immature or embryonic-appearing tissue. (See [Chapter 33](#), for further discussion of malignant teratomas.) Benign teratomas may contain a malignant component, usually in women older than 40 (mean age 48). The malignant component is generally a squamous carcinoma and is found in less than 1% of cases. Non-ovarian teratomas may arise in any midline structure of the body where the germ cell has resided during embryonic life.

Benign teratomas are among the most common ovarian neoplasms. They account for more than 90% of germ cell tumors of the ovary. These slow-growing tumors occur from infancy to the postmenopausal years. Depending on the series, dermoids represent 20% to 25% of all ovarian neoplasms and approximately 33% of all benign tumors, if follicular and corpus luteum cysts are excluded. Dermoids are the most common ovarian neoplasm in prepubertal females and are also common in teenagers. More than 50% of benign teratomas are discovered in women between the ages of 25 and 50 years. In one series of 118 women with dermoids, 86% of the women were younger than 40 years of age, and 3.4% had recurrences ([Fig. 18.57](#)). With routine obstetric ultrasound, the mean age at diagnosis is expected to fall. In most large series of benign tumors in postmenopausal women, dermoids account for approximately 20% of the neoplasms.

Dermoids vary from a few millimeters to 25 cm in diameter although they have been reported to weigh as much as 7657 g in an asymptomatic woman. However, 80% are less than 10 cm. These tumors may be single or multiple, with as many as nine individual dermoids having been reported in the same ovary. Benign teratomas occur bilaterally 10% to 15% of the time. Often, dermoid cysts are pedunculated. These cysts make the ovary heavier than normal, and thus they are usually discovered either in the cul-de-sac or anterior to the broad ligament. On palpation these tumors, which have both cystic and solid components, have a doughy consistency.

Figure 18.58 Mature cystic teratoma (dermoid cyst) filled with hair and keratinous debris with one solid nodular area (Rokitansky protuberance). (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

Figure 18.59 Bilateral mature cystic teratomas in pregnancy. The cyst is bilocular. Dermal papillae are noted. Teeth are also present in the left lobule. (From Russell P, Robboy SJ, Anderson MC. Germ cell tumors of the ovaries. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

The cysts are usually unilocular. The walls of the cyst are a smooth, shiny, opaque white color. When they are opened, thick sebaceous fluid pours from the cyst, often with tangled masses of hair and firm areas of cartilage and teeth ([Figs. 18.58 and 18.59](#)). The sebaceous material is a thick fluid at body temperature but solidifies when it cools in room air.

Benign teratomas are believed to arise from a single germ cell after the first meiotic division. Therefore they develop from

totipotent stem cells, and they are neoplastic sequelae from a transformed germ cell. Dermoids have a chromosomal makeup of 46,XX and the chromosomes of dermoids were different from the chromosomes of the host, leading one to postulate that dermoids began by parthenogenesis from secondary oocytes. An alternative hypothesis was that the dermoid resulted from fusion of the second polar body with the oocyte. One thing is certain—dermoids do not arise from somatic cells nor from an oogonium before the first stage of meiosis. The first meiotic division occurs at approximately 13 weeks of gestation. Thus dermoids begin in fetal life sometime after the first trimester.

Histologically, benign teratomas are composed of mature cells, usually from all three germ layers (Fig. 18.60). A combination of skin and skin appendages, including sebaceous glands, sweat glands, hair follicles, muscle fibers, cartilage, bone, teeth, glial cells, and epithelium of the respiratory and gastrointestinal tracts, may be visualized. Teeth are predominantly premolar and molar forms. The fluid in dermoid cysts is usually sebaceous. Most solid elements arise and are contained in a protrusion or nipple (mamilla) in the cyst wall, termed the *prominence or tubercle of Rokitansky*. This prominence may be visualized by ultrasound as an echodense region, thus aiding in the sonographic diagnosis. If malignancy occurs, it is almost always found in this nest of cells. The wall of the cyst will often contain granulation tissue, giant cells, and pseudoxanthoma cells.

From 50% to 60% of dermoids are asymptomatic and are discovered during a routine pelvic examination, coincidentally visualized during pelvic imaging, or found incidentally at laparotomy. Presenting symptoms of dermoids include pain and the

sensation of pelvic pressure. Specific complications of dermoid cysts include torsion, rupture, infection, hemorrhage, and malignant degeneration. Three medical diseases also may be associated with dermoid cysts: thyrotoxicosis, carcinoid syndrome, and autoimmune hemolytic anemia, the latter two being quite rare.

Adult thyroid tissue is discovered microscopically in approximately 12% of benign teratomas. Struma ovarii is a teratoma in which the thyroid tissue has overgrown other elements and is the predominant tissue (Fig. 18.61). Strumae ovarii constitute 2% to 3% of ovarian teratomas. These tumors are usually unilateral and measure less than 10 cm in diameter. Less than 5% of women with strumae ovarii develop thyrotoxicosis, which may be secondary to the production of increased thyroid hormone by either the ovarian or the thyroid gland.

Another rare finding with dermoids is the presence of a primary carcinoid tumor from the gastrointestinal or respiratory tract epithelium contained in the dermoid. One of three of these tumors is associated with the typical carcinoid syndrome even without metastatic spread. If the carcinoid is functioning, it may be diagnosed by measuring serum serotonin levels or urinary levels of 5-hydroxyindoleacetic acid. The autoimmune hemolytic anemia associated with dermoids is the rarest of the three medical complications.

Rupture or perforation of the contents of a dermoid into the peritoneal cavity or an adjacent organ is a potentially serious complication. The incidence varies between 0.7% and 4.6%. However, most series report less than 1%. Rupture is more common in pregnancy. If a rupture occurs during surgery, the abdomen should be copiously irrigated with saline, with careful removal of any particulate matter. Chemical peritonitis is reported in less than 1% of ruptured dermoids. Rupture may

Figure 18.60 Mature cystic teratoma. This cyst is lined by mature epidermis and is subtended by connective tissue containing exuberant dermal appendages (pilosebaceous follicles). (From Russell P, Robboy SJ, Anderson MC. Germ cell tumors of the ovaries. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

Figure 18.61 Struma ovarii. Variably sized banal thyroid follicles. (From Russell P, Robboy SJ, Anderson MC. Germ cell tumors of the ovaries. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

occur either catastrophically, which produces an acute abdomen, or by a slow leak of the sebaceous material. The latter is clinically more common, with the sebaceous material producing a severe chemical granulomatous peritonitis. Some warn that this possibility should be considered and a frozen section obtained so that the true diagnosis is established. Thus a young woman will not be mistakenly treated for suspected ovarian carcinoma with metastasis because of the identical gross appearance of a slow-leaking dermoid cyst. Infection, hemorrhage, and malignant degeneration are all unusual complications of dermoids, occurring in less than 1% of patients.

Torsion of a dermoid is the most frequent complication, occurring in 3.5% to 11% of cases. Because of its weight, the benign teratoma is often pedunculated, which may predispose to torsion. Torsion is more common in younger women. Small dermoid cysts, less than 6 cm in diameter, grow slowly at an approximate rate of 2 mm per year.

The diagnosis of a dermoid cyst is often established when a semisolid mass is palpated anterior to the broad ligament. Approximately 50% of dermoids have pelvic calcifications on radiographic examination. Often an ovarian teratoma is an incidental finding during radiologic investigation of the genitourinary or gastrointestinal tract. Most dermoids have a characteristic ultrasound picture. These characteristics include a dense echogenic area within a larger cystic area, a cyst filled with bands of mixed echoes, and an echoic dense cyst. Unfortunately, only one of three dermoids has this "typical picture." In one series of 45 patients with 51 biopsy-proved dermoid cysts, 24% of the dermoid cysts were predominantly solid, 20% were almost entirely cystic, and 24% were not visible. Ultrasound has a more than 95% positive predictive value and a less than 5% false-positive rate.

Operative treatment of benign cystic teratomas is cystectomy with preservation of as much normal ovarian tissue as possible. Laparoscopic cystectomy is an accepted approach. Rates of spillage are comparable with that from open laparotomy. However, adequate irrigation in such cases is essential and often more time consuming. Many authors use a 10-cm diameter cutoff as the upper limit for a laparoscopic approach.

When a teratoma is diagnosed incidentally during pregnancy, conservative management is acceptable. Though dermoids have a higher incidence of torsion and potential for rupture during pregnancy, most large series have not shown that an aggressive approach to asymptomatic teratomas less than 10 cm confers any advantage for the mother or pregnancy. Though laparoscopy is safe during pregnancy, a small periumbilical minilaparotomy may be a faster, less traumatic approach. The treatment is cystectomy, and with the recommendation for reduced intraoperative time this approach may be preferable during pregnancy.

Endometriomas

Endometriosis of the ovary is usually associated with endometriosis in other areas of the pelvic cavity. Approximately two out of three women with endometriosis have ovarian involvement. Interestingly, only 5% of these women have enlargement of the ovaries that is detectable by pelvic examination. However, because of the prevalence of the disease, endometriosis is one of the most common causes of enlargement of the ovary. Because most authors do not classify endometriosis as a neoplastic disease, the diagnosis of endometriosis may not be given due consideration in the differential diagnosis of an adnexal mass.

Ovarian endometriosis is similar to endometriosis elsewhere and is described in greater detail in [Chapter 19](#).

The size of ovarian endometriomas varies from small, superficial, blue-black implants that are 1 to 5 mm in diameter to large, multiloculated, hemorrhagic cysts that may be 5 to 10 cm in diameter ([Fig. 18.62](#)). Clinically, large ovarian endometriomas, greater than 20 cm in diameter, are extremely rare. Areas of ovarian endometriosis that become cystic are termed *endometriomas*. Rarely, large chocolate cysts of the ovary may reach 15 to 20 cm ([Fig. 18.63](#)). Larger cysts are frequently bilateral. The surface of an ovary with endometriosis is often irregular, puckered, and scarred. Depending on their size, endometriomas replace a portion of the normal ovarian tissue.

Although most women with endometriomas are asymptomatic, the most common symptoms associated with ovarian endometriosis are pelvic pain, dyspareunia, and infertility. Approximately 10% of the operations for endometriosis are for acute symptoms, usually related to a ruptured ovarian endometrioma that was previously asymptomatic. Smaller cysts generally have thin walls, and perforation occurs commonly secondary to cyclic hemorrhage into the cystic cavity.

Figure 18.62 Endometriosis of ovaries. Wall of endometriotic cyst is thickened and fibrotic. Inner surface shows areas of dark brown discoloration. (From Janovski NA, ed. *Color Atlas of Gross Gynecologic and Obstetric Pathology*. New York: McGraw-Hill; 1969:159.)

Figure 18.63 "Chocolate cyst" of ovary. The endometrioma is large, but it has not yet completely replaced the ovary. (From Robboy SJ. Endometriosis. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

On pelvic examination, the ovaries are often tender and immobile, secondary to associated inflammation and adhesions. Most commonly the ovaries are densely adherent to surrounding structures, including the peritoneum of the pelvic sidewall, the oviduct, the broad ligament, and sometimes the small or large bowel. Endometrial glands, endometrial stroma, and large phagocytic cells containing hemosiderin may be identified histologically (see Fig. 19-10). Pressure atrophy may lead to the loss of architecture of the endometrial glands. The ultrasound characteristics include a thick-walled cyst with a relatively homogeneous echo pattern that is somewhat echolucent. This appearance confers a greater than 95% positive predictive value in some studies.

The choice between medical and operative management depends on several factors, including the patient's age, future reproductive plans, and severity of symptoms. Medical therapy is rarely successful in treating ovarian endometriosis if the disease has produced ovarian enlargement. Often surgical therapy is complicated by formation of *de novo* and recurrent adhesions.

On pathologic examination, it is important to distinguish endometriosis from benign endometrial tumors, which are usually adenofibromas. The latter tumor is a true neoplasm, and there is a malignant counterpart.

Fibroma

Fibromas are the most common benign, solid neoplasms of the ovary. Their malignant potential is low, less than 1%. These tumors make up approximately 5% of benign ovarian neoplasms and approximately 20% of all solid tumors of the ovary.

Fibromas vary in size from small nodules to huge pelvic tumors weighing 50 pounds. One of the predominant characteristics of fibromas is that they are extremely slow-growing tumors. The average diameter of a fibroma is approximately 6 cm; however, some tumors have reached 30 cm in diameter. In most series, less than 5% of fibromas are greater than 20 cm in diameter. The diameter of a fibroma is important clinically, because the incidence of associated ascites is directly proportional to the size of the tumor. Many ovarian fibromas are misdiagnosed and are believed to be leiomyomas prior to operation. Ninety percent of fibromas are unilateral; however, multiple fibromas are found in the same ovary in 10% to 15% of cases. The average age of a woman with an ovarian fibroma is 48. Thus this tumor often presents in postmenopausal women. The tumor arises from the undifferentiated fibrous stroma of the ovary. Bilateral ovarian fibromas are commonly found in women with the rare genetic transmitted basal cell nevus syndrome.

The pelvic symptoms that develop with growth of fibromas include pressure and abdominal enlargement, which may be secondary to both the size of the tumor and ascites. Smaller tumors are asymptomatic because these tumors do not elaborate hormones. Thus there is no change in the pattern of menstrual flow. Fibromas may be pedunculated and therefore easily palpable during one examination yet difficult to palpate during a subsequent pelvic examination. Sometimes on pelvic examination the fibromas appear to be softer than a solid ovarian tumor because of the edema or occasional cystic degeneration.

Meigs' syndrome is the association of an ovarian fibroma, ascites, and hydrothorax. Both the ascites and the hydrothorax resolve after removal of the ovarian tumor. The ascites is caused by transudation of fluid from the ovarian fibroma; the incidence

of ascites is directly related to the size of the fibroma. Fifty percent of patients have ascites if the tumor is greater than 6 cm. However, true Meigs' syndrome is rare, occurring in less than 2% of ovarian fibromas. The hydrothorax develops secondary to a flow of ascitic fluid into the pleural space via the lymphatics of the diaphragm. Statistically the right pleural space is involved in 75% of reported cases, the left in 10%, and both sides in 15%. The clinical features of Meigs' syndrome are not unique to fibromas, and a similar clinical picture is found with many other ovarian tumors.

Grossly, fibromas are heavy, solid, well encapsulated, and grayish white. The cut surface usually demonstrates a homogeneous white or yellowish white solid tissue with a trabeculated or whorled appearance similar to that of myomas. The majority of fibromas are grossly edematous (Fig. 18.64). Less than 10% of fibromas have calcifications or small areas of hyaline or cystic degeneration. Histologically, fibromas are composed of connective tissue, stromal cells, and varying amounts of collagen interposed between the cells. The connective tissue cells are spindle-shaped, mature fibroblasts. They are arranged in an imperfect pattern. A few smooth muscle fibers may be occasionally identified. It is sometimes difficult to distinguish fibromas from nonneoplastic thecomas. Histologically the pathologist must differentiate fibromas from stromal hyperplasia, fibrosarcomas, and also look for epithelial elements of an associated Brenner tumor.

Figure 18.64 **A**, Fibroma of the ovary with a well-circumscribed light tan mass. **B**, Histology of fibroma of the ovary, demonstrating bland fibrous differentiation. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

The management of fibromas is straightforward because any woman with a solid ovarian neoplasm should have an exploratory operation soon after the tumor is discovered. Simple excision of the tumor is all that is necessary. Following excision of the tumor, there is resolution of all symptoms, including ascites. Because these tumors are frequently discovered in postmenopausal women, often a bilateral salpingo-oophorectomy and total abdominal hysterectomy are performed. Conversely, it is important to note that most women who preoperatively have the combination of a solid ovarian tumor and ascites are found to have ovarian carcinoma.

Transitional Cell Tumors: Brenner Tumors

Brenner tumors are rare, small, smooth, solid, fibroepithelial ovarian tumors that are generally asymptomatic. The semantic classification of neoplasms changes, and the current preferred term for benign Brenner tumor is *transitional cell tumor*. The benign, proliferative (low malignant potential), and malignant forms together constitute approximately 2% of ovarian tumors. These tumors usually occur in women ages 40 to 60 years. Approximately 30% of transitional cell tumors are discovered as small, solid tumors in association with a concurrent serous cystic neoplasia, such as serous or mucinous cystadenomas of the ipsilateral ovary. Some are microscopic, with the entire tumor contained in a single low-powered microscopic field, and others may reach a diameter of 20 cm; the majority are less than 5 cm in diameter. The tumor is unilateral 85% to 95% of the time.

The Brenner tumor was first described in 1898. In 1932, Robert Meyer postulated that it was a distinct, independent neoplasm from granulosa cell tumors. Since that time there has been a controversy in the gynecologic pathology literature as to the histogenesis of the neoplasm. Presently, most authorities accept the theory that most of these tumors result from metaplasia of coelomic epithelium into uroepithelium. Detailed three-dimensional histologic studies have demonstrated a downward growth in a cordlike fashion of epithelium from the surface of the ovary to deeper areas in the ovarian cortex. Others have postulated that sometimes the solid nests of epithelial cells of the tumor originate from the rete ovarii or Walthard rests. Electron microscopy confirmed the histologic and ultrastructural similarity between the epithelium in Brenner tumors and transitional epithelium. These authors argue that because of the histogenesis from coelomic inclusion cysts and also the mixture of Müllerian-type epithelium in 30% of Brenner tumors, it might be appropriate to classify Brenner tumors in the epithelial group of ovarian neoplasms.

Approximately 90% of these small neoplasms are discovered incidentally during a gynecologic operation, although large tumors may produce unilateral pelvic discomfort. Postmenopausal bleeding is sometimes associated with Brenner tumors, as endometrial hyperplasia is a coexisting abnormality in 10% to 16% of cases. It is postulated that luteinization of the stroma produces estrogen with resulting hyperplasia that leads to classic findings of ovarian Brenner tumors on CT or MRI. The extensive fibrous content of these tumors results in lower signal intensity in T2-weighted images. During CT scanning, Brenner tumors characteristically demonstrate a finding of extensive amorphous calcification within the solid components of the ovarian mass.

Grossly, Brenner tumors are smooth, firm, gray-white, solid tumors that grossly resemble fibromas. Similar to fibromas, transitional cell tumors are slow growing. On sectioning, the tumor usually appears gray; however, occasionally there is a yellowish

tinge with small cystic spaces (Fig. 18.65). Approximately 1% to 2% of these tumors undergo malignant change (Chapter 33). Histologically, Brenner tumors have two principal components: solid masses or nests of epithelial cells and a surrounding fibrous stroma. The epithelial cells are uniform and do not appear anaplastic (Fig. 18.66). The histology and ultrastructure

Figure 18.65 Brenner tumor. (From Clement PB, Young RH: *Atlas of Gynecologic Surgical Pathology*. Philadelphia: WB Saunders; 2000.)

Figure 18.66 Benign Brenner tumor. A cyst in the Brenner tumor is lined by an inner layer of endocervical-type mucinous cells and an outer layer of stratified transitional cells, a few of which have grooved nuclei. (From Clement PB, Young RH. *Atlas of Gynecologic Surgical Pathology*. Philadelphia: WB Saunders; 2000.)

of the epithelial cells of a Brenner tumor are similar to transitional epithelium of the urinary bladder. The pale epithelial cells have a coffee bean–appearing nucleus, which is also described as a longitudinal groove in the cell's nucleus.

Electron microscopy has demonstrated that the longitudinal groove during routine microscopy is produced by prominent indentation of the nuclear membrane. An additional ovarian neoplasm is frequently found associated with Brenner tumors. Balasa and colleagues, in a review of 302 tumors, reported 100 other concurrent neoplasms, with the majority being serous and mucinous cystadenomas or teratomas (Balasa, 1977).

Management of Brenner tumors is operative, with simple excision being the procedure of choice. However, as with ovarian fibromas, the patient's age is often the principal factor in deciding the extent of the operation.

Adenofibroma and Cystadenofibroma

Adenofibromas and cystadenofibromas are closely related. Both of these benign firm tumors consist of fibrous and epithelial components. The epithelial element is most commonly serous but histologically may be mucinous and endometrioid or clear cell. They differ from benign epithelial cystadenomas in that there is a preponderance of connective tissue. Most pathologists emphasize that at least 25% of the tumor consists of fibrous connective tissue. Obviously, cystadenofibromas have microscopic or occasional macroscopic areas that are cystic. The varying degree of fibrous stroma and epithelial elements produces a spectrum of tumors, which have resulted in a confusing nomenclature with terms such as *papillomas*, *fibropapillomas*, and *fibroadenomas*.

Adenofibromas are usually small fibrous tumors that arise from the surface of the ovary. They are bilateral in 20% to 25% of women. They usually occur in postmenopausal women and are 1 to 15 cm in diameter. Grossly, they are gray or white tumors, and it is difficult to distinguish them from fibromas. Papillary adenofibromas, which project from the surface of the ovary, at first glance may appear to be external excrescences of a malignant tumor. Histologically, small precursors of adenofibromas are identified in many normal ovaries. Under the microscope, true cystic gland spaces lined by cuboidal epithelium are characteristic. However, differing from serous cystadenomas, the fibrous connective tissue surrounding the cystic spaces is abundant and is the predominant tissue of the tumor.

Smaller tumors are asymptomatic and are only discovered incidentally during abdominal or pelvic operations. Large tumors may cause pressure symptoms or, rarely, undergo adnexal torsion. A small series of the MRI features of these tumors has been reported. Similar to Brenner tumors, the fibrous component produces a very low signal intensity on T2-weighted images. This interest in imaging results from an attempt to distinguish, prior to operation, whether a predominantly solid ovarian mass is benign or malignant. Because adenofibromas are usually discovered in postmenopausal women, the treatment of choice is bilateral salpingo-oophorectomy and total abdominal hysterectomy. Because these tumors are benign and because malignant transformation is rare, simple excision of the tumor and inspection of the contralateral ovary are appropriate in younger women.

Torsion

Torsion of the ovary or both the oviduct and the ovary (adnexal torsion) is uncommon but an important cause of acute lower abdominal and pelvic pain. Torsion may cause up to 3% of all acute abdomens presenting to emergency departments. Torsion of the ovary may occur separately from torsion of the fallopian tube, but most commonly the two adnexal structures are affected together.

Adnexal torsion occurs most commonly during the reproductive years, with the average patient being in her mid-20s. However, adnexal torsion is also a complication of benign ovarian tumors in the postmenopausal woman. Pregnancy appears to predispose women to adnexal torsion. Approximately one in five women are pregnant when the condition is diagnosed. Most susceptible are ovaries that are enlarged secondary to ovulation induction during early pregnancy. The most common cause of adnexal torsion is ovarian enlargement by an 8- to 12-cm benign mass of the ovary. However, smaller ovaries may also undergo torsion. Ovarian tumors are discovered in 50% to 60% of women with adnexal torsion. Torsion of a normal ovary or adnexum is also possible and occurs more frequently in children. Dermoids are the most frequently reported tumors in women with adnexal torsion. However, the relative risk of adnexal torsion is higher with parovarian cysts, solid benign tumors, and serous cysts of the ovary. The right ovary has a greater tendency to twist (3 to 2) than does the left ovary. Torsion of a malignant ovarian tumor is comparatively rare.

Patients with adnexal torsion present with acute, severe, unilateral, lower abdominal and pelvic pain. Often the patient relates the onset of the severe pain to an abrupt change of position. A unilateral, extremely tender adnexal mass is found in more than 90% of patients. Approximately two thirds of patients have associated nausea and vomiting. These associated gastrointestinal symptoms sometimes lead to a preoperative diagnosis of acute appendicitis or small intestinal obstruction. Many patients have noted intermittent previous episodes of similar pain for several days to several weeks. The hypothesis is that previous episodes of pain were secondary to partial torsion, with spontaneous reversal without significant vascular compromise. With progressive torsion, initially venous and lymphatic obstruction occurs. This produces a cyanotic, edematous ovary, which on pelvic examination presents as a unilateral, extremely tender adnexal mass. Further progression of the torsion interrupts the major arterial supply to the ovary, resulting in hypoxia, adnexal necrosis, and a concomitant low-grade fever and leukocytosis. Fever is more common in women who have developed necrosis of the adnexa. Approximately 10% of women with adnexal torsion have a repetitive episode affecting the contralateral adnexa.

Most patients with adnexal torsion present with symptoms and signs severe enough to demand operative intervention (Fig. 18.67). Some authors have reported the successful use of Doppler ultrasound to evaluate ovarian arterial blood flow to help diagnose torsion. Abnormal color Doppler flow is highly predictive of torsion of the ovary. However, approximately 60% of women with surgically confirmed adnexal torsion will have a normal Doppler flow study (Sasaki, 2014). The false-negative rate is high enough that normal Doppler studies should never trump clinical suspicion. Women with ovarian torsion may be treated via laparoscopic surgery. The most common gynecologic conditions that may be confused with

Figure 18.67 Adnexal torsion with hemorrhagic infarction. A benign cyst was found in the ovary. (From Clement PB, Young RH: *Atlas of Gynecological Surgical Pathology*. Philadelphia: WB Saunders; 2000.)

adnexal torsion are a ruptured corpus luteum or an adnexal abscess. In series emphasizing the early diagnosis of adnexal torsion, conservative operative management has been possible in 75% of cases.

Because the majority of cases of adnexal torsion occur in young women, a conservative operation is ideal. The clinician should maintain a high index of suspicion for adnexal torsion so that early and conservative surgery is possible. With severe vascular compromise, the appropriate operation is unilateral salpingo-oophorectomy. The vascular pedicle should be clamped with care so as not to injure the ureter, which may be tented up by the torsion.

Although salpingo-oophorectomy has been the routine treatment for ovarian torsion, large series of conservative management have been reported. Conservative surgery either through the laparoscope or via laparotomy entails gentle untwisting of the pedicle, possibly cystectomy, and stabilization of the ovary with sutures. The increasing use of de-torsion may result in re-torsion. A review noted that the risk of re-torsion in pregnancy was as high as 19.5% to 37.5%; among fertile women it was 28.6%. Based on observational studies, de-torsion and fixation of the ovary is a safe procedure that reduces the risk of recurrence (Hyttel, 2015).

The risk of pulmonary embolus (PE) with adnexal torsion is small, approximately 0.2%. One series noted the risk of PE to be similar when torsion was managed by conservative surgery with untwisting or adnexal removal without untwisting.

Ovarian Remnant Syndrome

Chronic pelvic pain secondary to a small area of functioning ovarian tissue following intended total removal of both ovaries is termed *ovarian remnant syndrome*. Most of the women who develop this condition had endometriosis or chronic pelvic inflammatory disease and extensive pelvic adhesions discovered during previous surgical procedures. A more recently described risk factor is laparoscopic oophorectomy.

Figure 18.68 Ovarian remnant syndrome. Ovarian tissue that was left behind at the time of oophorectomy has regrown and is functional. (From Robboy SJ, Bentley RC, Russell P, et al. The peritoneum. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

The chronic pelvic pain is usually cyclic and exacerbated following coitus. Approximately half of women present with pain, and half with a pelvic mass. Usually the masses are small, approximately 3 cm in diameter, and most commonly located in the retroperitoneal space immediately adjacent to either ureter. Histologically, the mass contains both ovarian follicles and stroma (Fig. 18.68). If the mass cannot be palpated during pelvic examination, imaging studies such as vaginal ultrasound or MRI are often helpful. Premenopausal levels of follicle-stimulating hormone or estradiol help to establish the diagnosis in a woman who has a history of a bilateral salpingo-oophorectomy. However, sometimes a small area of ovarian tissue does not produce enough circulating estrogen to suppress gonadotropins. Difficult cases have been diagnosed by challenging and stimulating the suspected ovarian remnant with either clomiphene citrate or a GnRH agonist.

Once the diagnosis is suspected, the most effective treatment is surgical removal of the ovarian remnant. The tissue should be removed by laparoscopy or laparotomy with wide excision of the mass using meticulous techniques so as to protect the integrity of the ureter. A review of 186 patients with a history of bilateral salpingo-oophorectomy who underwent removal of an ovarian remnant confirmed by pathology revealed an intraoperative complication rate of 9.6% (Magtibay, 2005). A retrospective review reported that laparoscopic and robotic surgery for the treatment of ovarian remnant syndrome had less blood loss, lower postoperative complications, and a shorter length of stay than laparotomy (Zapardiel, 2012).

ACKNOWLEDGMENTS

We thank Vern Katz for his contributions to this chapter in the previous edition, as well as Martha Goetsch for her advice with portions of this chapter in the previous edition.

KEY POINTS

- The most common large cyst of the vulva is a cystic dilation of an obstructed Bartholin duct, with a lifetime risk estimated to be 2%. These cysts occur most often during the third decade. Inflamed cysts may be treated with oral antibiotics or incision and drainage.
- The vulva contains 1% of the skin surface of the body, but 5% to 10% of all malignant melanomas in women arise from this region. Melanoma is the second most common malignancy arising in the vulva and accounts for 2% to 3% of all of the melanomas occurring in women.
- Ideally, all vulvar nevi should be excised and examined histologically. Special emphasis should be directed toward the flat junctional nevus and the dysplastic nevus, for they have the greatest potential for malignant transformation. The dysplastic nevus is characterized by being more than 5 mm in diameter, with irregular borders and patches of variegated pigment.
- The management of nonobstetric vulvar hematomas is usually conservative unless the hematoma is greater than 10 cm in diameter or rapidly increasing.
- In adult women, 50% of cases of chronic vulvovaginal pruritus are due to allergic and irritant contact dermatitis. The most common causes of vulvar contact dermatitis are cosmetic and local therapeutic agents. Initial treatment of severe lesions is removal of all irritants or potential allergens and application of topical steroids until the skin returns to normal.
- Women usually develop psoriasis during their teenage years, with approximately 3% of adult women being affected. Approximately 20% of these have involvement of the vulvar skin. The margins of psoriasis are better defined than the common skin conditions in the differential diagnosis, including candidiasis, seborrheic dermatitis, and eczema.
- Psoriasis does not involve the vagina, only the vulva.
- Lichen sclerosis does not involve the vagina, whereas lichen planus may involve the vagina.
- Vulvar pain, vulvodynia, is one of the most common gynecologic problems, reported by up to 16% of women in the general population; 30% of women will have spontaneous relief of their symptoms without any treatment.
- Classically, the symptoms associated with the urethral diverticulum are extremely chronic in nature and have not resolved with multiple courses of oral antibiotic therapy.
- Cervical stenosis may occur following loop electrocautery excision procedures (LEEPs). The volume of tissue removed and repeat excisional procedures have been reported to increase the risk for cervical stenosis.
- Endocervical polyps are smooth, soft, red, fragile masses. They are found most commonly in multiparous women in their 40s and 50s. After the endocervical polyp is removed, endometrial sampling should be performed to diagnose a coexisting endometrial hyperplasia or carcinoma.
- Endometrial polyps are noted in approximately 10% of women when the uterus is examined at autopsy. Approximately one in four women with abnormal bleeding will have an endometrial polyp.
- Leiomyomas are the most common benign neoplasms of the uterus. The lifetime prevalence of leiomyomas is greater than 80% among African-American women and approaches 70% among white women.
- Cytogenetically, leiomyomas are chromosomally normal and arise from a single cell (they are clonal). All the cells are derived from one progenitor myocyte.
- Abnormal bleeding is experienced by a third of women with myomas, the most common pattern being intermenstrual spotting. Women with myomas and abnormal bleeding should be thoroughly evaluated for concurrent causes of bleeding.
- Adenomyosis is frequently asymptomatic. If multiple serial sections of the uterus are obtained, the incidence may exceed 60% in women 40 to 50 years of age.
- Adenomyosis rarely causes uterine enlargement greater than a size that corresponds to 14 weeks' gestation unless there is concomitant uterine pathology.
- The initial management of a suspected follicular cyst is conservative observation. The majority of follicular cysts disappear spontaneously by either reabsorption of the cyst fluid or silent rupture within 4 to 8 weeks of the initial diagnosis.
- The practice of aspirating cysts laparoscopically should be limited to cysts that are completely simple and associated with normal CA-125 levels. The intraoperative spillage of malignant cystic tumors should be avoided if possible, although the true risk that spillage poses is unknown.
- The differential diagnosis of a woman with acute pain and a suspected ruptured corpus luteum cyst includes ectopic pregnancy, a ruptured endometrioma, and adnexal torsion.
- The treatment of unruptured corpus luteum cysts is conservative. However, if the cyst persists or intraperitoneal bleeding occurs, necessitating operation, the treatment is cystectomy.
- Drainage or fenestration is effective for follicular cysts and poorly effective for cystadenomas. They will tend to recur. When cysts are drained, it is essential to remember that the cytologic examination of cyst fluid has poor predictive value and poor sensitivity in differentiating benign from malignant cysts.
- Theca lutein cysts arise from either prolonged or excessive stimulation of the ovaries by endogenous or exogenous gonadotropins or increased ovarian sensitivity to gonadotropins. The condition of ovarian enlargement secondary to the development of multiple luteinized follicular cysts is termed *hyperreactio luteinalis*. Approximately 50% of molar pregnancies and 10% of choriocarcinomas have associated bilateral theca lutein cysts.
- Benign ovarian teratomas vary from a few millimeters to 25 cm, may be single or multiple, and are bilateral 10% to 15% of the time. Dermoids are believed to arise during fetal life from a single germ cell. They are 46,XX in karyotype.
- Operative treatment of benign cystic teratomas is via cystectomy with preservation of as much normal ovarian tissue as possible.

KEY POINTS—cont'd

- Fifty percent of patients with an ovarian fibroma will have ascites if the tumor is greater than 6 cm. The incidence of associated ascites is directly proportional to the size of the tumor.
- Transitional cell tumors (Brenner tumors) are small, smooth, solid, fibroepithelial tumors of the ovary. They usually occur in women between the ages of 40 and 60 and are predominantly unilateral.
- Adnexal torsion occurs most commonly in the reproductive years, with the average age of patients being in the mid-20s. Pregnancy predisposes to adnexal torsion.
- Ovarian tumors are discovered in 50% to 60% of women with adnexal torsion.
- Abnormal color Doppler flow is highly predictive of torsion of the ovary. However, approximately 50% of women with surgically confirmed adnexal torsion will have a normal Doppler flow study.
- Conservative surgery, either through the laparoscope or via laparotomy, entails gentle untwisting of the pedicle, possibly cystectomy, and stabilization of the ovary with sutures. De-torsion and fixation of the ovary is a safe procedure that reduces the risk of recurrence.
- The risk of pulmonary embolus with adnexal torsion is approximately 0.2%. The risk is similar regardless of whether the condition is managed by conservative surgery with untwisting or adnexal removal without untwisting.

Endometriosis Etiology, Pathology, Diagnosis, Management

Arnold Advincula, Mireille Truong, Roger A. Lobo

ENDOMETRIOSIS

Endometriosis is a benign but, in many women, a progressive and aggressive disease. The wide spectrum of clinical problems that occur with endometriosis has frustrated gynecologists, fascinated pathologists, and burdened patients for years. Although endometriosis was first described in 1860, the classic studies by Sampson in the 1920s were the first to emphasize the clinical and pathologic correlations of endometriosis (Sampson, 1927). Even today, many aspects of the disease remain enigmatic.

By definition, endometriosis is the presence and growth of the glands and stroma of the lining of the uterus in an aberrant or heterotopic location. Adenomyosis is the growth of endometrial glands and stroma into the uterine myometrium to a depth of at least 2.5 mm from the basalis layer of the endometrium. Adenomyosis is sometimes termed *internal endometriosis*; however, this is a semantic misnomer because most likely they are separate diseases.

It is usually stated that the incidence of endometriosis has been increasing since the 1980s. This opinion is secondary to an enlightened awareness of mild endometriosis as diagnosed by the increasing use of laparoscopy. Since the early 2000s, diagnostic delay, the average time to the first diagnosis of the disease, has decreased dramatically. However, it has been estimated to take an average time of 11.7 years in the United States and 8 years in the United Kingdom to make the diagnosis. Evers has advanced a provocative hypothesis that endometrial implants in the peritoneal cavity are a physiologic finding secondary to retrograde menstruation, and their presence does not confirm a disease process (Evers, 1994). The overall prevalence of endometriosis in reproductive aged women has been suggested to be as high as 11% (Buck Louis, 2011). The age-specific incidence or prevalence of endometriosis is not known and has only been estimated. Many patients are diagnosed incidentally during surgery performed for a variety of other indications. Conservative estimates find that endometriosis is present in 5% to 15% of laparotomies performed on reproductive-age females. The prevalence of active endometriosis is approximately 33% in women with chronic pelvic pain. The incidence of endometriosis is 30% to 45% in women with infertility. In a compilation of eight studies encompassing 162 patients with endometriosis, the natural course of endometriosis has been reported to increase or progress 31% of the time, to remain the same 32% of the time and to regress in 38% (Taylor,

2014). The cause of endometriosis is uncertain and involves many mechanisms including retrograde menstruation, vascular dissemination, metaplasia, genetic predisposition, immunologic changes, and hormonal influences, as discussed later. In addition, there is increasing evidence that environmental factors may also play a role, including exposure to dioxin and other endocrine disruptors. Clinically, it is most difficult to predict the natural course of endometriosis in any one individual. For example, the clinician cannot know which woman with mild disease in her 20s will progress to severe disease at a later age.

The typical patient with endometriosis is in her mid-30s, is nulliparous and involuntarily infertile, and has symptoms of secondary dysmenorrhea and pelvic pain, but it must be stressed that symptoms and signs may be extremely variable. The classic symptom of endometriosis is pelvic pain. However, in clinical practice the majority of cases are not “classic.” The diagnosis and treatment of infertility associated with endometriosis is discussed in [Chapter 42](#). Aberrant endometrial tissue grows under the cyclic influence of ovarian hormones and is particularly estrogen dependent; therefore, the disease is most commonly found during the reproductive years. However, 5% of women with endometriosis are diagnosed following menopause. Postmenopausal endometriosis is usually stimulated by exogenous estrogen. Endometriosis in teenagers should be investigated for obstructive reproductive tract abnormalities that increase the amount of retrograde menstruation. Although previously thought to be rare in adolescents, in teens with pelvic pain, endometriosis has been found in approximately half the cases.

Endometriosis is a disease not only of great individual variability but also of contrasting pathophysiologic processes. It is a benign disease, yet it has the characteristics of a malignancy—that is, it is locally infiltrative, invasive, and widely disseminating. Although the physiologic levels of estrogen stimulate the growth of ectopic endometrium, the use of contraceptive steroids of various doses is usually beneficial for treatment. Another contrast often noted is the inverse relationship between the extent of pelvic endometriosis and the severity of pelvic pain. Women with extensive endometriosis may be asymptomatic, whereas other patients with minimal implants may have incapacitating chronic pelvic pain. However, as would be expected, women with deep infiltrating endometriosis, especially in retroperitoneal spaces, often experience severe episodes of pain. Pelvic lesions of

endometriosis have been found to have positive immunostaining for smooth muscle as well as nerve cells (Medina, 2009).

The clinical variability in responses among women with endometriosis may relate to differences in immunologic function and variations in cytokine production.

ETIOLOGY

There are several theories to explain the pathogenesis of endometriosis. However, no single theory adequately explains all the manifestations of the disease. Most important, there is only speculation as to why some women develop endometriosis and others do not. One popular theory is that there is a complex interplay between a dose-response curve of the amount of retrograde menstruation and an individual woman's immunologic response (these in turn may depend on ethnic and genetic variability).

Retrograde Menstruation

The most popular theory is that endometriosis results from retrograde menstruation. Sampson suggested that pelvic endometriosis was secondary to implantation of endometrial cells shed during menstruation (Sampson, 1927). It has been suggested that the shedding of endometrial-based adult stem cells and mesenchymal cells may explain this phenomenon (Gargett, 2010). These cells attach to the pelvic peritoneum and under hormonal influence grow as homologous grafts. Indeed, reflux of menstrual blood and viable endometrial cells in the pelvis of ovulating women has been documented. Endometriosis is discovered most frequently in areas immediately adjacent to the tubal ostia or in the dependent areas of the pelvis.

Endometriosis is frequently found in women with outflow obstruction of the genital tract. The attachment of the shed endometrial cells involves the expression of adhesion molecules and their receptors. This is thought to be an extremely rapid process as demonstrated in vitro. Figures 19.1 and 19.2 depict the process of implants from retrograde menstruation and early invasion (Flores, 2007; Witz, 2001).

Metaplasia

In contrast to the theory of seeding from retrograde menstruation is the theory that endometriosis arises from metaplasia of the coelomic epithelium or proliferation of embryonic rests (Meyer, 1924). The Müllerian ducts and nearby mesenchymal tissue form the majority of the female reproductive tract. The Müllerian duct is derived from the coelomic epithelium during fetal development. The metaplasia hypothesis postulates that the coelomic epithelium retains the ability for multipotential development. The decidual reaction of isolated areas of peritoneum during pregnancy is an example of this process. It is well known that the surface epithelium of the ovary can differentiate into several different histologic cell types. Endometriosis has been discovered in prepubertal girls, women with congenital absence of the uterus, and rarely in men. These examples support the coelomic metaplasia theory.

Metaplasia occurs after an "induction phenomenon" has stimulated the multipotential cell. The induction substance may be a combination of menstrual debris and the influence of estrogen and progesterone. It has been hypothesized that the histogenesis of endometriosis in peritoneal pockets of the posterior pelvis results from a congenital anomaly involving rudimentary duplication of the Müllerian system (Batt, 1989). The peritoneal pockets that they describe are found in the posterior pelvis, the posterior aspects

Figure 19.1 Proposed establishment of peritoneal endometriotic implants via retrograde menstruation, attachment, proliferation, migration, neovascularization, inflammation, and fibrosis. *E*, Endometrial cell. (From Flores I, Rivera E, Ruiz LA, et al. Molecular profiling of experimental endometriosis identified gene expression patterns in common with human disease. *Fertil Steril*. 2007;87[5]:1180-1199.)

Figure 19.2 Early Invasion of an Endometrial Implant through the Mesothelium. The mesothelium is labeled with monoclonal antibody to cytokeratin and stained with diaminobenzidine (arrows). An endometrial stromal cell (arrowhead) passing through the mesothelium is thought to represent the initial step of invasion into the stroma of the peritoneum. Original magnification, $\times 31,000$. Counterstained with hematoxylin. (From Witz CA, Monotoya-Rodriguez I, Schenken RS. Whole explants of peritoneum and endometrium: a novel model of the early endometriosis lesion. *Fertil Steril*. 1999;71[1]:56-60.)

of the broad ligament, and the cul-de-sac (Fig. 19.3). Similarly, it has been postulated that metaplasia of the coelomic epithelium that invaginates into the ovarian cortex is the pathogenesis for the development of ovarian endometriosis (Nisolle, 1997).

Lymphatic and Vascular Metastasis

The theory of endometrium being transplanted via lymphatic channels and the vascular system (Halban, 1925) helps to explain rare and remote sites of endometriosis, such as the spinal column and nose. Endometriosis has been observed in the pelvic lymph nodes of approximately 30% of women with the disease.

Figure 19.3 Proposed derivation of endometriotic lesion in the rectovaginal septum. (From Strauss JF, Barbieri R. *Yen & Jaffe's Reproductive Endocrinology*. 5th ed. Philadelphia: Saunders; 2004:692-693.)

Hematogenous dissemination of endometrium is the best theory to explain endometriosis of the forearm and thigh, as well as multiple lesions in the lung.

Iatrogenic Dissemination

Endometriosis of the anterior abdominal wall is sometimes discovered in women after a cesarean delivery. The hypothesis is that endometrial glands and stroma are implanted during the procedure. The aberrant tissue is found subcutaneously at the abdominal incision. Rarely, iatrogenic endometriosis may be discovered in an episiotomy scar.

Immunologic Changes

One of the most perplexing, unanswered questions concerning the pathophysiology of endometriosis is that some women with retrograde menstruation develop endometriosis, but most do not. Multiple investigations have suggested that changes in the immune system, especially altered function of immune-related cells, are directly related to the pathogenesis of endometriosis. Whether endometriosis is an autoimmune disease has been intensely debated for many years. Studies have demonstrated abnormalities in cell-mediated and humoral components of the immune system in both peripheral blood and peritoneal fluid. **Box 19.1** depicts various cytokines and growth factors that have been implicated in the pathogenesis of endometriosis (McLaren, 1997).

Most likely the primary immunologic change involves an alteration in the function of the peritoneal macrophages so prevalent in the peritoneal fluid of patients with endometriosis. It has been hypothesized that women who do not develop endometriosis have monocytic-type macrophages in their peritoneal fluid that have a short life span and limited function. Conversely, women who develop endometriosis have more peritoneal

macrophages that are larger. These hyperactive cells secrete multiple growth factors and cytokines that enhance the development of endometriosis. The attraction of leukocytes to specific areas is controlled by chemokines, which are chemotactic cytokines (Halme, 1984) (Fig. 19.4). Changes in the expression of integrins also may be an important local factor. Following the theory of different macrophage populations in endometriosis is the finding that the destroying of normally extruded endometrial cells in endometriosis may be deficient. It has been shown that natural killer (NK) cells have decreased cytotoxicity against endometrial and hematopoietic cells in women with endometriosis. Also, peritoneal fluid of women with endometriosis has less influence of NK activity than is found in fertile women without endometriosis.

Another attractive theory is the finding of a protein similar to haptoglobin in endometriosis epithelial cells called Endo 1. This chemoattractant protein-enhanced local production of interleukin-6 (IL-6) self-perpetuates lesion/cytokine interactions. Further compounding the proliferative activity of endometriosis lesions are angiogenic factors that are increased in lesions. Here the expression of basic fibroblast factor, IL-6, IL-8, platelet-derived growth factor (PDGF), and vascular endothelial growth factor (VEGF) are all increased.

Steroid interactions also enhance the progression of disease. Estrogen production is enhanced locally, and there is evidence for upregulation of aromatase activity, increased COX-2 expression, and dysregulation of 17 β -dehydrogenase activity, where there is a deficiency in 17 β -dehydrogenase II activity and possibly an enhancement of type II activity favoring local estradiol production (Bulun, 2009). Figure 19.5 shows abnormalities of COX-2,

Figure 19.4 Hypothesis regarding pathophysiologic characteristics of human peritoneal macrophages in endometriosis. PG, Prostaglandins. (Modified from Halme J, Becker S, Haskill S, et al. Altered maturation and function of peritoneal macrophages: possible role in pathogenesis of endometriosis. *Am J Obstet Gynecol.* 1987;156:787.)

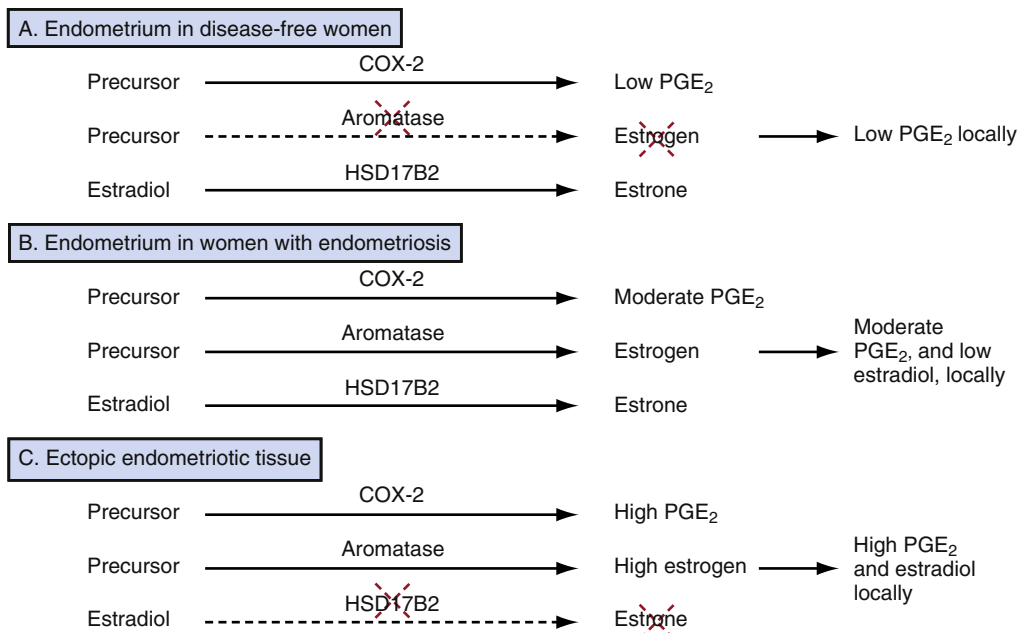

Figure 19.5 Normal Endometrium and Endometriosis. In normal endometrial tissue (*panel A*), activity of the enzyme cyclooxygenase-2 (CO-2), and thus production of prostaglandin E₂ (PGE₂), is low. Estrogen is not produced locally, owing to the absence of aromatase. During the luteal phase, the progesterone-dependent 17 β -hydroxysteroid dehydrogenase 2 (HSD17B2) enzyme catalyzes the conversion of the biologically active estradiol to estrone that is less estrogenic. In the endometrium of women with endometriosis (*panel B*), there is a subtle increase in COX-2 activity. In ectopic endometriotic tissue (*panel C*), full-blown molecular abnormalities include high COX-2 and aromatase levels. Increased PGE₂ formation in endometrial and endometriotic tissues can cause severe menstrual cramps and chronic pelvic pain. Tissue estradiol levels should be high, because estradiol is overproduced by aromatase and is not metabolized owing to deficient HSD17B2 activity. Increasing enzyme activity is denoted by the increasing thickness of arrows. (Modified from Bulun SE. Mechanisms of disease: endometriosis. *N Engl J Med.* 2009;360[3]:268-279.)

Figure 19.6 Disrupted paracrine action of progesterone in endometriotic tissue. (Modified from Bulun SE. Mechanisms of disease: endometriosis. *N Engl J Med*. 2009;360[3]:268–279.)

aromatase, and HSD 17 β 2 in disease-free women, and endometrium and ectopic lesions in women with endometriosis where high local concentrations of estrogen and prostaglandin E₂ predominate. Enhanced aromatase activity appears to be the result of overexpression of the orphan nuclear receptor steroidogenic factor-1 (SF-1) in lesions. The local production of estrogen through aromatase activity explains why progression of lesions may occur even with ovarian suppression. Further, there is evidence for progesterone “resistance” (Bulun, 2009) (Fig. 19.6). This is occasioned by a dysregulation of the isoform B of the progesterone receptor in most endometriotic lesions where levels may be undetectable. The latter propensity may be on a genetic basis, as discussed later.

Autoimmunity may well exist in women with endometriosis, and although the findings of abnormalities of the histocompatibility locus antigen (HLA) system have not been consistent, there are reports of increased B and T cells, and serum immunoglobulin (IgG, IgA, and IgM) autoantibodies in endometriosis. A survey of the U.S. Endometriosis Association has provided suggestive evidence of the higher prevalence of other autoimmune diseases. The association of all these immune processes in the symptoms and signs of endometriosis is depicted in Figure 19.7.

Genetic Predisposition

Several studies have documented a familial predisposition to endometriosis with grouping of cases of endometriosis in mothers and their daughters. An investigation by Simpson and coworkers demonstrated a sevenfold increase in the incidence of endometriosis in relatives of women with the disease compared with controls (Simpson, 1980). One of 10 women with severe endometriosis will have a sister or mother with clinical manifestations of the disease. The incidence of endometriosis in first-degree relatives, women with severe endometriosis, has been thought to be 7%. Women who have a family history of endometriosis are likely to develop the disease earlier in life and to have more advanced disease than women whose first-degree relatives are free of the disease. Studies have identified deletions of genes, most specifically increased heterogeneity of chromosome 17 and aneuploidy, in women with endometriosis compared with controls (Kosugi, 1999). Loci on 7p and 10q have also been found to increase the susceptibility for endometriosis (Painter, 2011; Treloar, 2005). The expression of this genetic liability most likely depends on an interaction with environmental and epigenetic factors, with many factors being involved. Preliminary data suggest some bilateral ovarian endometrial cysts may arise independently from different clones. Although no consistent abnormality has been found in women with endometriosis, there are several candidate genes. Box 19.2 provides a partial list of genes and gene products aberrantly expressed in endometriosis.

Several of these aberrantly expressed gene products, for example, the matrix metalloproteinases (MMPs) and integrins, have important implications for endometrial lesion attachment and for implantation defects, which may exist in infertile women with endometriosis. Reflux of MMPs into the peritoneal cavity at menstruation may contribute to peritoneal attachment in susceptible women.

Finally, Bulun and others have suggested that genetic predisposition or exposure to environmental factors (Bulun, 2009), may program fetal progenitor cells in an epigenetic way to over-express SP1 and estrogen receptor β , which increase the risk of developing endometriosis (Bulun, 2009).

Certain ethnic groups have an increased risk of having endometriosis. This is particularly striking in Asian women, in whom a ninefold increase has been suggested (Jacoby, 2010).

Pathology

The majority of endometrial implants are located in the dependent portions of the female pelvis (Fig. 19.8). The ovaries are the most common site, being involved in two of three women with endometriosis. In most of these women the involvement is bilateral. The pelvic peritoneum over the uterus; the anterior and posterior cul-de-sac; and the uterosacral, round, and broad ligaments are also common sites where endometriosis develops. Pelvic lymph nodes have been found to be involved in up to 30% of cases.

The cervix, vagina, and vulva are other possible pelvic locations. Brosens has emphasized the importance of distinguishing between superficial and deep lesions of endometriosis (Brosens, 2000). Deep lesions, penetrations of greater than 5 mm, represent a more progressive form of the disease. Distinguishing superficial implant lesions on peritoneal surfaces, including the ovary, from deep endometriotic ovarian cysts and cul-de-sac nodules is important for therapy (discussed later end parens here? in that these latter abnormalities may suggest different causes of the disease (e.g., metaplasia), which require a surgical approach.

of sites, including the umbilicus, areas of previous surgical incisions of the anterior abdominal wall or perineum, the bladder, ureter, kidney, lung, arms, legs, and even the male urinary tract (Table 19.1).

Gross pathologic changes of endometriosis exhibit wide variability in color, shape, size, and associated inflammatory and fibrotic changes. The visual manifestations of endometriosis in the female pelvis are protean and have many appearances. Increased awareness and anticipation have focused on the subtle lesions of endometriosis. Clinicians closely inspect the pelvic peritoneum to identify abnormal areas and small, nonhemorrhagic lesions. More emphasis has been placed on biopsy confirmation of endometriosis because of increasing awareness of subtle lesions. The gross appearance of the implant depends on the site, activity, relationship to the day of the menstrual cycle, and chronicity of the area involved. The color of the lesion varies widely and may be red, brown, black, white, yellow, pink, clear, or a red vesicle. The predominant color depends on the blood supply and the amount of hemorrhage and fibrosis. The color also appears related to the size of the lesion, the degree of edema, and the amount of inspissated material (Table 19.2). Figure 19.9 depicts the spectrum of lesions with black and white lesions reflecting older lesions with inflammatory and fibrotic changes. Other peritoneal lesions that grossly appear similar to endometriosis, but on histologic examination are not, include necrotic areas of an ectopic pregnancy, fibrotic reactions to suture, hemangiomas, adrenal rest, Walthard rest, breast cancer, ovarian cancer, epithelial inclusions, residual carbon from laser surgery, peritoneal inflammation, psammoma bodies, peritoneal reactions to oil-based hysterosalpingogram dye, and splenosis.

New lesions are small, bleblike implants that are less than 1 cm in diameter. Initially these areas are raised above the surrounding tissues. Red, blood-filled lesions have been shown, by histologic and biochemical studies, to be the most active phase of the disease

Figure 19.9 Proposed establishment of peritoneal endometriotic implants via retrograde menstruation and the like. (From Strauss JF, Barbieri R. *Yen & Jaffe's Reproductive Endocrinology*. 5th ed. Philadelphia: Saunders; 2004:692-693.)

(see Fig. 19.9; also see Video 19.1). With time, the areas of endometriosis become larger and assume a light or dark brown color, and they may be described as “powder burn” areas or “chocolate cysts.” The older lesions are white, have more intense scarring, and are usually puckered or retracted from the surrounding tissue. White or mixed colored lesions are more likely to provide histologic confirmation of endometriosis. Also, the progression from red to white lesions also seems to correlate with age.

The pattern of ovarian endometriosis is also variable. Individual areas range from 1 mm to large chocolate cysts greater than 8 cm in diameter (Fig. 19.10). The associated adhesions may be filmy or dense. Larger cysts are usually densely adherent to the surrounding pelvic sidewalls or broad ligament.

The three cardinal histologic features of endometriosis are ectopic endometrial glands, ectopic endometrial stroma, and hemorrhage into the adjacent tissue (Fig. 19.11). Previous hemorrhage can be discovered by identifying large macrophages filled with hemosiderin near the periphery of the lesion. In the majority of cases, the aberrant endometrial glands and stroma respond in cyclic fashion to estrogen and progesterone. These changes may or may not be in synchrony with the endometrial lining of the uterus. The ectopic endometrial stroma will undergo classic decidual changes similar to pregnancy when exposed to high physiologic or pharmacologic levels of progesterone.

In approximately 25% of cases of endometriosis, viable endometrial glands and stroma cannot be identified. Repetitive episodes of hemorrhage may lead to severe inflammatory changes and result in the glands and stroma undergoing necrobiosis

(From www.ispub.com/journal, 2007.)

secondary to pressure atrophy or lack of blood supply. In these cases, a presumptive diagnosis of endometriosis is made by visualizing the intense inflammatory reaction and the large macrophages filled with blood pigment.

The natural history of endometriosis has been discussed here, and although clinicians usually think of endometriosis as a progressive disease, this is not always the case, as it has been shown to be progressive only about one third of the time. The pathophysiology of progression from subtle endometriosis to severe disease may be expected from the multiple mechanisms of potential disease acceleration discussed earlier, with immune function most likely involved.

CLINICAL DIAGNOSIS

Symptoms

It is important to reemphasize that endometriosis has many clinical presentations, with one in three women being asymptomatic.

Most important, the disease has an extremely unpredictable course. The classic symptoms of endometriosis are cyclic pelvic pain and infertility. The chronic pelvic pain usually presents as secondary dysmenorrhea or dyspareunia (or both). Secondary dysmenorrhea usually begins 36 to 48 hours prior to the onset of menses. However, approximately one third of patients with endometriosis are asymptomatic, with the disease being discovered incidentally during an abdominal operation or visualized at laparoscopy for an unrelated problem. Conversely, endometriosis is discovered in approximately one of three women whose primary symptom is chronic pelvic pain.

Clinicians have appreciated the paradox that the extent of pelvic pain is often inversely related to the amount of endometriosis in the female pelvis. Women with large, fixed adnexal masses sometimes have minor symptoms, whereas other patients with only a few small foci with deep infiltration may experience moderate to severe chronic pain. The cyclic pelvic pain is related to the sequential swelling and the extravasation of blood and menstrual debris into the surrounding tissue. The chemical mediators of this intense sterile inflammation and pain are believed to be prostaglandins and cytokines. Infiltrative endometriosis, which involves extensive areas of the retroperitoneal space, often is associated with moderate to severe pelvic pain. Studies of pain mapping by laparoscopy under minimal sedation have found that pelvic pain arises from areas of normal peritoneum adjacent to areas of endometriosis.

Secondary dysmenorrhea is a common component of pain that varies from a dull ache to severe pelvic pain. It may be unilateral or bilateral and may radiate to the lower back, legs, and groin. Patients often complain of pelvic heaviness or a perception of their internal organs being swollen. Unlike primary dysmenorrhea, the pain may last for many days, including several days before and after the menstrual flow.

The dyspareunia associated with endometriosis is described as pain deep in the pelvis. The cause of this symptom seems to be immobility of the pelvic organs during coital activity or direct pressure on areas of endometriosis in the uterosacral ligaments or the cul-de-sac. Sometimes patients describe areas of point tenderness. The acute pain, experienced during deep penetration, may continue for several hours following intercourse.

Abnormal bleeding is a symptom noted by 15% to 20% of women with endometriosis. The most frequent complaints are premenstrual spotting and menorrhagia. Usually this abnormal bleeding is not associated with anovulation and may be related to abnormalities of the endometrium. On the other hand, patients with endometriosis frequently have ovulatory dysfunction. Approximately 15% of women with endometriosis have coincidental anovulation or luteal dysfunction.

An increased incidence of first-trimester abortion in women with untreated endometriosis has been reported, although this notion has been challenged and remains an unproven association. Less common, yet troublesome, are the symptoms resulting from endometriosis influencing the gastrointestinal and urinary tracts. Cyclic abdominal pain, intermittent constipation, diarrhea, dyschezia, urinary frequency, dysuria, and hematuria are all possible symptoms. Bowel obstruction and hydronephrosis may occur. One rare clinical manifestation of endometriosis is catamenial hemothorax, bloody pleural fluid occurring during menses. Massive ascites is a rare symptom of

Figure 19.12 Ultrasound of Endometriosis. **A**, Endovaginal ultrasound showing an endometrioma. Note low-level echoes. **B**, Doppler showing increased flow (RI = 0.48), which suggests a malignancy. **C**, T1-weighted MRI showing an endometrioma (arrow) with a high-intensity similar to fat. (Modified from Web MD, img.medscape.com.)

endometriosis, but it is important because the disease process initially masquerades as ovarian carcinoma.

Clinical Findings (Physical Exam)

The classic pelvic finding of endometriosis is a fixed retroverted uterus, with scarring and tenderness posterior to the uterus. The characteristic nodularity of the uterosacral ligaments and cul-de-sac may be palpated on rectovaginal examination in women with this distribution of the disease. Advanced cases have extensive scarring and narrowing of the posterior vaginal fornix. The ovaries may be enlarged and tender and are often fixed to the broad ligament or lateral pelvic sidewall. The adnexal enlargement is rarely symmetric, as one may expect in some benign pelvic conditions. Speculum examination may demonstrate small areas of endometriosis on the cervix or upper vagina. Lateral displacement or deviation of the cervix is visualized or palpated by digital exam of the vagina and cervix in approximately 15% of women with moderate or severe endometriosis. Carrying out a pelvic examination during the first or second day of menstrual flow may aid in the diagnosis as it is the time of maximum swelling and tenderness in the areas of endometriosis. The diagnosis can be confirmed in most cases by direct laparoscopic visualization of endometriosis with its associated scarring and adhesion formation. In many patients, endometriosis was discovered for the first time during an infertility investigation, although routine laparoscopy is no longer being carried out in the infertility investigation. Biopsy of selected implants confirms the diagnosis.

Imaging

Imaging can be a useful adjunct to the clinical presentation and physical exam for evaluation of endometriosis, especially with deep infiltrating endometriosis (DIE).

Ultrasound examination shows no specific pattern to screen for pelvic endometriosis but may be helpful in differentiating solid from cystic lesions and may help distinguish an endometrioma from other adnexal abnormalities. Because the lesions are vascular, increased Doppler flow may be demonstrated in endometriosis (Fig. 19.12). More recent studies have demonstrated a fair sensitivity from 49% to 91%, with high specificity (93% to 100%) when using transvaginal ultrasound (TVUS) to detect DIE, with the greatest sensitivity and specificity for detection of rectosigmoid lesions. Modified

techniques such as rectal water contrast transvaginal ultrasound can increase the probability of detecting a DIE lesion, which is now considered to be the more sensitive technique for the diagnosis of DIE (Noventa, 2015).

Magnetic resonance imaging (MRI) provides the best overall diagnostic tool for endometriosis but is not always a practical modality for its diagnosis. With a detection ratio and specificity of around 78% for implants, MRI for endometriosis has a reported sensitivity and specificity of approximately 91% to 95%. There is a characteristic hyperintensity on T1-weighted images and a hypointensity on T2-weighted images (de Venecia, 2015).

Diagnostic Laparoscopy

When laparoscopy is undertaken to establish the diagnosis of endometriosis, it is important to describe systematically the extent of the pathology. The American Society for Reproductive Medicine developed a point-scoring system in 1996, designed primarily to record the extent of the disease in fertility patients (ASRM, 1997). The focus here was intended to provide characterization of disease extent for fertility and not for pain assessment. Nevertheless, there are no data supporting this correlation of scoring with pregnancy rates. More recently, a proposed scoring system by Adamson focuses on the fertility potential of patients with endometriosis, the Endometriosis Fertility Index (EFI), and it has been shown in prospective evaluation to correlate with pregnancy rates (Adamson, 2010). For example, a low score of 0.3 was shown to have a 3-year cumulative pregnancy rate of only 10% to 11%.

Figures 19.13 and 19.14 illustrate ultrasound and MRI findings in retrocervical endometriosis as well as endometriosis infiltrating the bowel.

Although a benign disease, endometriosis exhibits characteristics of both malignancy and sterile inflammation. Therefore, the common considerations in the differential diagnosis include chronic pelvic inflammatory disease, ovarian malignancy, degeneration of myomas, hemorrhage or torsion of ovarian cysts, adenomyosis, primary dysmenorrhea, and functional bowel disease.

Occasionally a large endometrioma of the ovary may rupture into the peritoneal cavity. This results in an acute surgical abdomen and brings into the differential diagnosis conditions such as ectopic pregnancy, appendicitis, diverticulitis, and a bleeding corpus luteum cyst.

MONITORING THE COURSE OF DISEASE: ARE THERE MARKERS?

Serial pelvic examinations are a poor indicator of progression of disease. Serum levels of cancer antigen-125 (CA-125) have been used as a marker for endometriosis. CA-125 levels are elevated in most patients with endometriosis and increases incrementally with advanced stages. However, assays for serum levels of CA-125 have a low specificity because they also increase with other pelvic conditions such as leiomyomas, acute pelvic inflammatory disease, and the first trimester of pregnancy. Similarly, serum CA-125 levels have a low sensitivity for the diagnosis of early or minimal endometriosis (Cheng, 2002).

Glycodelin, previously known as *placental protein 14*, has been shown to be elevated in endometriosis and is produced in endometriotic lesions. Levels also fall with removal of the disease. However, because of great variability in levels, glycodelin has not proved to be useful clinically. The most predictive markers appear to be Il-1, chemoattractant protein-1 and interferon gamma, with Il-1 being the most useful marker (Othman, 2007). There has been interest in proteomic analyses as well (Fassbender, 2012).

Although it is generally thought that endometriosis improves during pregnancy, this is not always the case, and an increase in lesions has been documented, although primarily in the first trimester. Ovarian endometriomas, which may have a different pathogenetic origin, from surface implants of endometriosis on the ovary may persist during pregnancy. Also, ovarian endometriosis rupture during pregnancy may occur.

Endometriosis may be associated with ovarian cancer. Not only are lesions found at the time of diagnosis of ovarian cancer, but the risk of developing ovarian cancer may increase fourfold in women with endometriosis. Loss of heterozygosity and mutations in suppressor genes, for example, *p53*, may explain this association (Dinulescu, 2005; Pearce, 2012). These findings warrant caution in the long-term follow-up of women who have extensive disease and ovarian endometriomas, particularly with large masses and those that increase in size.

The association of other cancers with endometriosis, although suggested, has not been substantiated. However, cervical endometriosis is a particular condition that can produce abnormalities in cervical cytology.

Endometriosis is dependent on ovarian hormones to stimulate growth. With natural menopause, there is a gradual relief of

symptoms. Following surgical menopause, areas of endometriosis rapidly disappear. However, it is important to note that 5% of symptomatic cases of endometriosis present after menopause. The majority of cases in women in their late 50s or early 60s are related to the use of exogenous estrogen.

TREATMENT

The two primary short-term goals in treating endometriosis are the relief of pain and promotion of fertility. The primary long-term goal in the management of endometriosis is attempting to prevent progression or recurrence of the disease process. Presently, there is a paucity of definitive, evidence-based literature to select the most appropriate method of treatment. A Cochrane review of evidence-based therapies lists a variety of agents that may be helpful but does not specify a clearly preferred agent (Hickey, 2014). This is because there have been few prospective head-to-head comparisons and because the disease is heterogeneous with vast differences in the spectrum of clinical symptoms and extent of disease from one woman to another. Therefore the treatment plan must be individualized. Choice of therapy, for women whose primary symptom is pelvic pain, depends on multiple variables, including the patient's age, her future reproductive plans, the location and extent of her disease, the severity of her symptoms, and associated pelvic pathology. Although the gold standard for making a diagnosis is laparoscopy to establish the nature and extent of endometriosis, this is not always possible, particularly in a younger population. Imaging techniques may only be helpful if a mass is identified, and the suggestion of performing an endometrial biopsy (discussed later) may be too invasive for younger nulliparous woman. If other gynecologic conditions such as chronic pelvic inflammatory disease or neoplasia have been ruled out, empiric medical therapy for 3 months is a reasonable option. Various suppressive treatments and where they act in the pathophysiology of endometriosis may be found in Figure 19.15.

Treatment of endometriosis can be medical, surgical, or a combination of both. Most of the sex steroids, alone or in combination, have been tried in clinical studies to suppress the growth of endometriosis. Optimal regression secondary to medical treatment is observed in small endometriomas that are less than 1 to 2 cm in diameter. Response in larger areas of endometriosis may be minimal with medical therapy. A poor therapeutic result may be governed by the reduction of blood supply to the mass caused by surrounding scar tissue. Some data have suggested that with certain suppressive therapies, such as the use of dienogest, there is a decrease in nerve fiber density in endometriosis lesions (Tarjanne, 2015).

Surgical therapy is divided into conservative and definitive operations. Conservative surgery involves the resection or destruction of endometrial implants, lysis of adhesions, and attempts to restore normal pelvic anatomy. Definitive surgery involves the removal of both ovaries, the uterus, and all visible ectopic foci of endometriosis. This type of surgery is analogous to cytoreductive surgery in ovarian carcinoma.

MEDICAL THERAPY

Medical therapy is aimed at suppression of lesions and associated symptoms, particularly pain. This is best achieved by menstrual

suppression, ideally without inducing hypoestrogenism. Unfortunately, once suppressive therapy is stopped, symptoms tend to recur at variable rates. The choice of medical therapy should be individualized, weighing in potential adverse effects, side effects, cost of therapy, and expected patient compliance. The clinical effectiveness, as measured by relief of symptoms and recurrence rates of current medical therapies, are largely similar. The recurrence rate following medical therapy is 5% to 15% in the first year and increases to 40% to 50% in 5 years. Obviously the chance of recurrence is directly related to the extent of initial disease. In summary, medical therapy usually suppresses symptomatology and prevents progression of endometriosis, but it does not provide a long-lasting cure of the disease. The recurrence rate in women who initially had minimal disease is approximately 35%, whereas in those women whose initial disease was severe the rate is approximately 75%. Although there are several medical therapies for endometriosis, the Food and Drug Administration (FDA) has approved only danazol and gonadotropin-releasing hormone (GnRH) agonists. Other therapies include traditional oral contraceptives (OCs), novel progestogens such as gestinone and dienogest, an oral GnRH antagonist, the levonorgestrel-releasing intrauterine system (IUS), the aromatase inhibitor letrozole, and certain selective progesterone receptor modulators.

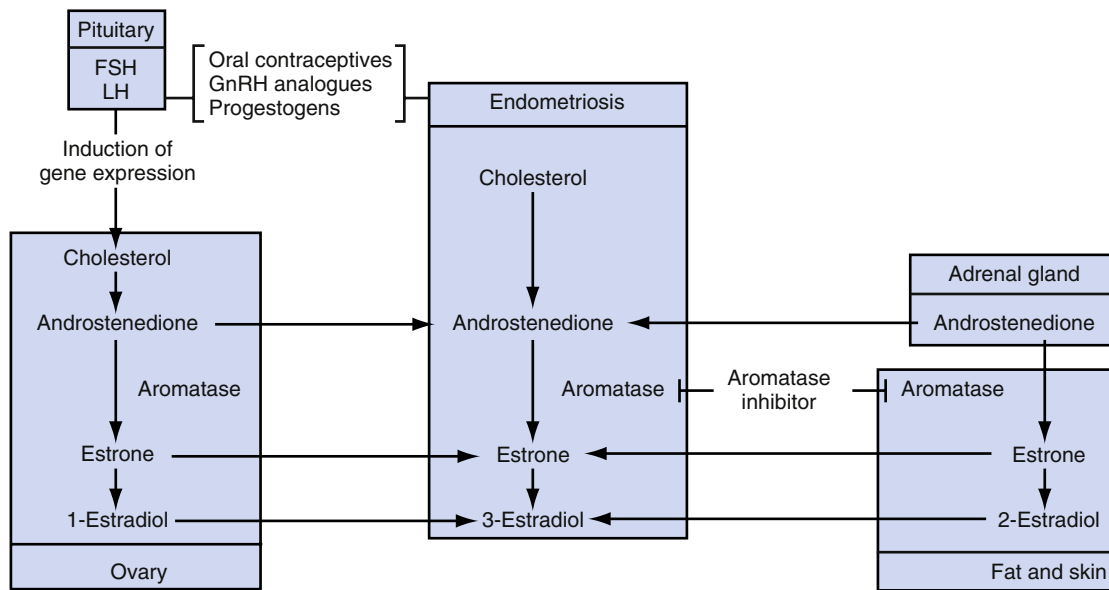

Danazol

Although approved for use in the 1970s, clinicians rarely prescribe danazol (because of lack of familiarity, its side effect profile, and the availability of other agents) and most frequently select GnRH agonists, progestogens, or oral contraceptives. Danazol is also prescribed for women with benign cystic mastitis, menorrhagia, and hereditary angioneurotic edema. Danazol is an attenuated androgen that is active when given orally. Chemically it is a synthetic steroid that is the isoxazole derivative of ethisterone (17- α -ethinyltestosterone). Many years ago, oral androgens such as methyl testosterone were also used, as they induce endometrial atrophy. Danazol produces a hypoestrogenic and hyperandrogenic effect on steroid-sensitive end organs. The drug is mildly androgenic and anabolic leading to its side-effect profile.

Danazol induces atrophic changes in the endometrium of the uterus and similar changes in endometrial implants. It may also modulate immunologic function. Although doses of 400 to 800 mg of danazol have been prescribed, many clinicians reduce the total daily dosage of the drug to 200, and even 100, mg of danazol daily. Danazol is usually begun during menses (days 1 to 5). Because the relief of the symptoms is directly related to the incidence of amenorrhea, the lower dosages of danazol are not as effective. Side effects of the hormonal changes are encountered by 80%, and approximately 10% to 20% of women discontinue danazol because of side effects. There have been reports of deepening of the voice that did not resolve after discontinuation. Mild elevation in serum liver enzyme levels has been reported in women treated for endometriosis, and women who take danazol for longer than 6 months should have serum liver enzyme determinations. An androgenic effect on lipids occurs, with reduction in high-density lipoprotein (HDL) cholesterol and triglycerides and an increase in low-density lipoprotein (LDL) cholesterol.

The standard length of treatment with danazol is 6 to 9 months. Approximately three of four patients note significant

A. Sources of estradiol in endometriotic tissue

B. Survival and inflammation of endometriotic tissue

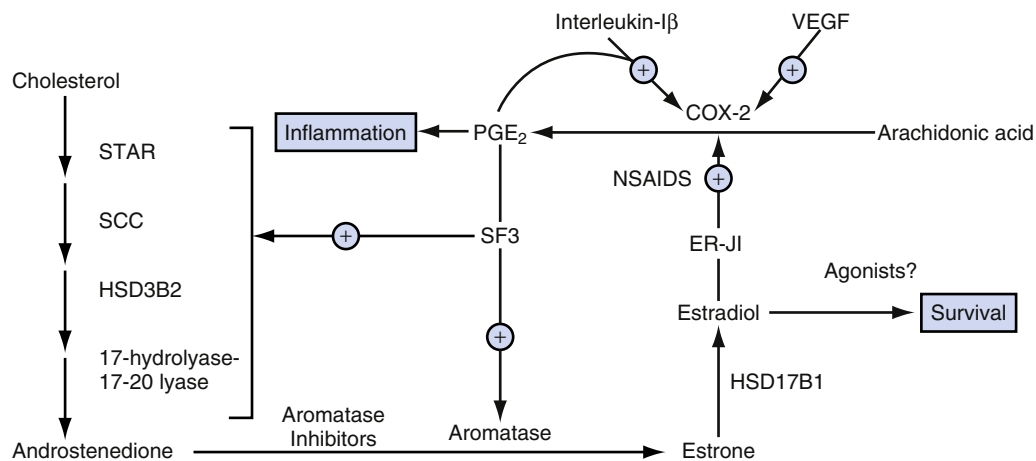

Figure 19.15 Molecular Distinctions between Endometriotic Tissue and Endometrium.

A. The three sources of estradiol, biologically active estrogen, in endometriotic tissue. The first sources are follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which induce the expression of ovarian steroidogenic genes, including aromatase, for biosynthesis of estradiol. Ovarian secretion of estradiol can be reduced through suppression of FSH and LH by gonadotropin-releasing hormone (GnRH) analogues, combination oral contraceptives, or progestins. The second source of estrogen is the estradiol that arises from aromatase activity in fat or skin. The third source of estradiol is local production in endometriotic tissue. Aromatase inhibition in peripheral tissue (fat and skin) and endometriotic tissue stops estradiol biosynthesis and is therapeutic in endometriosis. As shown in **B**, high levels of local estradiol and prostaglandin E_2 (PGE_2) are maintained in endometriotic tissue by autoregulatory positive-feedback mechanisms (indicated by plus signs) that involve nuclear receptors (steroidogenic factor 1 [SF1] and estrogen receptor β [ER- β]), enzymatic pathways, cytokines, and growth factors. COX-2 denotes cyclooxygenase-2, HSD17B1 17 β -hydroxysteroid dehydrogenase 1, HSD3B2 3 β -hydroxysteroid dehydrogenase 2, side-chain cleavage (SCC) enzyme, steroidogenic acute regulatory (STAR) protein, and vascular endothelial growth factor (VEGF). (Modified from Bulun SE. Mechanisms of disease: endometriosis. *N Engl J Med*. 2009;360[3]:268-279.)

improvement in their symptoms, and about 90% have objective improvement discovered at a second-look laparoscopy. The uncorrected fertility rate following danazol therapy is approximately 40%. Unfortunately, symptoms will recur in 15% to 30% of women within 2 years following therapy.

Several randomized, double-blind clinical studies have compared the therapeutic effectiveness of danazol with GnRH agonists. The results do not show significant differences between the efficacies of these two drugs.

GONADOTROPIN-RELEASING HORMONE AGONISTS

Several GnRH agonists have been developed and approved for the treatment of endometriosis. Representative agonists are leuprolide acetate (Lupron, injectable), nafarelin acetate (Synarel, intranasal), and goserelin acetate (Zoladex, subcutaneous implant). The usual dose of leuprolide acetate is 3.75 mg intramuscularly once per month or an 11.25-mg depot injection every 3 months. Nafarelin acetate nasal spray is given in a dose of one spray (200 µg) in one nostril in the morning and one spray (200 µg) in the other nostril in the evening up to a maximum of 800 µg daily. Goserelin acetate is given in a dosage of 3.6 mg every 28 days in a biodegradable subcutaneous implant.

Studies have determined the dose-response curve of the GnRH agonists, establishing the optimal dose to produce sufficient down-regulation and desensitization of the pituitary to produce extremely low levels of circulating estrogen and amenorrhea. Chronic use of GnRH agonists produces a “medical oophorectomy.” A dramatic reduction occurs in serum estrone, E_2 , testosterone, and androstenedione to levels similar to the hormonal levels in oophorectomized women. There are no significant changes in total serum cholesterol, HDL, or LDL levels during therapeutic periods as long as 6 months. Endometrial samples obtained after several months of chronic agonist therapy demonstrated either atrophic or an early proliferative endometrium.

The side effects associated with GnRH agonist therapy are primarily those associated with decreased estrogen, similar to menopause. The three most common symptoms are hot flashes, vaginal dryness, and insomnia. A decrease in bone mineral content has been demonstrated in the trabecular bone of the lumbar spine by quantitative computer tomography. This decrease in

bone density is not seen in the compact bone of the distal radius. There is a decrease in measured bone mass of 2% to 7% during a 6-month course of agonist therapy. However, it has been established that the decrease in bone density associated with 6 months of therapy completely recovers between 12 and 24 months.

The clinical response to agonist therapy depends on when the therapy is initiated in regard to the menstrual cycle. If agonist therapy is begun during the follicular phase, an agonist phase results in an initial rapid rise in follicle-stimulating hormone (FSH) and E_2 for approximately 3 weeks. FSH levels fall to basal levels by the third to fourth week of therapy. E_2 levels rapidly decline after 21 days of therapy. The expected surge in luteinizing hormone (LH) does not occur, and serum progesterone levels do not become elevated. Amenorrhea is induced within 6 to 8 weeks. In contrast, beginning agonist therapy during the luteal phase or if artificially manipulated by the concurrent administration of oral progestogen, serum E_2 levels are suppressed within 2 weeks. Amenorrhea is induced in 4 to 5 weeks. It is important to ensure that the patient is not pregnant when beginning GnRH agonist therapy during the luteal phase.

GnRH agonist therapy improves symptoms in 75% to 90% of patients with endometriosis, depending on the extent of the disease in the study group. Growth of endometriosis is arrested, diminished, or eliminated. The greatest therapeutic effects are seen when areas of endometriosis are less than 1 cm in diameter. Ovarian function usually returns to normal in 6 to 12 weeks after 6 months of GnRH agonist therapy. Large ovarian endometriomas and severe adhesive disease have not responded to hormonal therapy.

Currently, many clinicians “add back” hormone replacement therapy with dosages similar to those used in menopausal therapy in combination with chronic GnRH agonist regimens. The clinical hypothesis is that the add-back medication will reduce or eliminate the vasomotor symptoms and vaginal atrophy and also diminish or overcome the demineralization of bone. Barbieri has suggested that there is a therapeutic window that he estimates is a circulating level of approximately 30 pg/mL of E_2 (Barbieri, 1992). He postulated that this level of E_2 is enough to protect the body from substantial bone loss and is not high enough to interfere with the inhibition of growth of endometriosis (Fig. 19.16). Multiple randomized trials have demonstrated that add-back therapy does not interfere with the effectiveness of agonists to relieve the pelvic pain from endometriosis. The majority of studies have also

Figure 19.16 Estradiol Therapeutic Window. The concentration of estradiol required to cause the growth of endometriosis lesions may be greater than the concentration required to stabilize bone mineral density. (From Barbieri RL. Hormone treatment of endometriosis: the estrogen threshold hypothesis. *Am J Obstet Gynecol.* 1992;166[2]:740-745.)

demonstrated no diminished therapeutic efficacy when add-back therapy is initiated simultaneously with the GnRH agonist. Some clinicians additionally give bisphosphonates and calcium with the low-dose progestins and estrogen, but bisphosphonates are not recommended in younger women who may wish to become pregnant. Add-back regimens not only reduce or eliminate adverse clinical and metabolic side effects associated with hypoestrogenism but also facilitate safe and effective prolongation of GnRH agonist therapy for up to 12 months. Additional agents that have been used for add back therapy are tibolone and raloxifene.

GnRH antagonists have also been considered an attractive option in that they have no “flare” effect. A direct effect on lesions has also been hypothesized. Novel oral agents are also in early development. In a phase 2 randomized trial of oral elagolix (GnRH antagonist) at 150 and 250 mg versus leuprolide acetate in women with endometriosis pain, it was suggested that there was equal efficacy of elagolix with leuprolide and less bone loss with the antagonist (Ezzati, 2015).

For women not wishing to conceive, who predominantly have pain and no indication for surgery (which may include failed medical therapy), stopping and starting various treatments and interchanging them is a reasonable approach to control symptoms.

ORAL CONTRACEPTIVES

In the late 1950s, very large doses of norethynodrel with mestranol daily were given to produce amenorrhea and a “pseudopregnancy.” Most of the published studies involved the first-generation, high-estrogen-content oral contraceptives. However, more recent reports have established that the present low-estrogen monophasic combination pills, specifically the ones with a relatively high progestin potency, are equally effective when used in a continuous fashion. It has been accepted that the most economical regimen for the treatment of women with mild or moderate symptoms of endometriosis has been continuous daily oral contraceptives for 6 to 12 months. Continuous dose regimens are aimed at more complete suppression, with an advantage over cyclic use (Zorbas, 2015) and the only concern is with breakthrough bleeding, which can be dealt with in a variety of ways as with contraceptive therapy (see Chapter 13).

One potential risk of using oral contraceptives or progestogens is that there is some risk of rupture if a large endometrioma is present. Rupture of large endometriomas may result in an acute surgical abdomen during the first 6 weeks of oral contraceptive therapy. During prolonged therapy the endometrial glands atrophy and the stroma undergoes a marked decidual reaction. Some smaller endometriomas (~3 cm) can undergo necrobiosis and resorption.

The most common side effects of inducing amenorrhea with oral contraceptives include weight gain and breast tenderness. Approximately one in three women discontinues this therapy because of side effects.

The results of continuous oral contraceptive therapy include a decrease in symptomatology in approximately 80% of patients during therapy.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs (NSAIDs) are beneficial for pain relief and as concomitant therapy may improve the bleeding control of patients on oral contraceptives. There may also be

a direct therapeutic value in endometriosis. Although cyclooxygenase-2 (COX-2) inhibitors are now infrequently used because of cardiovascular concerns in older individuals, this therapy for endometriosis has a rationale in that lesions of endometriosis have been found to express high levels of COX-2 (see Fig. 19.15). In summary, anti-inflammatory agents may be beneficial for pain relief as well as potentially for the treatment of endometriosis, particularly when other suppressive therapy cannot be used.

Other Hormonal Treatments

For women who cannot tolerate the high dosage of estrogen in an oral contraceptive or who have a contraindication to estrogen therapy, treatment with progestogens only has been successful. Medroxyprogesterone acetate (Provera) in a dosage of 20 to 30 mg orally per day or depo-medroxyprogesterone acetate (Depo-Provera) in a dosage of 150 mg intramuscularly every 3 months to a maximum of 200 mg every month will produce a prolonged amenorrhea. The medication is most appropriate for the older woman who has completed childbearing. The time of resumption of ovulation following discontinuation of injectable medroxyprogesterone is prolonged and extremely variable. Some women will not ovulate for more than a year after their last injection. Therefore this form of therapy should not be prescribed for a young woman who is contemplating pregnancy in the near future. Oral medroxyprogesterone in a dosage of 30 mg/day is an alternative mode of therapy, as is norethindrone acetate (10 to 40 mg) daily. This more androgenic progestogen, although quite effective, has a similar symptom profile to that for continuous medroxyprogesterone.

Gestrinone is a progestogen originally developed as a once-a-week oral contraceptive. This drug has undergone clinical trials for endometriosis with dosages ranging from 2.5 to 7.5 mg/week. Gestrinone acts as an agonist-antagonist of progesterone receptors and an agonist of androgen receptors and also binds weakly to estrogen receptors. At completion of therapy in a randomized trial, a tendency for prolonged pain relief was observed for gestrinone when compared with GnRH agonist, and showed similar efficacy (Gestrinone Italian Study Group, 1996).

Dienogest is a selective progestogen that causes anovulation, has an antiproliferative effect on endometrial cells, and may inhibit cytokine secretion. In clinical trials at 2 mg/day orally, it has been found to be as effective as GnRH agonists (Ferrero, 2015).

The levonorgestrel IUS has been shown to be beneficial for pain relief in women with endometriosis compared to expectant management. It is particularly suited for women who have rectocervical and cul-de-sac disease (Fedele, 2001; Petta, 2005).

Aromatase inhibitors (anastrozole 1 mg, and letrozole 2.5 and 5 mg) have been found to be beneficial in that not only does estrogen tend to cause proliferation of the disease but also endometriosis lesions have been found to contain the aromatase enzyme (Bulun, 2009). When given alone to premenopausal women it will cause stimulation of gonadotropins and has been used to induce ovulation; but in postmenopausal women and in the premenopausal women in combination with a progestogen or oral contraception pills there is good promise that it will be beneficial for the treatment of endometriosis (Attar, 2006).

OTHER POSSIBLE MEDICAL THERAPIES

There are several other less well-proved therapies. These include the peroxisome proliferator-activated receptor (PPAR) ligands,

which have been shown to inhibit macrophage action in animal models (Lebovic, 2007); targeting haptoglobin because of structural similarity to Endo-1; targeting MMPs; and tumor necrosis factor α and VEGF (Falconer, 2008). Newer antiprogestogens have also shown efficacy in small clinical trials, (Chabbert-Buffet, 2005); and several compounds are being studied further. ER β agonists may also play some role in the future trials in that some of the estrogen action involved in increasing VEGF and angiogenic factors are mediated through ER β (see Fig. 19.15). ER β may also modulate immune function. It should be noted that selective estrogen receptor modulators, specifically tamoxifen and raloxifene, have not been shown to be beneficial (Stratton, 2008). Another anti-inflammatory immunomodulator, pentoxifylline, has also shown promise.

Various medicinal herbs have been suggested for use based on their antiproliferative and anti-inflammatory and pain-relieving properties (Wieser, 2007). However, no rigorous clinical trial data are available at present.

ROUTE OF ADMINISTRATION

Delivering various progestogens or danazol locally (intrauterine as with the levonorgestrel IUS or vaginally) may also enhance effectiveness. Small clinical trials have suggested the benefit of using suppositories and local agents, particularly in those women with cul-de-sac disease.

SURGICAL THERAPY

Surgery therapy can serve as an adjunct or alternative to medical therapy and can help prevent or delay further disease progression. The main roles of surgical therapy in the management of endometriosis are to provide symptomatic relief (pain) and to improve fertility outcomes.

Surgical management includes conservative and definitive approaches that address three main categories of lesions: superficial endometriosis (see Video 19.1), endometriomas and deep infiltrating endometriosis (DIE).

Conservative surgery involves preservation of reproductive organs and restoration of normal pelvic anatomy while removing all macroscopic endometriotic lesions or endometriomas and performing lysis of adhesions. Definitive surgery involves removing the uterus and cervix along with any visible lesions while preserving or removing either one or both of the ovaries.

Minimally invasive surgical approaches such as laparoscopy and robotic surgery have largely replaced the need for laparotomy due to advantages such as improved visualization, shorter recovery period, decreased blood loss, and decreased risks of complications.

Surgical techniques for endometriosis may vary from surgeon to surgeon, but key surgical principles should be maintained. A survey of the abdomen and pelvis should always be performed while identifying key anatomic structures including the ureter (Videos 19.2 to 19.4). Restoring normal pelvic anatomy, preventing adhesions, and limiting tissue damage is essential for successful endometriosis surgery. It is often helpful to start dissections going from normal anatomy toward abnormal anatomy. Energy should be used judiciously and cautiously especially with difficult dissections with distorted anatomy and when adjacent to vital structures such as major blood vessels, the ureter, bladder, or bowel. Although both techniques of ablation and excision

have shown improvement in outcomes compared to expectant management, there is still debate on which is most effective. A randomized study demonstrated no difference at 1 year, but at 5 years, excision resulted in greater reduction in pain, notably dyspareunia (Healey, 2014).

SURGICAL MANAGEMENT FOR PAIN

In women suffering from chronic pelvic pain due to endometriosis who have failed conservative medical therapy, surgery can be an effective treatment, especially in cases of moderate or severe endometriosis in which pelvic adhesive disease is present along with the involvement of nonreproductive organs.

In a prospective randomized trial, Sutton compared the effect of laser laparoscopy over expectant management after diagnostic laparoscopy. Pain decreased by 62.5% compared with 22.6% with expectant management, and pain relief continued in 55% of women over 72 months. The placebo response was noted to be 22%. Another randomized trial demonstrated an 80% improvement in symptoms with a 30% placebo response rate from surgery. The median time to pain recurrence after surgery has been estimated to be 20 months and reported to be approximately 15% at 1 year, 36% at 5 years, and 50% by 7 years. A study by Weir and colleagues predicted that 25% of women are likely to undergo additional surgery for endometriosis within 4 years, and 10% will need a hysterectomy.

Definitive surgical treatment, involving hysterectomy, is effective for symptomatic relief with reoperation free rates of 86% (with ovarian preservation) and 91% (without ovarian preservation) at 5 years. Although removal of the ovaries may decrease the risk of disease recurrence, this should be balanced with the risks associated with removing the ovaries and therefore should be individualized based on the patient's age, clinical presentation, and goals. Approximately one out of three women will develop recurrent symptoms and subsequently have a second operation involving oophorectomy. Though debatable, postsurgical hormonal suppression with progestins or oral contraceptives may be considered in order to decrease risks of recurrence, especially if there is any residual or unresectable disease at the time of surgery.

Other surgical treatments include presacral neurectomy and photodynamic therapy. In select patients with midline pain, presacral neurectomy may be an option for short-term improvement in symptoms, but complications can include bowel and bladder dysfunction. Photodynamic therapy for endometriosis is undergoing preliminary trials. This procedure involves intravenous injection of a special dye that is concentrated in areas of endometriosis. A laser light produces a photochemical reaction to destroy the areas.

SURGICAL MANAGEMENT FOR FERTILITY

Management of patients with endometriosis undergoing assisted reproductive treatment can be challenging. Medical therapy may sometimes be required for symptomatic control while waiting for fertility treatment; however, this is generally not recommended. There have been studies suggesting improved fertility outcomes with prolonged GnRH agonist use when administered prior to assisted reproductive treatment. Surgical management in these women can be considered, though there has been debate

Figure 19.17 Mechanisms of endometriosis associated infertility. ART, Assisted reproductive technologies. (Modified from de Ziegler, Borghese B, Chapron C. Endometriosis and infertility: pathophysiology and management. *Lancet*. 2010;376[9742]:730-738. Data from Strauss J, Barbieri R. *Yen and Jaffe's Reproductive Endocrinology*. 7th ed. Philadelphia: Elsevier; 2014.)

about the timing and risks/benefits of surgery in the setting of in vitro fertilization (IVF).

For stage I/II endometriosis, excision or ablation of endometriosis has been shown to increase live birth and ongoing pregnancy rates and is therefore recommended when visible lesions are present. Although there is lack of randomized trials, for stage III/IV, surgical treatment has also been suggested to increase pregnancy rates (see [Therapy for Subfertility](#) later in this chapter).

Endometriomas

Conservative management of endometriomas (see Video 19.2) has potential risks such as infection of the endometriomas, interfering with response to infertility treatments and oocyte retrieval, risks of complications in pregnancy, and malignancy. Endometriomas may also decrease ovarian reserve. Despite these theoretic risks, surgical removal of endometriomas is not generally recommended prior to IVF. Evidence suggests that surgery for endometriomas does not necessarily increase fertility outcome while it can further compromise ovarian reserve, increase the risk of premature ovarian failure, and induce early menopause. On the other hand, surgical treatment of endometriomas can be beneficial for certain cases such as in symptomatic patients (i.e., pelvic pain) or in those with difficult access to follicles. Surgical excision of endometriomas greater than 3 cm were previously thought to improve pregnancy rates, but studies show no difference compared to expectant management. Excision of endometriomas is preferable over ablation or drainage, as this technique has been shown to increase clinical pregnancy rates.

In patients failing to conceive spontaneously after the initial surgery, assisted reproductive therapy is recommended, as

this has been shown to be more effective than repeat surgery. Although controversial, repeat surgery can be considered after failed assisted reproductive treatments, but further studies are needed to determine optimal management of such patients.

THERAPY FOR SUBFERTILITY

The subfertility that occurs in women with endometriosis can be the result of multiple mechanisms (Fig. 19.17).

Medical therapy cannot be first-line treatment for endometriosis because suppression of ovulation interferes with the ability to conceive. Occasionally as an adjunct, more prolonged (than usual) GnRH agonist therapy may be used before IVF. In this section, surgical options are considered.

It is clear that for symptomatic women with ovarian endometriomas, laparoscopic surgical excision should be undertaken. However, in cases of extensive pelvic disease where in vitro fertilization/embryo transfer (IVF-ET) is a necessary approach, and when pelvic pain is not a significant issue, the removal of endometriomas is of no benefit and may be harmful in that it may compromise ovarian reserve. Some data suggest that women with endometriosis may have a lower ovarian reserve, as reflected by lower levels of anti-Müllerian hormone; surgery only decreases levels further (Roustan, 2015). The size of an endometrioma also comes into play in cases of IVF-ET; if all visible normal ovarian tissue is replaced by endometriomas (typically endometriomas around 4 cm or greater), surgical excision may be necessary. Otherwise for small lesions (~2 cm), follicle aspiration can be accomplished avoiding the endometriomas. In general, the presence of endometriomas tends to decrease the number of oocytes aspirated but may not impair oocyte or embryo quality. Again, it

Figure 19.18 Meta-analysis of the two randomized trials assessing the efficacy of laparoscopic surgery in the treatment of subfertility associated with minimal-to-mild endometriosis. Combining live birth and ongoing pregnancy data from the two studies shows an improvement with laparoscopic surgical treatment (OR 1.64, 95%; CI 1.05-2.57). Df, Degrees of freedom. (From Jacobson TZ, Barlow DH, Koninckx PR, et al: Laparoscopic surgery for subfertility associated with endometriosis. *Cochrane Database Syst Rev.* 2002;4:CD001398.)

is generally agreed (systemic review and meta-analysis) that surgery for endometriomas does not improve IVF rates (Hamdan, 2015); therefore the consideration for surgery should only be selected on an individual basis.

There has long been a debate as to whether treating *mild* endometriotic lesions or implants would improve fertility. Two prospective randomized trials have provided some guidance. Data from the Canadian and Italian studies, taken together, suggest that the pregnancy rates improve with implant ablation (Jacobson, 2002) (Fig. 19.18). Thus one additional pregnancy may be expected for eight surgical procedures. The way these data should be extrapolated into practice is that if a laparoscopy is being performed in a woman wishing to conceive, visible lesions should be ablated if technically possible rather than ignoring them.

Apart from the mechanical factors (endometriomas, adhesions, fibrosis) affecting pregnancy rates, in endometriosis, macrophage and cytokine abnormalities are thought to play a significant role in inhibiting fertility (see Fig. 19.17). These factors may affect oocyte quality, fertilization, and embryo quality as well as endometrial receptivity. Therefore, in addition to ablating lesions when present, several strategies have been devised to enhance fecundity. Controlled ovarian stimulation along with intrauterine insemination, an approach to enhance fecundity in women with unexplained infertility, has been found to be beneficial in women with endometriosis. Finally, if IVF-ET is undertaken (because of mechanical factors or with other failed approaches), there has been controversy as to whether pregnancy rates and live birth rates are affected by having the disease. Although an older meta-analysis suggested an approximate 20% reduction in pregnancy rates, (Barnhart, 2002) data suggest that pregnancy rates are comparable unless endometriosis is severe (Hamdan, 2015). However, at the same time, prior suppressive therapy (before initiation of an IVF cycle) has been shown to be benefit. A Cochrane systematic review of three RCTs found that prior suppression of endometriosis with a GnRH agonist for 3 to 6 months prior to IVF-ET improves outcomes with an odds ratio of 9.19 (Sallam, 2006). This reemphasizes the pathophysiologic consequences involved with having endometriosis (described earlier).

The role of surgical therapy in the management of endometriosis is very much dependent on the clinical presentation of the patient and her desire for future fertility. Although there can be a beneficial effect for fertility, a detrimental effect can also be seen. Advanced stages of disease, particularly those involving extrapelvic locations (discussed later), are often best managed in a multidisciplinary fashion.

ENDOMETRIOSIS AT OTHER SITES

GASTROINTESTINAL TRACT ENDOMETRIOSIS

The incidence of gastrointestinal tract involvement in a series of women with histologically proven endometriosis varies from 3% to 37%. Most large series document an incidence of approximately 5%. Implants that involve the gastrointestinal tract are the most common site of extrapelvic endometriosis but can be the most challenging to manage. The severity and extent of involvement of the bowel by ectopic endometrium varies from the incidental finding of a spot on the serosa of the bowel to obstruction of the rectosigmoid. In the majority of cases, endometriosis of the gastrointestinal tract involves the sigmoid colon and the anterior wall of the rectum, accounting for approximately 90% of cases (see Video 19.4).

Involvement of the appendix is the next common type of gastrointestinal (GI) tract endometriosis with an incidence reported to be between 1% and 13%. In a series of more than 100 consecutive patients with endometriosis, 13% had histologic evidence of endometriosis in the appendix, whereas only 60% of these cases are detected on gross examination. Endometriosis of the small bowel (Video 19.5) is rare, where only approximately 200 cases of endometriosis of the ileum have been reported in the literature. Of note, 48% of patients with rectosigmoid lesions will also have endometriosis of the ovaries, and 84% will have rectocervical lesions (Hemming, 2009). (Fig. 19.19; also see Video 19.3).

In most cases, the implants do not produce clinical symptoms. Classic symptoms of endometriosis of the large bowel include dysmenorrhea (cyclic pelvic cramping and lower abdominal pain) and dyschezia (rectal pain with defecation), especially during the menstrual period. Other associated symptoms include deep

Figure 19.19 Endometriosis involving the sigmoid colon. (From Hemmings R, Falcone T. Endometriosis. In: Falcone T, Hurd WW. *Clinical Reproductive Medicine and Surgery*. Philadelphia: Mosby; 2007.)

dyspareunia, change in bowel function, diarrhea or constipation (or both), and occasionally hematochezia. Studies have demonstrated that 25% to 35% of women with advanced endometriosis of the large bowel experience episodic rectal bleeding due to endometriosis extending into the submucosa. A distinct dysfunction of the enteric nervous system has been suggested to be the primary cause of the abnormalities of bowel function in women with endometriosis. It is difficult to differentiate the symptoms associated with endometriosis from the overlapping constellation of symptoms associated with inflammatory disease of the colon or malignancy. Hence, early diagnosis of gastrointestinal endometriosis and differentiation from other GI conditions are important. Women with a gastrointestinal malignancy usually experience intermittent rather than cyclic intestinal bleeding. Although acyclic bowel symptoms can occur with GI endometriosis, cyclic GI symptoms generally occur up to 89% cases, and therefore suspicion of GI endometriosis should be high with this type of presentation.

Physical exam can also help with diagnosis of deep infiltrating endometriosis invading the rectosigmoid such as by palpation of a pelvic mass or “rectal shelf” on rectovaginal examination. Sigmoidoscopy usually demonstrates absence of a mucosal lesion in addition to fixation and immobility of the anterior rectal wall. Donnez and coworkers speculated that endometriosis of the rectovaginal septum is a disease process more closely related to foci of adenomyosis than endometriosis (Donnez, 1997).

Endometriosis involving the GI tract is usually unresponsive to medical therapy and often requires surgical excision. Surgery should generally be performed in coordination with a multidisciplinary team. Complete excision of these lesions sometimes necessitates bowel resection. Although no consensus exists, bowel resection generally is indicated in symptomatic women when lesions are greater than 2 cm, greater than 30% of the circumference is involved, and when there is invasion into the inner muscularis layer, which may require bowel resection (see Video 19.4). When surgery is indicated, while still unclear which is better, bowel resection can be done via either segmental or discoid resection. Parameters that should be considered in surgical planning include size, number and depth of lesions, extent of bowel circumference involvement, distance to anal verge, and presence of lymph node involvement.

After surgical resection, up to 70% of patients have improvement of symptoms with a recurrence rate of 0 to 34%. Pregnancy rates have been reported to be between 24% to 66%.

URINARY TRACT ENDOMETRIOSIS

Endometriosis in the female pelvis occasionally produces dysfunction in adjacent pelvic organs. Approximately 10% of women with endometriosis have involvement of the urinary tract, which most commonly involves endometriotic implants and associated retroperitoneal fibrosis located in the peritoneum overlying the ureter or the bladder. In most cases an incidental finding of aberrant endometrial glands and stroma is discovered on the bladder peritoneum and anterior cul-de-sac. The most serious consequence of urinary tract involvement is ureteral obstruction, which occurs in about 1% of women with moderate or severe pelvic endometriosis. The pathogenesis of endometriosis of the bladder is controversial. Interestingly, approximately 50% of women with endometriosis of the urinary tract have a history of previous pelvic surgery. The lesions may develop from implanted endometrium during cesarean delivery or may be an extension from adenomyosis of the anterior uterine wall.

Patients with endometriosis involving the urinary tract have nonspecific clinical presentations. Hematuria and flank pain are experienced by less than 25% of women. One of three women with documented complete ureteral obstruction secondary to endometriosis has no pelvic symptoms whatsoever. The clinical challenge is to diagnose minimal ureteral obstruction at an early stage, before loss of renal function. The obstruction is almost always in the distal one third of the course of the ureter. The importance of an imaging study to diagnose ureteral compromise in all women with retroperitoneal endometriosis cannot be overemphasized.

Endometriosis of the bladder is discovered most often in the region of the trigone or the anterior wall of the bladder (Video 19.6). Bladder endometriosis produces midline, lower abdominal, and suprapubic pain, dysuria, and, occasionally, cyclic hematuria. Treatment of endometriosis of the peritoneum over the bladder can be accomplished by medical or surgical means. Ureteral obstruction may be intrinsic, from active endometriosis, or extrinsic, from long-standing fibrotic reactions to retroperitoneal inflammation. Extrinsic endometriosis is three to five times more common than the intrinsic form. There are few reports of endometriosis of the ureter responding to danazol or GnRH agonists. However, long-term follow-up with serial ultrasound imaging or intravenous pyelograms must be undertaken to ensure that the disease process does not recur.

Surgical therapy is the preferred treatment for ureteral obstruction secondary to endometriosis (Video 19.7). The operations are rare and should be individualized. The most common surgical approaches include removal of the uterus and both ovaries and the relief of urinary obstruction by ureterolysis or by ureteroneocystostomy. Ureteral resection is often needed if hydronephrosis is present. If ureterolysis is performed, peristalsis in the involved segment of the ureter should be observed, along with adequate resection of the endometriosis and surrounding inflammation in the retroperitoneal space. Ureteroneocystostomy has the advantage of bypassing the urinary obstruction and making it technically easier to resect the area of endometriosis and associated retroperitoneal fibrosis.

Figure 19.20 **A**, Fibrotic-type endometriosis involving the right hemidiaphragm. The lesions are seen above the liver. Most are obscured by the liver. **B**, Hemorrhagic-type endometriosis lesions of the right hemidiaphragm. (From Hemmings RR, Falcone T. Endometriosis. In: Falcone T, Hurd WW. *Clinical Reproductive Medicine and Surgery*. Philadelphia: Mosby; 2007:741.)

EXTRA PELVIC ENDOMETRIOSIS

Endometriosis can also involve the diaphragm (Fig. 19.20). This may be an incidental finding at laparoscopy and can be asymptomatic. However, if a patient is symptomatic, the most common presentation of diaphragmatic endometriosis is right-sided

catamenial pneumothorax. Other signs and symptoms can include dyspnea, chest pain, shoulder pain, hemoptysis, and the presence of pulmonary nodules. Medical suppressive therapy is the first approach, although surgery, including pleurodesis, may be considered. These patients should be referred to thoracic surgery.

KEY POINTS

- Endometriosis is a benign, usually progressive, and sometimes recurrent disease that invades locally and disseminates widely.
- Possible causal factors of endometriosis include retrograde menstruation, coelomic metaplasia, vascular metastasis, immunologic changes, iatrogenic dissemination, and a genetic predisposition.
- Endometriosis lesions produce estrogen locally and have increased secretion of prostaglandins and inflammatory cytokines, which can cause pain and contribute to infertility. There is also a relative resistance to progesterone in endometriosis lesions.
- Grossly, endometriosis appears in many forms, including red, brown, black, white, yellow, pink, or clear vesicles and lesions. Red, blood-filled lesions are in the most active phase of endometriosis.
- Approximately 10% of teenagers who develop endometriosis have associated congenital outflow obstruction.

Continued

KEY POINTS—cont'd

- The two primary short-term goals in treating endometriosis are the relief of pain and the promotion of fertility. The primary long-term goal in the management of a woman with endometriosis is attempting to prevent progression or recurrence of the disease process.
- There are several established treatments for endometriosis (such as oral contraceptives and GnRH agonists and danazol) and some novel therapies undergoing trials such as the use of oral antagonists, aromatase inhibitors, progesterone receptor modulators, and cytokine inhibitors.
- The recurrence rate following medical therapy is 5% to 15% in the first year and increases to 40% to 50% in 5 years.
- The side effects associated with GnRH agonist therapy are primarily those associated with estrogen deprivation, similar to menopause. The three most common symptoms are hot flashes, vaginal dryness, and insomnia. A decrease in bone mineral content of trabecular bone has been demonstrated in the cortical bone on the lumbar spine by quantitative computed tomography.
- Many clinicians “add back” very low doses of estrogen, low doses of progestins, or both in combination with chronic GnRH agonist therapy.
- The incidence of endometriosis is 30% to 45% in women with infertility. There is probably some benefit to abrading endometriosis lesions when seen at laparoscopy. In patients with endometriosis, the success of IVF-ET decreases only in women with severe disease.
- Classic symptoms of endometriosis of the large bowel include cyclic pelvic cramping and lower abdominal pain and rectal pain with defecation, especially during the menstrual period.
- Endometriosis of the bladder is discovered most often in the region of the trigone or the anterior wall of the bladder. Bladder endometriosis produces midline, lower abdominal, and suprapubic pain, dysuria, and, occasionally, cyclic hematuria.

Anatomic Defects of the Abdominal Wall and Pelvic Floor

Abdominal Hernias, Inguinal Hernias, and Pelvic Organ Prolapse: Diagnosis and Management

Anna C. Kirby, Gretchen M. Lentz

The structural supports of the abdomen and pelvis are susceptible to a number of stresses. In the female, these supports are affected by congenital anatomic weaknesses, the stresses of child-bearing, injury, surgical damage, and straining. In addition, a combination of chronic stresses, such as lifting heavy objects, chronic cough, straining at stool, or activities that require frequent stretching, plus the aging process, may make older women more susceptible to such abnormalities. This chapter considers hernias of the abdominal wall and pelvic region, as well as conditions that are a result of the loss of pelvic supports.

ABDOMINAL WALL HERNIAS

The abdominal wall is made up of the following structures beginning externally: skin; subcutaneous connective tissue; external oblique, internal oblique, and transversus abdominis muscles with their investing fascia; and parietal peritoneum. The rectus abdominis muscles run longitudinally in the midline from the xiphoid to the pubic symphysis. The investing fasciae of the external oblique, internal oblique, and transversus abdominis muscles completely encase the rectus abdominis muscles cephalad to the semilunar line. Caudally from the semilunar line the muscle is completely behind the aponeurosis of the fasciae of these muscles and lies directly on the peritoneum (Fig. 20.1). Normally the investing fasciae join in the midline after surrounding the rectus abdominis muscles.

In the male, the descent of the testes from their original retroperitoneal site to the scrotum necessitates passing through the abdominal wall to the inguinal region. At the level of the transversalis fascia where the descent begins, the internal inguinal ring is formed. The inferior epigastric artery defines the medial margin of this ring as it courses from the external iliac artery medially and superiorly into the rectus sheath. The inguinal canal runs from the internal inguinal ring obliquely downward, emerging through the external inguinal ring and opening in the external oblique aponeurosis just above the pubic spine, and then continuing into the scrotum. This allows for passage of the testes and for the presence of part of the spermatic cord.

In the female, the round ligament courses in the same direction but ends short of the labia.

An **inguinal hernia**—that is, a bulge of peritoneum through the internal inguinal ring and into the inguinal canal—is less common in the female than in the male and is frequently identified after stretching of the abdominal wall during or after pregnancy. It may be related to a congenital weakness of this area. Occasionally a femoral-type groin hernia may develop. In this case, the defect in the transversalis fascia occurs in the Hesselbach triangle, which is an area bounded laterally by the inferior epigastric artery, inferiorly by the inguinal ligament, and medially by the lateral margin of the rectus sheath (Fig. 20.2). The hernia sac passes under the inguinal ligament into the femoral triangle rather than coursing through the inguinal canal. **Femoral hernias** are more common in females than in males and have higher risk of strangulation (Fitzgibbons, 2015).

With a **reducible hernia**, the contents can be returned to the abdominal cavity. If the contents cannot be reduced, the hernia is said to be incarcerated. An **incarcerated hernia** may be acute, accompanied by pain, or long-standing and asymptomatic. If the blood supply to the incarcerated structure is compromised, the hernia is said to be *strangulated*. Because the hernia sac is primarily prolapsed peritoneum, the hernia itself is not strangulated but only its contents. On rare occasions, a portion of the wall of the hernia sac is composed of an organ such as the sigmoid colon or the cecum. In these instances, the hernia is called a **sliding hernia**.

A **ventral hernia** occurs in the abdominal wall away from the groin. Examples include **umbilical hernias**, which are caused by congenital relaxation of the umbilical ring, and **incisional hernias**, which are herniations through separation of fascial planes after operative incision. Incisional hernias generally involve the separation of the fascia of the abdominal wall with the hernia sac palpated beneath the skin and subcutaneous tissue. The sac wall is composed of peritoneum. Because the umbilicus consists of a fusion of skin, fascia, and peritoneum, an umbilical hernia generally occurs because the fascial ring is grossly separated, allowing the hernia sac to protrude. This occurs most frequently in obese women. The hernia sac itself is made up of peritoneum

Figure 20.1 Layers of the abdominal wall. **A**, Above semilunar line. **B**, Below semilunar line.

Figure 20.2 Right femoral (**A**) and right inguinal (**B**) hernias in the female.

and subcutaneous tissue beneath the skin (Fig. 20.3). Two special ventral hernias include the epigastric hernia, which occurs in a defect of the linea alba above the umbilicus, and the rare **spigelian hernia**, which is a herniation at a point where the vertical linea semilunaris joins the lateral border of the rectus muscle.

Figure 20.3 Umbilical hernia.

Spigelian hernias are rare and result from congenital or acquired defects. These are rather rare hernias (1% to 2% of all hernias).

Rectus diastasis is an acquired abdominal wall defect in which the rectus muscles on either side of the midline separate. This is not a true hernia, as there is no fascial defect, but it is mentioned here for differential diagnosis purposes. Pregnancy is a common risk factor for rectus diastasis.

ETIOLOGY

Hernias may be the result of a congenital malformation. The umbilical hernia is the best example. Before 10 weeks' gestation, the abdominal contents are partially herniated through the umbilicus into the extra embryonic coelomic cavity. However, after 10 weeks the viscera normally return to the abdominal cavity, and the defect in the abdominal wall closes during subsequent fetal growth. Generally at birth only the space occupied by the umbilical cord remains patent. After the cutting of the cord, the area heals so that the skin in the area of the umbilicus fuses above the closed fascial layer. Some infants at birth will show a small umbilical hernia, but in most instances the fascial defect closes during the first 3 years of life. If it does not close, an umbilical hernia will form. Black infants have umbilical hernias

more often than do white infants. Occasionally, umbilical hernias occur in adults after the distention of the abdominal cavity with pregnancy or with ascites.

In rare cases the abdominal wall closure process is less complete during gestation, leading to an **omphalocele**, which is a hernia sac at the umbilicus covered only by peritoneum and including bowel and other abdominal contents. Omphaloceles are usually seen in infants with other malformations and possibly chromosome anomalies, such as trisomy 13.

Hernias that occur in adults are often associated with trauma or injury. In many instances, the hernia bulge develops slowly after years of heavy labor. It is likely that a congenital anatomic defect was always present but became exaggerated over time, leading to the development of a hernia. Zimmerman and Anson suggested that inguinal lesions resulted from inadequate muscle support at the lower area of the inguinal canal, primarily caused by a defect in the internal oblique muscle. Stretching of this area in pregnancy may initiate a hernia, but other factors, such as chronic cough caused by smoking or chronic respiratory disease, may be responsible.

Incisional hernias generally occur because of poor healing of the fascia after surgery. This may be secondary to poor nutrition, infection, obesity, or necrosis of the fascia secondary to suturing. It may also occur because absorbable suture loses its tensile strength before healing is complete or excessive wound tension. Stress and strain secondary to chronic cough or vomiting in the postoperative period may contribute to the process. Emergency surgery increases the risk of incisional hernia. Other conditions that inhibit wound healing include obesity, smoking, connective tissue disorders, and immunosuppressant medications. Incisional hernias may develop in 10% to 15% of patients after abdominal laparotomy incisions.

SYMPTOMS, SIGNS, AND DIAGNOSIS

Bulges in the abdominal wall lead to the discovery of most ventral or groin hernias in women, either by a physician at the time of physical examination or by the patient. Occasionally, excessive straining or trauma will be implicated, and the patient may experience a feeling of tearing of tissue. Frequently the bulges are noted during an increase in intraabdominal pressure such as with coughing, pregnancy, or ascites. Most hernias are asymptomatic, but in some cases, particularly with larger ones, there may be aching or discomfort. Should intraabdominal organs move into the sac, the patient may experience some discomfort. Organs that strangulate within the sac cause acute pain and discomfort. Incarcerated organs may give nonspecific visceral pain, which is most likely the result of mesenteric stretching. An incisional hernia with incarceration may present with a bowel obstruction.

In cases in which a hernia exists but no contents are within the sac, physical examination reveals a weakening at the site of the hernia. It is often possible to feel the “ring” of the hernia as one palpates the defect through the skin and subcutaneous tissue. The patient’s straining will generally accentuate the hernia, making it more palpable and visible. In the case of inguinal and femoral hernias, it may be necessary for the patient to be standing for one to palpate the hernia.

When there are intraabdominal contents within the hernia sac, the hernia is more easily palpated. The physician should then decide, based on his or her attempts to gently milk the contents from the sac back through the defect ring, whether the contents are reducible. For a hernia that does not reduce easily but in which there is no evidence of vascular compromise, it is

sometimes useful to apply ice packs to the abdomen in the area of the incarcerated hernia before additional attempts are made to reduce it. In cases of **strangulated hernia**, evidence of devitalization of an organ, such as fever, leukocytosis, and evidence for an acute abdomen, may be noted.

With classic presentation of strangulated hernia on history and physical exam, surgical management should be pursued without imaging confirmation. If symptoms are present, but the exam cannot confirm a hernia, ultrasonography can be ordered. Computed tomography (CT) and magnetic resonance imaging (MRI) provide more anatomic detail and accuracy, but at increased cost and radiation exposure with CT.

MANAGEMENT

Nonoperative management of ventral wall and incisional hernias in women is often feasible. Umbilical hernias in little girls will generally close by age 3 or 4 years and rarely become incarcerated. Unincarcerated groin hernias are often small and become uncomfortable only with an increase in intraabdominal pressure, such as occurs with pregnancy. Many authors advocate repair, however, because the small neck of these hernias may make incarceration more likely. With pregnancy, the opportunity for incarceration is reduced because the increasing size of the uterus pushes bowel contents away from the area of the herniation. Trusses and other supports are generally difficult to fit and are of little value in women.

Larger hernias, hernias that continuously contain intraabdominal contents, hernias that cause continuing discomfort, and those that have been incarcerated should be repaired. Most incisional hernias should be repaired, but asymptomatic groin hernias can be safely managed conservatively. Some general principles of operative repair can be stated. The first principle involves the anatomy of the hernia. The hernia almost always consists of a sac of peritoneum with a narrow neck and a fascial defect of some sort. In rare instances, if a peritoneal sac is broad based, it may be possible to simply reduce the sac through the fascial defect without opening it and then to repair the fascial defect. However, if a narrow-necked sac exists, it must be dissected free of the fascial defect, emptied of its contents, and then excised and sutured at the neck (base). The fascial defect is then mobilized completely to remove stress and scarring, and it is closed with permanent suture. In many cases the fascial defect may be large, and the degree of mobilization that is required may be impossible. In such instances, patching with inert material, such as polypropylene mesh, may be necessary. Mesh repairs have become the preferred technique for incisional hernias because the recurrence rate is lowered. Studies are conclusive regarding lower recurrence risk for hernia using permanent mesh. However, the infection risk is higher. Sutured repair without mesh is still acceptable for small hernias (<2 to 3 cm).

The second principle involves management of the contents of the hernia sac. Usually the hernia sac reduces with ease, but if intraabdominal contents are fixed to the sac wall by adhesions, the sac must be opened and the adhesions carefully separated. Care must be taken not to damage the organs or their blood supply. When these organs are reduced from the sac, the sac may be handled in the usual fashion. When incarceration has occurred, the organs must be inspected for viability before replacement.

Umbilical Hernia Repair

To surgically repair an umbilical hernia, a curved incision is made at the inferior margin of the umbilicus (Fig. 20.4). The umbilicus

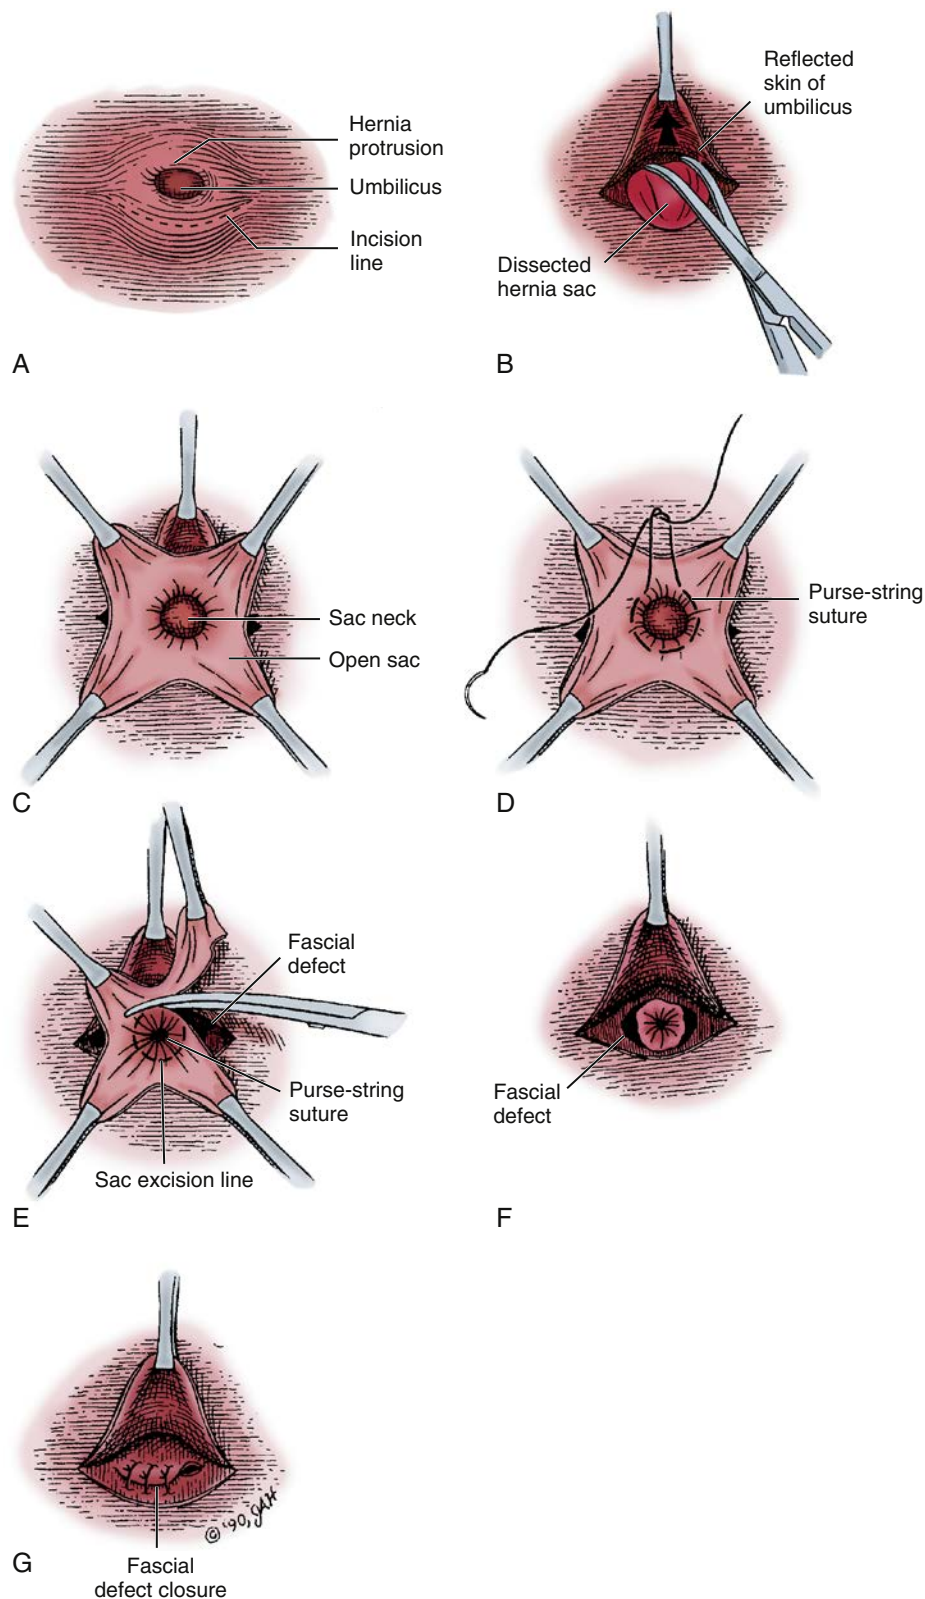

Figure 20.4 Repair of umbilical hernia. **A**, Site of incision. **B**, Umbilicus dissected free of sac and reflected upward. **C**, Appearance of sac that is cut open. **D**, Placement of purse-string suture at neck of sac. **E**, Sac dissected free of fascial defect after suture is tied. **F**, Appearance of fascial defect after sac has been excised. **G**, Fascial defect closed; umbilicus will be tacked to it.

is dissected free of the sac and reflected upward. The sac is then dissected free of the fascial defect and either reduced or excised, depending on the circumstances. The fascial edges are freshened and either closed by direct approximation anterior to posterior using nonabsorbable sutures or mobilized and closed in a “vest over pants” manner, suturing the anterior edge to the posterior edge in an overlapping fashion. Studies have not shown that neither of these closures is superior to the other, and the approach taken generally is the one that best fits the circumstances. The umbilicus is then tacked to the fascial defect and the skin margin approximated. Large defects may require mesh placement to avoid tension on the closure (Aslani, 2010). Laparoscopic repair is also possible.

Incisional Hernia

Repair of an incisional hernia can be accomplished by incising the skin through the old scar or via a parallel incision and dissecting through the subcutaneous tissue to identify both margins of the separated fascial defect. The peritoneum of the hernia sac is then isolated, dissected free of the margins, and reduced in the most appropriate fashion, with the surgeon exercising care not to damage any organs that may be fixed in the sac by adhesions. The fascial edges are then mobilized completely and closed with a mass suture technique. Outcome studies show a sutured repair is more likely to result in a recurrence than a mesh repair, although sutured repair may be adequate for small hernias (<2 or 3 cm) and when the risk of using a mesh prosthesis is unacceptable. Laparoscopic repairs

are increasingly common. In a meta-analysis of five randomized controlled trials involving 611 patients, the recurrence risk and length of hospital stay were similar, but laparoscopic repairs had reduced risk of wound infection compared to open repairs (Al Chalabi, 2015).

Prevention of incisional hernias bears mention because 10% to 15% of abdominal incisions will develop a hernia. Preventing wound infection with appropriate antibiotic prophylaxis if indicated and careful surgical technique is worthwhile because the hernia rate increases to 23% with postoperative wound infection. A meta-analysis of abdominal fascial closure concluded that a continuous nonabsorbable suture closure resulted in the lowest rates of incisional hernia. Weight loss and smoking cessation should be recommended, as these are risk factors for hernia development.

PELVIC ORGAN PROLAPSE

Pelvic organ prolapse (POP) is a condition characterized by the failure of various anatomic structures to support the pelvic viscera. It is defined as the descent of one or more of the vaginal walls or cervix: **anterior vaginal wall prolapse (cystocele, urethrocele, paravaginal defect)**, **posterior vaginal wall prolapse (rectocele or enterocele)**, **uterine/cervical prolapse**, or **vaginal vault prolapse** (after hysterectomy, often with an enterocele) (Fig. 20.5). Symptoms can include vaginal bulging, pelvic pressure, vaginal bleeding or discharge,

Figure 20.5 Photographs in lithotomy position and sagittal magnetic resonance image showing vaginal wall prolapse. Prolapse might include (top to bottom): bladder (cystocele), small bowel (enterocele) or rectum (rectocele). Purple: bladder; orange: vagina; brown: colon, and rectum; green: peritoneum. (From Jelovsek JE, Maher C, Barber MD. Pelvic organ prolapse. *Lancet*. 2007;369:1027-1038.)

Figure 20.6 Prevalence of prolapse symptoms per the pelvic organ prolapse quantification (POPQ) system. The percentage of patients who report urinary splinting, digital assistance, and vaginal bulge is demonstrated for each relevant POPQ measurement. (Modified from Tan JS, Lukacz ES, Menefee SA, et al. Predictive value of prolapse symptoms: a large database study. *Int Urogynecol J Pelvic Floor Dysfunct.* 2005;16:203-209.)

low backache, and the need to replace the prolapse (**splint**) in order to void or defecate (Haylen, 2010), or POP can be asymptomatic. Symptoms are more common when the prolapse extends beyond the hymen (Fig. 20.6) (Tan, 2005). POP usually involves more than one wall of the vagina.

RISK FACTORS

POP is common, particularly in parous women, although many are asymptomatic. Although the prevalence of POP is 30% to 50%, the prevalence of symptomatic POP is closer to 3% (Nygaard, 2008). As demonstrated in Figure 20.7, most POP does not require treatment. A woman in the United States has a 13% lifetime risk of undergoing prolapse surgery (Wu, 2014). More than 360,000 surgical repairs are performed each year for POP in the United States (FDA, 2011). White and Latina women have four to five times higher risk of symptomatic POP compared with African-American women, and white women have the highest risk of having POP at or beyond the hymen (Whitcomb, 2009). Pelvic support structure defects have been associated with age, vaginal childbirth-related injury (neurologic or muscular or both), obesity, diabetes, connective tissue disorders, genetics/family history, and neurologic diseases (Cartwright, 2014; Memon, 2013) (Box 20.1). A single vaginal childbirth is associated with up to 10-fold higher odds of POP (Quiroz, 2010), and the risk

TREATMENT PATTERNS FOR PELVIC ORGAN PROLAPSE

Figure 20.7 Prolapse diagnosis and rates of different management patterns among female Medicare beneficiaries. (From Khan AA. Trends in management of pelvic organ prolapse among female Medicare beneficiaries. *Am J Obstet Gynecol.* 1015;212[4]:463.e1-463.e8.)

of surgery for POP may increase with each additional vaginal delivery (Larsson, 2009). In some cases, the injury from childbirth is subtle, but sometimes it is obvious, as shown in the images of this woman who had complete right-sided avulsion of her puborectalis (one of the levator ani muscles) after a normal vaginal delivery (Fig. 20.8).

Frequently, damage to the pelvic floor results in urinary incontinence instead of or in addition to POP. Urinary incontinence is discussed in detail in Chapter 21.

NORMAL ANATOMY AND PATHOPHYSIOLOGY

Normal support of pelvic organs is provided by several key anatomic structures, including the pelvic floor muscles and connective tissue attachments (Fig. 20.9). Level I support of the vaginal apex and cervix is provided by the uterosacral and cardinal ligaments and associated connective tissue, level II support of the mid-vagina is provided by connective tissue attachments to the arcus tendineus fasciae pelvis on the lateral pelvic side walls, level III support of the distal (inferior) vagina is provided by the perineal membrane and muscles, (DeLancey, 1992), and all of the attachments are connected through endopelvic connective tissue.

The vagina is a hollow, fibromuscular tube composed of three layers: nonkeratinizing stratified epithelium, lamina propria

(loose connective tissue), and muscularis (fibromuscular tissue with collagen and elastin). It is supported by attachments to the sacrum, coccyx, and lateral pelvic sidewalls. Anteriorly, the vagina supports the base of the bladder and urethra. The rectum is located posterior to the vagina behind the rectovaginal septum superiorly, and the perineal body is fused with the vaginal muscularis inferiorly. Although the connective tissues that lie between the vagina and surrounding organs have commonly been called *endopelvic fascia* and distinct planes can often be found during surgical dissection, DeLancey found that histologically this tissue is composed of connective tissue and muscle rather than fascia.

The pathophysiology of POP is probably multifactorial. Bump and Norton outlined a useful concept for looking at risk factors as predisposing, inciting, promoting, or decompensating events (Fig. 20.10). Although imaging is not usually necessary in the evaluation of POP, imaging techniques including ultrasonography and MRI are increasing our understanding of support defects. Three-dimensional (3D) color thickness mapping was used to compare the levator ani of 30 women: 10 asymptomatic, 10 with urodynamic stress incontinence, and 10 with POP. Thicker, bulkier levator ani muscles were found in the asymptomatic women. Loss of levator muscle bulk was found in women with POP and stress incontinence (Fig. 20.11) (Hoyte, 2004). Theoretic explanations for these findings include muscle atrophy from denervation from childbirth injuries or muscle wasting from muscle insertion detachment also from childbirth, and possibly age and hormonal status. More women with POP had levator muscle defects and increased size of the levator hiatus on MRI compared to women with stress urinary incontinence and controls. MRI studies of POP demonstrate a more vertical vaginal axis and wider genital hiatus in women with POP compared to controls, in whom the upper two thirds portion of the vagina is nearly horizontal (Fig. 20.12).

The middle image shows a rendered volume (axial plane, translabial three-dimensional ultrasound scan) 3 months postpartum, and the right image shows magnetic resonance imaging findings (single slice in the axial plane) at 3.5 months postpartum. *Top arrows* indicate the site of avulsion on the inferior pubic ramus, and *bottom arrows* show the retracted stump of puborectalis. (From Dietz HP, Gillespie A, Phadke P. Avulsion of the pubovisceral muscle associated with large vaginal tear after normal vaginal delivery at term: a case report. *Aust NZ J Obstet Gynaecol.* 2007;47:341-344.)

Figure 20.9 Level I (suspension) and level II (attachment) support of the vagina. In level I the paracolpium (uterosacral ligaments) suspends the vagina from the lateral pelvic walls. Fibers of level I extend both vertically and posteriorly toward the sacrum. In level II support, the vagina is attached to the arcus tendineus fasciae pelvis and superior fascia of the levator ani by condensations of the levator ani (e.g., endopelvic and pubocervical fascia). In level III support, the vaginal wall is attached directly to adjacent structures without intervening paracolpium (i.e., urethra anteriorly, perineal body posteriorly, and levator ani muscles laterally). GENERAL SYMPTOM ASSESSMENT

Symptoms of POP are often not specific to the area that is prolapsing, and many women have no symptoms. The classic symptoms of prolapse include vaginal heaviness and pressure, a vaginal bulge, pelvic pain, or vaginal bleeding (from erosions of exposed vaginal epithelium). Back pain and pelvic pain are not reliably associated with prolapse. If a woman with objective prolapse does not have any bothersome symptoms or evidence of associated medical risks such as urinary retention or renal impairment from urethral or ureteral kinking, she does not

need treatment. Because more than one pelvic floor disorder is often present, urinary, bowel, and sexual symptoms should be assessed in addition to prolapse symptoms in any woman with POP (Box 20.2). Urinary symptoms can include urinary incontinence, difficulty voiding, slow urinary stream, or a sensation of incomplete bladder emptying. Bowel symptoms such as constipation, straining, incomplete evacuation, fecal incontinence, or splinting (reducing the prolapse) to achieve bowel movements can be present. Sexual symptoms may include discomfort, irritation, and decreased sexual desire. She should also be asked about how these symptoms affect her quality of life, emotional health, and social interactions as well as whether or not they affect her ability to do usual daily chores, exercise, and participate in social events. Validated, self-administered questionnaires are available such as the Pelvic Organ Prolapse Quality of Life (P-QOL) scale and the Urinary Distress Inventory, which cover these categories. Understanding the woman's goals for treatment is important, because often there are multiple symptoms in each of these areas that cause varying degrees of bother and distress.

QUANTIFICATION OF PELVIC ORGAN PROLAPSE

There are several systems for objectively measuring pelvic organ prolapse. In one system that is commonly used but imprecise, prolapse into the upper barrel of the vagina is called **first degree**, prolapse to the introitus is **second degree**, prolapse past through the introitus is **third degree**, and complete eversion of the vagina is **fourth degree** prolapse. In the Baden-Walker system, **grade 0** is normal position, **grade 1** is descent halfway to the hymen, **grade 2** is descent to the hymen, **grade 3** is descent halfway past the hymen, and **grade 4** is maximum possible descent (Baden, 1972). Although these systems are commonly used and reasonable, they provide no information regarding which walls of the vagina are prolapsed and are rather imprecise regarding the severity of the prolapse, so in 1996 the Pelvic Organ Prolapse Quantitative (POP-Q) system was developed (Bump, 1996). A comparison of these measurement systems is shown in Figure 20.13.

PELVIC ORGAN PROLAPSE QUANTITATIVE

In 1996, the International Continence Society (ICS), the American Urogynecologic Society (AUGS), and the Society of Gynecologic Surgeons (SGS) adapted a standardized terminology for the description of female pelvic organ prolapse and pelvic floor dysfunction and a standard measurement system for POP: the POP-Q (Bump, 1996). POP-Q is an objective, site-specific system for describing, quantifying, and staging pelvic support and was developed to enhance both clinical and academic communication with respect to individual patients and populations of patients. The new terminology, which refers to anterior vaginal wall, posterior vaginal wall, and vaginal vault prolapse, makes no assumptions regarding the organs behind the walls. It was designed to replace terms such as *cystocele*, *rectocele*, and *enterocele* with anatomic landmarks rather than organs, but the old terminology is still in wide clinical use and is often appropriate when it is known which organs are prolapsing behind the vaginal walls.

In the POP-Q system, as shown in [Figure 20.14](#), all of the measurements are performed while the patient strains (bears down) except for total vaginal length (TVL). Point Aa is a point located in the midline of the anterior wall 3 cm proximal to the urethral meatus and is roughly the location of the urethrovesical crease ([Fig. 20.15](#)). Point Ba represents the most distal position of the anterior vaginal wall between Aa and the cervix or cuff. Point C represents either the most distal edge of the cervix or the leading edge of the vaginal cuff if a hysterectomy has been performed. Point D represents the location of the posterior fornix (pouch of Douglas) or the posterior point of attachment of the uterosacral ligaments (there is debate among the experts) in a woman with a cervix. Point Bp is a point most distal of any part of the upper posterior vaginal wall between Ap and the cervix or cuff, and point Ap is a point located in the midline of the posterior vaginal wall 3 cm proximal to the hymen. To record measurements, these points should be expressed in centimeters above or below the hymen (i.e., negative measurements are above the hymen and positive measurements are below the

hymen). PB, which is the length of the perineal body between the posterior vagina and rectum, and GH, which is the genital hiatus measurement from the urethra to the posterior vagina, are measured during strain and do not have positive or negative values because they are not compared to the hymen. The most severe prolapse measurement on any of the vaginal walls can then be used to assign the **stage** of prolapse as described in [Box 20.3](#): **stage 0**: no prolapse, **stage 1**: the most distal prolapse is more than 1 cm above (inside) the hymen, **stage 2**: prolapse between 1 cm above and 1 cm below the hymen, **stage 3**: prolapse more than 1 cm beyond the hymen but no farther than TVL – 2 cm, and **stage 4**: complete eversion/procidentia.

These organizations hope that by using this system, a clearer understanding of a patient's prolapse will be achieved and the transmittal of this information to others will be made more accurate. They also expect that this system will make it possible to standardize research information. Because the old terminology remains commonly used outside academic centers, both will be referred to in this chapter.

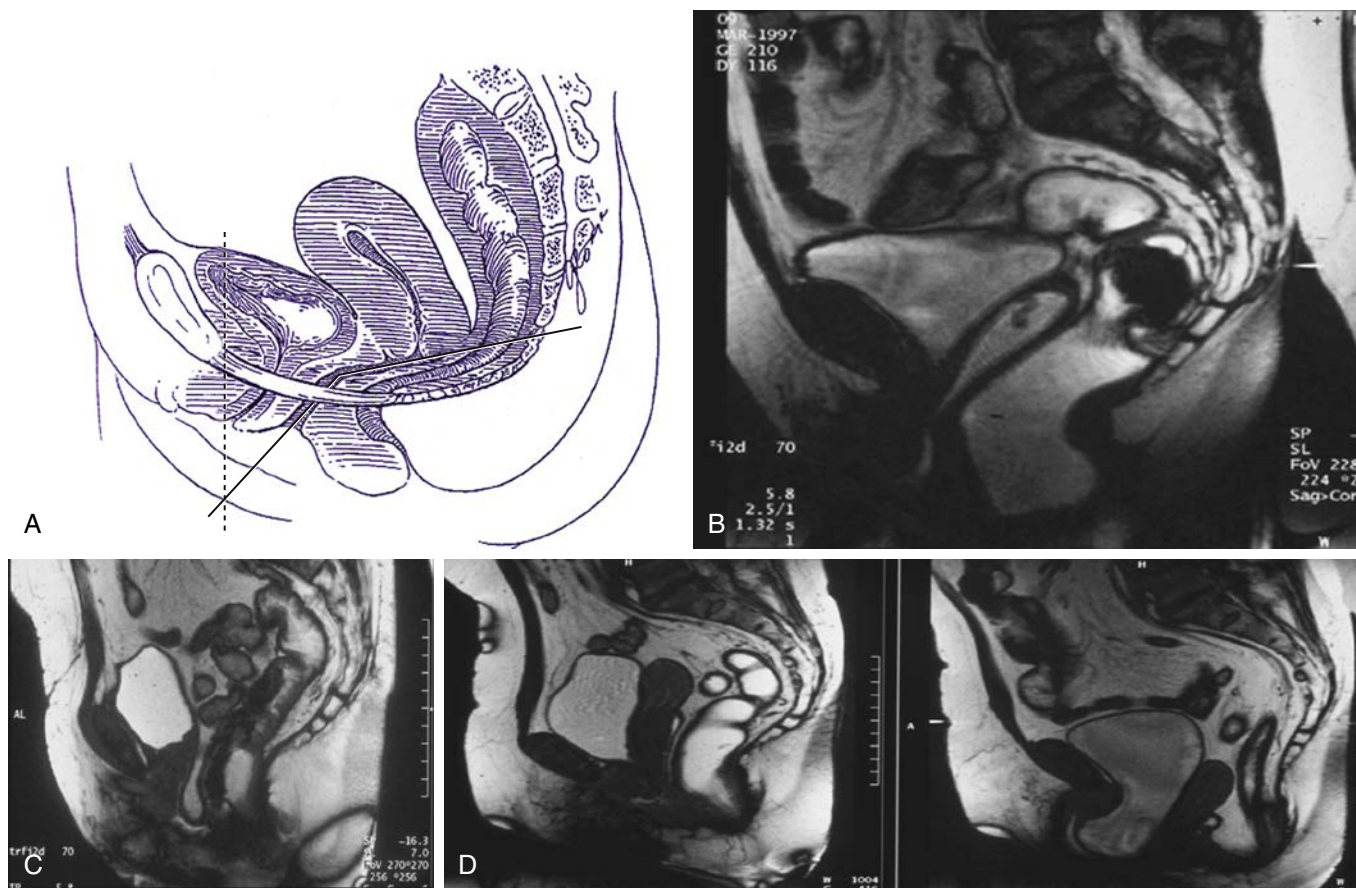

Figure 20.12 **A** and **B**, In the nulliparous patient, the lower one third of the vagina is oriented more vertically, whereas the upper two thirds deviate horizontally, thereby maintaining the vaginal axis in an almost horizontal position. **C**, During stressful maneuvers such as coughing or straining, the levator hiatus is shortened anteriorly by contraction of the pubococcygeus muscles. **D**, In the case of genital prolapse when the levator ani support is lost, the vaginal axis becomes more vertical, the urogenital hiatus broadens, and fascial supports are strained. (From Chapple CR, Milsom I. Urinary incontinence and pelvic prolapse. In: Wein AJ, Kavoussi LR, Novick AC, et al. *Campbell-Walsh Urology*. 10th ed. Philadelphia: Elsevier; 2012:1871-1895.e7.)

ANTERIOR VAGINAL WALL PROLAPSE (URETHROCELE AND CYSTOCELE)

Loss of anterior vaginal wall support is the most common site of primary POP. Anterior vaginal wall most commonly involves a cystocele, in which the bladder protrudes or descends with the vaginal wall relaxation, and it can less commonly include an enterocele in which the small bowel descends behind the upper

vagina. Anterior compartment defects may also allow the descent of the urethra (urethrocele) and bladder neck. Normal support of the anterior vaginal wall depends on level I apical support as well as level II support from the endopelvic connective tissue and its attachments to the bony pelvis and pelvic muscles. The trapezoidal anterior vaginal wall has distal and medial attachments near the pubic symphysis, lateral attachments to the arcus tendineus fascia pelvis, and proximal and lateral attachments near the ischial spines. Anatomic studies have identified breaks in these attachments in women with POP. Lateral breaks are thought to cause paravaginal defects. Distal detachments from near the pubic symphysis may result in urethroceles or urethral hypermobility. Anterior vaginal wall prolapse can be associated with stress urinary incontinence from urethral hypermobility or urinary retention from urethral kinking that causes obstruction (Fig. 20.16).

Symptoms and Signs

Symptoms of POP include a sensation of fullness, pelvic pressure, vaginal bulge, and a feeling that organs are falling out. With anterior vaginal wall prolapse, the woman may also report a feeling of incomplete emptying with voiding, a slow urinary stream, or urinary urgency. The patient and the physician note a soft, bulging mass of the anterior vaginal wall. In some patients this mass must be replaced manually before the patient can void. Strain, cough, or prolonged standing often accentuates the bulge. Often POP symptoms are less bothersome in the morning and worsen later in the day after upright activities. The mass may descend to or beyond the introitus. Although urethroceles and cystoceles almost always occur in parous women, they have been noted in nulliparous women who have poor structural supports. This is particularly true in women who have congenital malformations or

Figure 20.13 Visual comparison of systems used to quantify pelvic organ prolapse. (From Theofrastous JP, Swift SE. The clinical evaluation of pelvic floor dysfunction. *Obstet Gynecol Clin North Am.* 1998;25[4]:783-804.)

weaknesses of the endopelvic connective tissue and musculature of the pelvic floor. Most parous women demonstrate some degree of cystocele, and when asymptomatic, they do not require therapy.

Women with prolapse often have concurrent urinary symptoms. Some women have stress incontinence caused by urethral hypermobility or weak urethral sphincter, but others are

continent despite a lack of urethral support. Another group of women may have occult or latent stress incontinence (stress incontinence on prolapse reduction) because their continence depends on urethral kinking or obstruction from severe prolapse. Treating the prolapse with a pessary support or surgery could unkink the urethra and result in stress urinary incontinence.

Figure 20.14 **A**, Landmarks for the Pelvic Organ Prolapse Quantification System (POP-Q) system. **B**, POP-Q points of reference. (**A**, from Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol.* 1996;175[1]:10-17. **B** from and **A** also modified from Kobashi KC. Evaluation of patients with urinary incontinence and pelvic prolapse. In: Wein AJ, Kavoussi LR, Novick AC, et al. *Campbell-Walsh Urology*. 10th ed. Philadelphia: Elsevier; 2012:1896-1908.e30.)

Figure 20.15 Measuring point Aa. At rest, the Aa point is marked 3 cm proximal to the urethral meatus along the anterior vaginal wall (left). Then the patient is asked to strain, and the location of this point is measure in relation to the plane of the hymenal remnant (right). In this case, Aa is equal to +2 cm (2 cm past the hymen). In clinical practice, an imaginary mark is used. (From Reid F: Assessment of pelvic organ prolapse. *Obstet Gynaecol Reprod Med.* 2011;21[7]:190-197.)

Sexual function symptoms should be considered. Dyspareunia, vaginal dryness or irritation, and other difficulty with intercourse may occur with POP in any compartment.

Diagnosis

Pelvic organ prolapse is best measured with a patient straining in the lithotomy position, although the physician should ask the patient if this reproduces her maximum bulge and, if not, repeat the examination in the standing position. Maximum prolapse is more likely to be observed with a full bladder in the standing position at the end of the day. To observe and measure anterior vaginal wall prolapse, a retractor or posterior wall blade of a Graves speculum is used to depress the posterior vaginal wall. The patient is then asked to strain, and the degree of anterior vaginal wall

prolapse is noted. It is important to measure the amount of apical and posterior prolapse as well in order to not miss significant defects in the other compartments by focusing only on the most prominent prolapse. The physician should palpate the bladder neck and note whether it is well supported. Generally, if the supports of the bladder neck are adequate, the urethra is adequately supported. If a cystocele and urethrocele are present, it invariably follows that the bladder neck is not supported. Although determining the type of anterior vaginal wall prolapse—central or lateral/paravaginal—is no longer as important as once thought, a ring/sponge forceps can be used with the split speculum. If supporting the lateral anterior vaginal walls to the arcus tendineus fascia pelvis with an open ring forceps causes the cystocele to disappear with straining, a paravaginal defect is present. If apical support with the ring forceps causes the cystocele to resolve with straining, an apical or central defect is present.

It is important to perform POP-Q or at least qualitative measurements of the whole vagina, as often more than one compartment is affected. Checking the vaginal tissues for ulceration and bleeding should also be done. Pelvic floor muscle bulk, symmetry, and function should be assessed during the bimanual exam by asking the woman to tighten her muscles like she is trying to inhibit voiding or flatus.

Urethroceles should be differentiated from inflamed and enlarged Skene glands and urethral diverticula. Cystoceles must be differentiated from bladder tumors and bladder diverticula, both of which are rare but may occur. Urethroceles and cystoceles are generally soft, pliable, and nontender. Although diverticula may be reducible, a sensation of a mass is usually present. Inflamed Skene glands are generally tender. With diverticula or Skene glands, it may be possible to express pus from the urethra when they are palpated. In such cases, gonococcal, chlamydial, and other bacterial infections should be considered.

If surgical management of prolapse is being considered, the physician may want to perform a **preoperative prolapse reduction standing stress test** to evaluate for stress urinary

Box 20.3 Staging of Pelvic Floor Prolapse Using International Continence Society Terminology

Stage 0

No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at -3 cm, and either point C or D is between total vaginal length -2 cm.

Stage I

Criteria for stage 0 are not met, but the most distal portion of the prolapse is >1 cm above the level of the hymen.

Stage II

The most distal portion of the prolapse is ≤ 1 cm proximal or distal to the plane of the hymen.

Stage III

The most distal portion of the prolapse is >1 cm below the plane of the hymen but protrudes no farther than 2 cm less than the total vaginal length in centimeters.

Stage IV

Essentially complete eversion of the total length of the lower genital tract.

Figure 20.16 Urethral kinking caused by large cystocele. < > Fluorourodynamic study shows a large cystocele before (A) and after (B) strain maneuver was performed. The urethra (arrow) clearly can be seen to “kink off” during the strain maneuver. The patient demonstrated severe stress incontinence after prolapse reduction. (From Gallentine ML, Cespedes RD. Occult stress urinary incontinence and the effect of vaginal vault prolapsed on abdominal leak point pressures. *Urology*. 2001;57[1]:40-44.)

incontinence. With a comfortably full bladder (ideally around 300 mL), usually in the standing position, the patient is asked to cough while the prolapse is replaced in its normal anatomic position. If she leaks during this test, she has latent or occult stress urinary incontinence that is likely to present after surgical repair of the prolapse. In women who underwent apical suspension for POP and were randomized to surgery with or without an anti-incontinence procedure, women with positive preoperative prolapse reduction stress tests had a 71.9% chance of urinary incontinence after surgery without a sling compared to a 29.6% chance of urinary incontinence without a sling. Women with negative preoperative prolapse reduction stress tests in this trial had a 38.1% chance of urinary incontinence without a sling and a 20.6% chance with a sling (Wei, 2012). With this information, the patient and physician can decide whether or not to do an anti-incontinence procedure at the time of prolapse repair.

Management

Treatment of anterior vaginal wall prolapse may be nonoperative or operative depending on patient preferences and goals. If the patient is not bothered by the prolapse, it can be left alone and managed expectantly unless it is causing urinary retention or renal hydronephrosis. Women with mild (e.g., Stage 2) POP may elect for nonoperative management with pelvic floor physical therapy and Kegel exercises, which can decrease the risk of prolapse progression and can be effective at improving the sensation of pressure from mild POP (Kegel exercises are described in Chapter 21). Pelvic floor physical therapy can also treat associated urinary, bowel, and sexual dysfunction.

In one study, 447 women were randomized to receive individualized pelvic floor muscle training or a prolapse lifestyle advice leaflet with no muscle training (control group). At 6 and 12 months, the women assigned to pelvic floor muscle training had fewer prolapse symptoms as measured by a prolapse symptom questionnaire (POP-SS) than the control group.¹⁹ Another randomized controlled trial investigated morphologic and functional changes after pelvic floor muscle training in 109 women with stage I-III POP (Braekken, 2010). This supervised training led to a 44% increase in muscle strength, a 15% increase in muscle thickness, a decreased levator hiatus area, shortened muscle length, and elevation of the bladder and rectum position. It took 6 months of muscle hypertrophy training to achieve these results, so this option requires motivated patients. A follow-up study by the same group reported that 11 (19%) of women in the exercise group improved one stage on the Pelvic Organ Prolapse Quantification system compared with 4 (8%) of controls. This did correlate with reduced frequency and bother of vaginal bulging and heaviness by 74% and 67%, respectively. It is reasonable to offer pelvic floor muscle training for POP symptoms because it is without adverse effects. Women who have performed Kegel exercises on their own and have not improved may still benefit from working with a physical therapist.

In an older woman, the use of a vaginal estrogen product may improve vaginal atrophy and patient comfort if the prolapsed vaginal epithelium is irritated or ulcerated. There is no evidence that estrogen therapy will prevent or treat POP. Behavioral modification may help urinary symptoms such as urgency and will be discussed in Chapter 21.

Nonoperative support of the POP can also be achieved with a vaginal **pessary** (Fig. 20.17), or even with the intermittent use

Figure 20.17 Examples of pessaries: **A**, inflatable; **B**, donut; **C**, Gellhorn; **D**, cube; **E**, ring with support.

of a large tampon (pessaries are discussed in more detail under Uterine Prolapse in this chapter). If pelvic floor strengthening and pessary do not adequately control the prolapse symptoms or if a patient declines these options, then surgery can be considered. A young woman should be encouraged to avoid operative repair until she has completed her family. If pessary management is not adequate and the abnormality is so uncomfortable that repair must be performed before childbearing is complete, cesarean delivery should be considered for subsequent pregnancies.

Operative repair of anterior vaginal wall prolapse is generally performed in conjunction with the repair of all other pelvic support defects. It is unusual for anterior supports of the vagina to relax without an accompanying relaxation of the apical compartment. Repair therefore usually consists of an anterior colporrhaphy as well as correction of uterine descensus or apical defect posthysterectomy. If noted, posterior vaginal wall prolapse may also be repaired at the same time.

Anterior wall repair (**colporrhaphy**) is performed by plicating the connective tissue of the anterior vaginal in the midline. After placement of a Foley catheter, the vaginal epithelium is incised from just distal to the anterior lip of the cervix or cuff to just proximal to the urethrovesical junction or bladder neck, which can be identified using the inflated bulb of a Foley catheter (Fig. 20.18). If the woman has undergone a hysterectomy in the past, the incision may be made approximately 1 to 1.5 cm anterior to the vaginal scar. The longitudinal incision is made by through the vaginal epithelium to but not through the underlying connective tissue. When the longitudinal incision is complete, the cut edge of the vagina is held under tension, and the fibromuscular tissue underneath (sometimes called *pubocervical fascia*, although it is technically not fascia) is separated from it using sharp and blunt dissection. This is repeated on each side. The connective tissue is imbricated in the midline by placing absorbable or delayed absorbable 0 or 2-0 sutures laterally on each side of the defect and tying them in the midline. For larger cystoceles, a two-layer plication may be needed. The excess vaginal epithelium can be trimmed and then closed over the repair using absorbable suture such as 2-0 polyglycol.

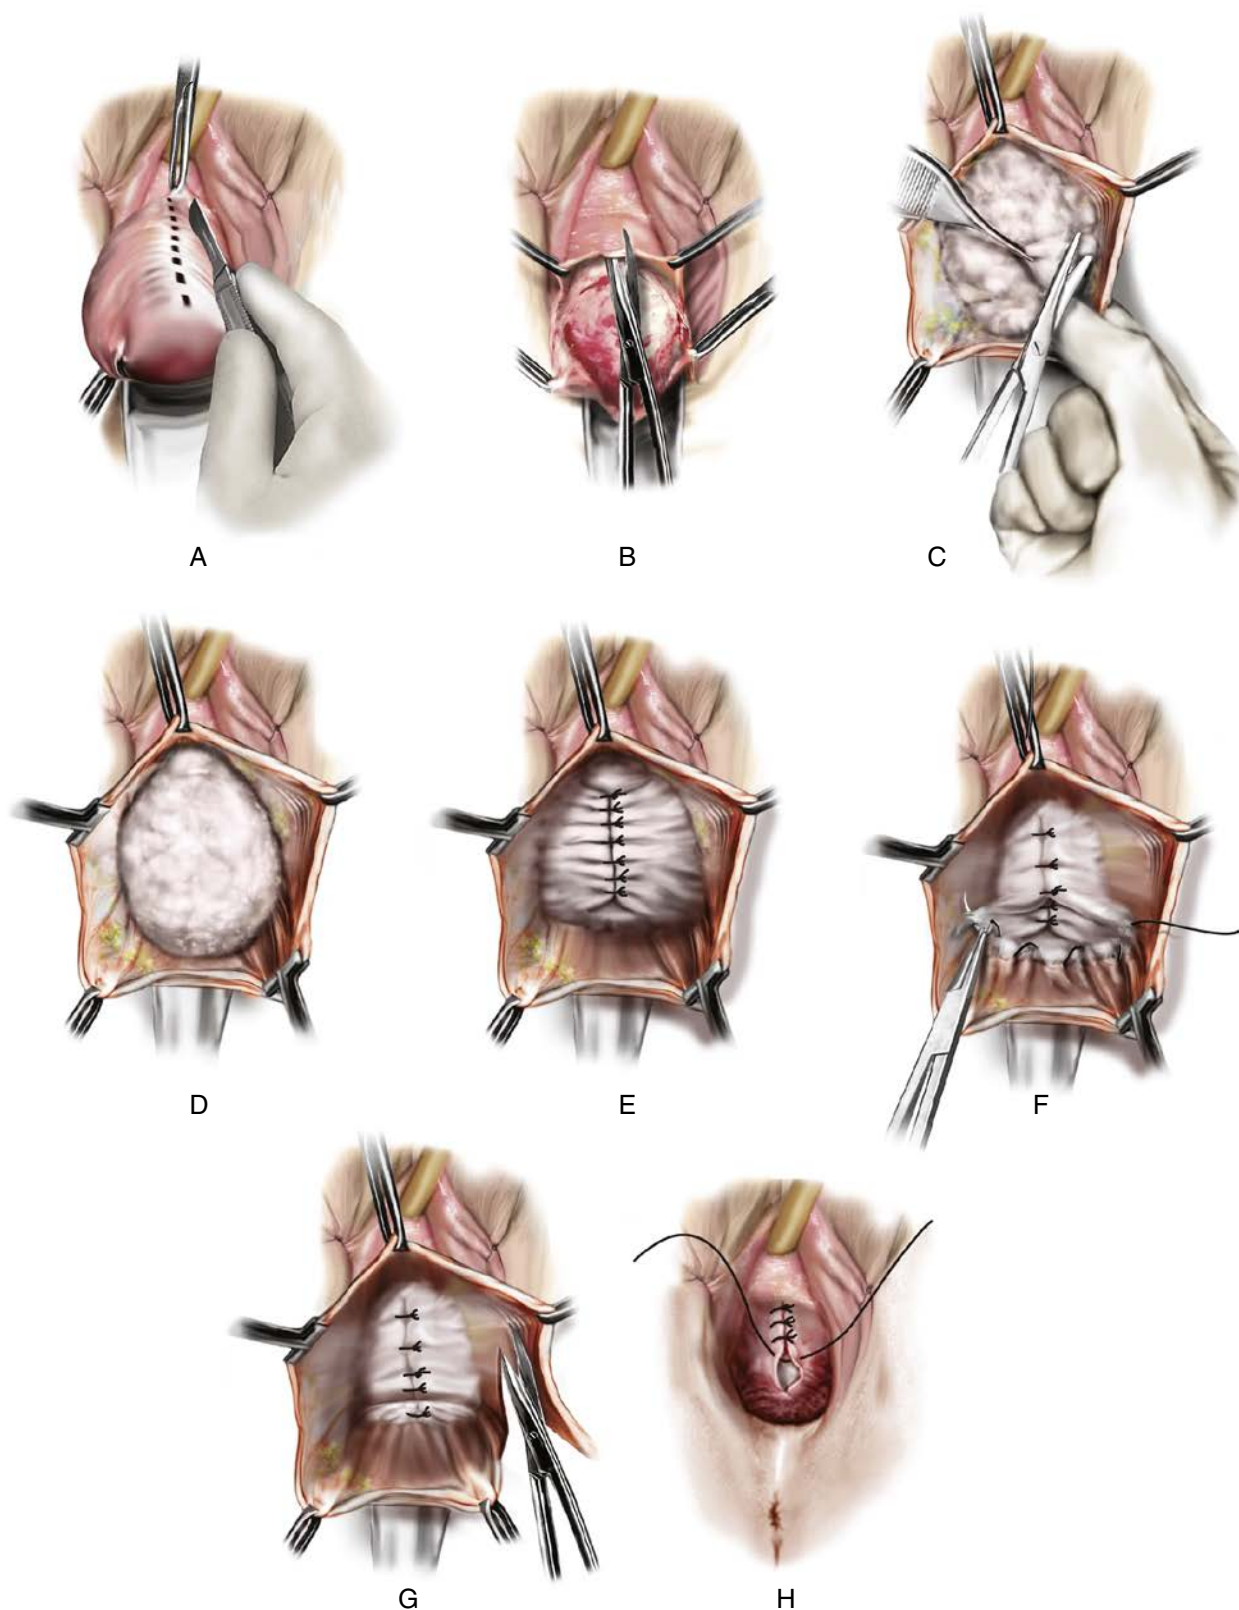

Figure 20.18 Classic anterior colporrhaphy. **A**, The initial midline anterior vaginal wall incision is demonstrated. **B**, The midline incision is extended using scissors. **C**, Dissection of the vaginal epithelium off the underlying connective tissue and fibromuscular layer. **D**, The dissection is complete. **E**, The initial plication layer is placed. **F**, The second plication layer is placed, if needed. **G**, Trimming of excess vaginal epithelium. **H**, Closure of vaginal epithelium. (From Maher CF, Karram MM. Surgical management of anterior vaginal wall prolapse. In: Karram MM, Maher CF, eds. *Surgical Management of Pelvic Organ Prolapse*. Philadelphia: Elsevier; 2013:117-137.)

Cystoscopy should be performed to assess bladder and ureteral integrity after the procedure is completed.

Midurethral sling surgery for associated stress urinary incontinence or **stress urinary incontinence on prolapse reduction** (occult or latent stress incontinence) can then be performed through a separate incision over the midurethra. These and other anti-incontinence procedures are discussed in [Chapter 21](#).

Alternatively, if midurethral slings are not available or depending on physician comfort, a Kelly plication can be performed to treat the urethrocele and decrease the patient's risk of stress urinary incontinence, although the success rates are lower than the success rates for other anti-incontinence surgeries, including mesh midurethral slings, Burch urethropexies, and fascial slings. In this case, the longitudinal incision can be continued under the urethra and the Kelly plication performed prior to the anterior colporrhaphy. A suture over the bladder neck (Kelly stitch) brings together the connective tissue on either side. The stitch should be placed as lateral as possible without tension, parallel to the urethra on each side, and then tied. The most appropriate tie for this closure is also 0 or 2-0 polyglycol suture.

POSTOPERATIVE VOIDING DYSFUNCTION

Postoperatively, the bladder should be drained as long as there is a vaginal packing in place, usually for about 1 day, normally with a 16-French urethral catheter. Because there is a risk of urinary retention immediately after surgery, a voiding trial should be performed after removing any vaginal pack and prior to discharging the patient. There are two common ways to provide a **voiding trial**: back fill and auto fill. For the back fill, the bladder is retrograde filled with 300 mL of sterile saline, and then the catheter is removed. For auto fill, the catheter is removed, and the bladder is allowed to fill spontaneously. The voided volume is measured, and the residual volume is measured with a bladder ultrasound or straight catheterization in either type of voiding trial, or it can be calculated after a back fill. The patient can be considered to have passed the voiding trial if she voids at least two thirds of the total bladder volume (i.e., a postvoid residual of less than 100 mL after voiding 200 mL of a 300 mL total bladder volume). Two randomized trials of the two voiding trial techniques revealed that the back fill technique was a better predictor of adequate postoperative bladder emptying than the auto fill technique, and it was also preferred by patients ([Pulvino, 2010](#); [Geller, 2011](#)). Notably, 40% or more of patients had an unsuccessful voiding trial after prolapse or incontinence surgeries and were discharged home with a catheter. It is helpful to counsel women on this high chance of going home with a catheter, given short hospital stays after these procedures.

After an anterior repair if voiding does not occur prior to hospital discharge, the woman may be treated with a Foley catheter for continuous drainage or clean intermittent self-catheterization (CISC) for 1 to 7 days and rechecked for voiding and residual urine as an outpatient. Prophylactic antibiotics are rarely recommended; however, symptomatic lower urinary tract infections are common and should be treated as they occur.

Alternatives to voiding trials include suprapubic catheter drainage or teaching all patients how to perform CISC. With a suprapubic catheter, the drainage tube can be clamped, allowing the patient to void when she can and allowing residual

urine measurements to be taken. The suprapubic technique is simple to use and seems to have a lower incidence of infection than does transurethral catheterization, but patients may complain of extravasation of urine around the site and occasionally of hematoma formation. CISC can be intimidating for patients to learn, but once learned, many patients prefer not having an indwelling catheter and can measure their own postvoid residual urine volumes. CISC is generally not necessary if short periods of catheterization are anticipated. The surgeon should decide which method is best suited to the patient's needs and develop a system that the surgeon and nursing team understand and can follow.

POSTOPERATIVE RESTRICTIONS

Although there are no data regarding postoperative restrictions, in general patients are advised to avoid straining from constipation, heavy lifting, and strenuous activity for about 6 weeks ([Nygaard, 2013](#)). Nothing should be placed in the vagina until it heals. On the other hand, women should be able to resume other nonstrenuous normal activities as soon as they feel ready.

RECURRENT ANTERIOR VAGINAL WALL PROLAPSE

Because recurrent POP is common after anterior colporrhaphy, augmentation of anterior vaginal wall prolapse repairs with graft materials has been proposed. However, although it may improve the anatomic result compared to traditional native tissue anterior colporrhaphy, it is associated with increased complications such as mesh exposure, pelvic pain, and dyspareunia. [Figure 20.19](#) shows the excision of exposed vaginal mesh that had been placed in a prior POP surgery. In 2008, a public health notification issued by the U.S. Food and Drug Administration (FDA) summarized more than 1000 reports of surgical complications associated with mesh-augmented repairs. Subsequently in 2011, the FDA issued a Safety Communication that summarized its review of surgical mesh for transvaginal repair of POP: complications are not rare, and it is not clear that it is more effective than traditional non-mesh repair ([FDA, 2011](#)). A 2013 Cochrane Database systematic review concluded that the risk of recurrent prolapse symptoms and anterior vaginal wall prolapse on examination are decreased with the use of biologic or synthetic grafts, but disadvantages include longer operative times, greater blood loss, prolapse in other areas of the vagina, new onset stress urinary incontinence, and an 11% rate of vaginal mesh exposure ([Maher, 2013](#)). The 5-year cumulative risk for repeat surgery has been found to be higher after anterior prolapse surgeries that involved mesh than those that did not (15.2% versus 9.8%) when mesh revisions/removals were included. In this same study, the 5-year risk of recurrent surgery for POP was similar between vaginal mesh and native tissue repair groups (10.4% versus 9.3%) ([Jonsson, 2013](#)). Certainly careful patient selection, detailed patient counseling, and a skilled surgeon with proper training is needed for these procedures and to manage the complications.

Recurrent anterior vaginal wall prolapse remains a frustrating problem for gynecologic surgeons and patients. In fact, George R. White was quoted in 1909 saying, "Ahlfet states that the only problem in plastic gynecology left unsolved by the gynecologist is

Figure 20.19 Surgical Technique of Mesh Excision. **A**, Anterior vaginal wall with 2- × 2-cm perigee mesh exposure. **B**, Undermining the mesh. **C**, Transecting the mesh, which has folded over on itself. **D**, Dissecting between mesh and bladder. **E**, Most of the mesh has been excised. **F**, Closure with interrupted suture. that of permanent cure of cystocele.” It remains a problem even now, with reported failure rates of 30% to 46% after anterior colporrhaphy based on strict anatomic criteria: POP-Q stage 0 or 1, which was consistent with a 2001 National Institutes of Health (NIH) Standardization Workshop’s recommendations at the time (Weber, 2001). However, it is increasingly recognized that strict anatomic “success” may not be clinically relevant for patients with POP. When this same study was reanalyzed with the more patient-centered outcomes of no POP beyond the hymen, no symptoms, and no retreatment, the success rate was 89% (Chmielewski, 2011). Because paravaginal repairs and mesh-reinforcement have

not significantly decreased the rate of recurrence, and addition of mesh grafts increases the reoperation rate compared to native tissue repairs because of mesh complications as noted earlier, anterior colporrhaphy remains the procedure of choice for isolated anterior vaginal wall prolapse. Notably, the rate of recurrence has been found to significantly decrease with the addition of apical vaginal support (Eilber, 2013). In the setting of apical support defects associated with anterior vaginal wall prolapse, repairs such as uterosacral ligament suspension, sacrospinous ligament suspension, and sacral colpopexy may be indicated. These procedures are discussed later in this chapter.

POSTERIOR VAGINAL WALL PROLAPSE (RECTOCELE)

The prevalence of posterior vaginal wall prolapse in community-dwelling women in the United States ranges from 18% to 40% and 9% to 76% in urogynecology clinics, depending on the definition used (Grimes, 2012).

Symptoms and Signs

As with other forms of POP, the patient with a rectocele often complains of pelvic pressure, a “falling out” feeling in the vagina, a vaginal bulge, or disruption in sexual activity. Protrusion of the prolapse may worsen later in the day and be aggravated by prolonged standing or exertion. With a rectocele, the woman may also complain of constipation, difficulty with bowel movements, a feeling of incomplete emptying of the rectum, and the need to push on the vagina or perineum (splint) to have a bowel movement. Obstructed defecation symptoms may be reported by 9% to 60% of women with pelvic floor disorders, with 18% to 25% splinting, 27% straining, and 26% incompletely evacuating (Grimes, 2012). Although reported symptoms might be related to the rectocele, there are many other potential causes of evacuation problems that are not (constipation, sigmoidocele, rectal prolapse, rectal intussusception). Defecatory symptoms frequently but not always improve after rectocele repair.

Diagnosis

Posterior vaginal wall prolapse is descent of the posterior vaginal wall and may include an enterocele (small bowel), a rectocele (rectum), or both. Posterior vaginal wall prolapse may be identified by retracting the anterior vaginal wall upward with one half of a Graves or Pederson speculum and asking the patient to strain (Fig. 20.20). POP-Q measurements should be performed

Figure 20.20 Rectocele. Although this may appear to be a cystocele, split speculum exam revealed a rectocele.

of all compartments of the vagina. An example POP-Q for a women with isolated posterior vaginal wall prolapse is shown, although in reality POP usually involves more than one compartment, particularly after hysterectomy (Fig. 20.21). The physician should then place one finger in the rectum and one in the vagina and palpate the defect. Often the rectovaginal septum is paper thin, and the rectocele can be palpated to its upper margin. One finger in the rectum can also evaluate for the presence of a “pocket” or bulge into the vaginal canal where stool may get trapped. If an enterocele is present, it may be possible to differentiate it from the rectocele by having the patient strain. Frequently, however, the diagnosis of a small enterocele is established only at the time of operation. Evacuation symptoms suggestive of an obstructive process or seeming out of proportion to the degree of rectocele bear further investigation by an expert, possibly with anal manometry, defecography, or dynamic MRI.

Management

Nonoperative management of a rectocele is similar to that mentioned for a cystocele. Pessaries, Kegel exercises, and estrogen may be useful in the appropriate situations. Gastrointestinal symptoms must be thoroughly evaluated, including screening for colorectal cancer if appropriate. If constipation and straining are issues, a dietary fiber and fluid intake review should be obtained. At least 25 g of fiber, adequate hydration, regular exercise, and allowing time for defecation after meals can be recommended to regulate bowel habits as first-line therapy. Polyethylene glycol can be used as needed if these first-line therapies do not adequately normalize stool consistency.

Operative management of posterior vaginal wall prolapse usually involves posterior colporrhaphy or a site-specific repair, plus or minus surgical correction of apical prolapse and

Figure 20.21 Line drawing example of posterior support defect. The anterior compartment is well supported. The leading point of the prolapse is point Bp (+5), which is 5 cm beyond the hymen. Total vaginal length is 8 cm, and point C (–6), the cuff position, has descended 2 cm. (From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol.* 1996;175[1]:10-17.)

anterior vaginal wall prolapse if present. Most women with posterior vaginal wall prolapse also have a gaping genital hiatus and a defect in their perineal body. Therefore, a **perineorrhaphy** to rebuild the perineal body is often performed at the same time, as shown in [Figure 20.22](#). The surgeon should estimate at the time of starting the posterior repair what degree of perineorrhaphy he or she wishes to perform. The margins of the perineum to be narrowed are generally marked by placing Allis clamps on the hymen such that reapproximating the clamps results in a normal genital hiatus ([Fig. 20.23](#)). The tissue between these clamps is then removed with a scalpel or curved Mayo scissors. To perform a posterior colporrhaphy, the vaginal epithelium is incised in the midline to the top of the bulge or left intact depending on surgeon preference. The vaginal epithelium is separated from the underlying fibromuscular tissue laterally and proximally toward the apex of the vagina above the limit of the rectocele using sharp and blunt dissection. At this point, a site-specific repair, posterior colporrhaphy, or a combination of both can be performed to reduce the bulge. Both methods have high success rates.

To complete a posterior colporrhaphy either alone or in addition to a site-specific repair, after the vaginal wall is incised, the edges are grasped and placed under tension, and the perirectal connective tissue is separated from the vaginal epithelium by blunt and sharp (if necessary) dissection. This is carried out bilaterally until it is possible for the operator to palpate the perirectal

space on each side. The operator then places a delayed absorbable suture into the perirectal fibromuscular tissue on either side and brings the tissue together in the midline. The operator may choose to place these sutures with one finger in the rectum, and if not, should at least check the rectum after the completion of the repair to ensure that no suture is placed into the rectum. When the sutures are tied, these tissues are interposed between rectum and vagina, thereby reducing the rectocele. Care must be taken to avoid creating a “shelf” in the posterior vaginal wall, which may narrow the vagina too much and lead to dyspareunia. Levator ani plication appears to increase dyspareunia, so it is not indicated in sexually active women.

To perform a site-specific posterior vaginal repair, the fibromuscularis is examined after the dissection is performed and any defects individually isolated and repaired with delayed absorbable suture.

If vaginal vault prolapse is also present, a separate repair is indicated for support of the vaginal apex, and this is discussed later. The vaginal edges are then trimmed and the vagina closed with a row of either continuous or interrupted absorbable sutures.

Attention is then turned to the perineorrhaphy when there is perineal muscle separation and a perineal body defect. It is closed in the following fashion. Absorbable sutures such as 0 Polyglycol sutures are placed in the lateral margins of the transverse incision, essentially bringing bulbocavernosus and superficial perineal muscles together from either side to the midline. The operator can be sure that the bulbocavernosus muscle insertions are included in the sutures by pulling on the suture and noting whether the tension identifies the muscle bundles. Over-tightening the introitus may cause dyspareunia. The remainder of the perineal incision is then closed with a row of 2-0 polyglycol sutures to the deep tissue, and the skin of the perineum is closed with either interrupted or continuous subcuticular suture of 3-0 absorbable suture.

Figure 20.22 Perineorrhaphy. Following the completion of the repair of the rectocele, the perineal body may need to be reconstructed. The bulbospongiosus and the superficial transverse perineus muscles are plicated in the midline with absorbable sutures. (From Muir TW. Surgical treatment of rectocele and perineal defects. In Walters MD, Karam MM. *Urogynecology and Reconstructive Pelvic Surgery*. 4th ed. Philadelphia: Elsevier; 2015:342-359.)

RECURRENT POSTERIOR VAGINAL WALL PROLAPSE

Successful repair of posterior vaginal wall prolapse may be slightly higher for posterior colporrhaphy (96%) than site-specific repair (89%) when defined as no prolapse beyond the hymen; recurrence is uncommon. Because of low recurrence rates of posterior vaginal wall prolapse and the increased risks of augmenting posterior repairs with grafts, a Cochrane Review concluded that evidence does not support the use of any grafts at the time of posterior vaginal repair.²⁴ Although anatomic position is often corrected by a posterior repair, function may not be corrected. Defecatory problems may remain, so patients should be forewarned.

ENTEROCELE

An **enterocele** is a herniation of the pouch of Douglas (cul-de-sac) between the uterosacral ligaments into the rectovaginal septum containing small bowel. It frequently occurs after an abdominal or vaginal hysterectomy and generally is the result of a weakened support for the pouch of Douglas and the loss of vaginal apical support by the uterosacral ligaments. To decrease the risk of developing an enterocele after a hysterectomy, the uterosacral and cardinal ligaments, which are the most important support

Figure 20.23 Repair of Rectocele. **A**, Placement of Allis clamps at margins of perineal incision; perineal incision is being made. **B**, Reflected vaginal epithelium with rectum bulging. **C**, Depression of rectum identifying margins of levator ani muscle. **D**, Placement of sutures in perirectal tissue and levator ani bundles.

structures for the vagina, should be incorporated into the vault repair as described later under Management.

Diagnosis

An enterocele is not always easy to diagnose. It is a true hernia of the peritoneal cavity emanating from the pouch of Douglas between the uterosacral ligaments and into the rectovaginal septum (Figs. 20.24 and 20.25). It may be noticed as a separate bulge above the rectocele, and at times it may be large enough to prolapse through the vagina (Figs. 20.26 and 20.27). If such is the case, it may be possible to make the specific diagnosis of enterocele by transilluminating the bulge and seeing small bowel

shadows within the sac. It may also be possible to differentiate the enterocele from a rectocele by rectovaginal examination. The contents of an enterocele are always small bowel and may also include omentum. The contents may be easily reducible or may be fixed to the peritoneum of the sac by adhesions.

Management

Enteroceles may be managed expectantly if asymptomatic, or they can be treated with pessaries or surgery. They rarely occur in isolation, so surgical management usually also involves vaginal vault suspension as described later in this chapter with or without anterior and posterior repairs if indicated. When repairing an

Figure 20.24 Enterocele and uterine prolapse. (From Symmonds RE: Relaxation of pelvic supports. In Benson RC, ed. *Current Obstetric and Gynecologic Diagnosis and Treatment*. 5th ed. Los Altos, CA: Lange Medical; 1984.)

Figure 20.26 Elderly patient with stage IV apical eversion and enterocele with vaginal ulcers.

A loop of small bowel has descended anterior to the rectum to form a large enterocele (black arrows). Note the coexistent cystocele (white arrows) and small collapsed rectocele (arrowhead). (From Taylor SA. Imaging pelvic floor dysfunction. *Best Pract Res Clin Gastroenterol*. 2009;23[4]:487-503.)

Figure 20.27 Enterocele with Vaginal Apical Prolapse. Split speculum exam and digital exam with palpation of bowel in the sac helped define this defect.

enterocele transabdominally, the sac should be reduced upward if possible and dissected free from the bladder and rectum. If the uterosacral ligaments are present, these may be brought together in the midline and attached to the vaginal cuff. If the uterosacral ligaments cannot be identified, as with large enteroceles after previously performed hysterectomy, concentric purse-string sutures in the connective tissue over the vagina and rectum may obliterate the cul-de-sac. Care must be taken to avoid damaging

the ureters, rectum, and sigmoid colon. It is best to perform this procedure with permanent sutures. Because the enterocele has probably occurred because of weakening of the apical supports (uterosacral ligaments), an apical suspension surgery such as abdominal sacrocolpopexy is often necessary for resuspension and closure of the enterocele defect.

If uterosacral ligaments can be identified at the time of a vaginal hysterectomy, they can be used to repair and prevent

enterocele formation. This can be accomplished by fixing the uterosacral ligaments to the peritoneum of the sac and the vaginal vault connective tissue using a suture of absorbable or delayed absorbable suture, beginning on one side of the vagina and continuing through the uterosacral ligament of that side, the peritoneum of the sac, and the uterosacral ligament and then vagina on the opposite side. Multiple sutures can be placed if space allows. This technique was described by McCall and is often called the *McCall stitch* or *McCall culdoplasty*. It effectively shortens the cul-de-sac and supports the enterocele neck.

Repair of an enterocele can be carried out transvaginally at the time of the apical repair with or without anterior or posterior vaginal wall repair. The sac will be visualized as the vagina is separated from the rectum. The sac can then be dissected free of underlying tissue and isolated at its neck. It should be opened to ensure that all contents are replaced. The neck of the hernia is then sutured with a purse-string permanent suture ligature and the sac excised (Fig. 20.28).

It is important to support the neck of the enterocele sac as much as possible. Approximating the anterior and posterior vaginal connective tissue is also important to close the defect. Usually with an enterocele, support of the vaginal apex such as a sacrospinous ligament suspension is needed for optimal repair.

Correctly repaired enteroceles usually will not recur. Enteroceles repaired without proper attention to ligation of the neck of the sac, closure of the anterior and posterior vaginal connective tissue of the vaginal cuff, and concurrent rectocele repair may recur. In such cases, a subsequent operation with special attention to these surgical principles is indicated.

UTERINE PROLAPSE (DESCENSUS, PROCIDENTIA)

Prolapse of the uterus and cervix into or through the barrel of the vagina is associated with injuries of the endopelvic connective tissue and level I support structures, including the cardinal and uterosacral

Figure 20.28 Repair of Enterocele. A, Appearance of enterocele sac with vaginal wall reflected. B, Appearance of open enterocele sac with sac neck identified. C, Placing of purse-string suture at the neck of the enterocele sac. D, Excision of enterocele sac.

ligaments, as well as injury to the neuromuscular unit with relaxation of the pelvic floor muscles, particularly the levator ani muscles (Fig. 20.29). Uterine prolapse is almost always associated with rectocele and cystocele and, at times, enterocele, supporting the concept of overall damage to the pelvic support structures.

Symptoms and Signs

Again, common symptoms noted by patients with uterine prolapse are a feeling of pelvic pressure and heaviness, fullness, bulge or “falling out” in the perineal area. Because uterine prolapse is almost always associated with anterior and posterior vaginal wall prolapse, symptoms that were reported earlier for cystocele and rectocele may be present as well. In cases in which the cervix and uterus are low in the vaginal canal, the cervix may be seen protruding from the introitus, giving the patient the impression that a tumor is bulging out of her vagina. Where stage III or IV prolapse has occurred, the patient may be aware that a mass has actually prolapsed out of the introitus. In stage IV prolapse, the vagina is everted around the uterus and cervix and completely exteriorized. When this occurs, the patient is in danger of developing dryness, thickening, and chronic inflammation of the vaginal epithelium and cervix. She may also have pain and bleeding, for example, from ulcerations. There is often discharge, and secondary infection can occur. Stasis ulcers may result from edema and interference with blood supply to the vaginal wall. Evisceration of abdominal contents is a rare complication, but a surgical emergency. In almost every case of acquired prolapse, the perineal supports are poor, and the perineal body is damaged.

Management

As with other forms of prolapse, mild or asymptomatic uterine prolapse does not need treatment or can be treated with pelvic floor muscle strengthening. If the prolapse is causing symptoms, infection, urinary retention, or hydronephrosis (from ureteral kinking), it can be treated with a pessary or surgery. Degrees of prolapse that place the cervix at or through the introitus probably cause greater discomfort and are usually more bothersome to the patient.

Nonoperative management of such conditions involves the use of a pessary (see Fig. 20.17). All women should be offered

pessary management for prolapse. Pessary management should be particularly encouraged rather than surgery in women with medical conditions that make surgery dangerous (i.e., poor surgical candidates) and in women who have not completed childbearing. Pessaries involve replacement of the uterus to its normal position in the pelvis and then the institution of support using one of these devices. Pessaries are available in varying shapes and sizes and should be properly fitted to the patient. In general, the perineum must be capable of holding the pessary in place, or the pessary will frequently fall out. There is currently no evidence from randomized controlled trials on pessary use to direct the selection of the device or to compare pessaries with other treatments or surgery. The ring pessary is the most commonly used shape. Usually a support pessary is tried first, such as a ring or Gehrung because they are easier for the patient to use. Space-occupying pessaries such as the cube, Gellhorn, donut, and inflatable, are a second option. Gellhorn pessaries may be more successfully fit for stage IV POP more often than rings, but it is reasonable to start with the smallest and easiest to use shapes first. A prospective trial found that 75% of 203 women fitted with a pessary successfully retained the device at 2 weeks (Fernando, 2006). Failure to retain the pessary was significantly associated with increasing parity, prior POP surgery, and past hysterectomy. Forty-eight percent of the women completed a questionnaire at 4 months. The pessary reduced symptoms of POP, including general symptoms of a vaginal bulge. It also relieved urinary symptoms such as voiding problems in 40% of women, urinary urgency in 38%, urgency urinary incontinence in 29%, bowel evacuation in 28%, fecal urgency in 23%, and urge fecal incontinence by 20%. There was no improvement in stress urinary incontinence.

Complications from vaginal pessaries are rare with proper use. This includes regular removal, cleaning, and replacement, as well as use of vaginal estrogen cream for postmenopausal women with vaginal atrophy. Complications include vaginal infections, bleeding, discomfort, vaginal erosion and ulceration, and pessary incarceration. More serious complications such as erosion into the bladder and rectum have been rarely reported, usually from neglect.

If a woman with advanced prolapse is pregnant, it is important to replace the uterus before it enlarges and becomes trapped in the lower pelvis or vagina. If this happens, edema may cause incarceration and even loss of blood supply to the uterus. In a postmenopausal woman, estrogen replacement for at least 30 days with vaginal estrogen cream may help improve the vitality of the vaginal epithelium, the cervix, and the vasculature of these organs, making fitting of a pessary or the operative procedure and the healing process more efficient.

Operative repair for prolapse of the uterus and cervix can be transabdominal or transvaginal. The surgical approach will depend on patient comorbidities, patient preferences regarding risks and durability, and surgeon expertise. Common surgical options to treat uterovaginal prolapse include vaginal hysterectomy with vault suspension to the uterosacral or sacrospinous ligaments, abdominal (open, laparoscopic, or robotic) supracervical hysterectomy with sacrocolpopexy, and colpocleisis. Other surgeries including abdominal (open laparoscopic, or robotic) uterosacral ligament suspension with or without hysterectomy, transvaginal hysterectomy with or without mesh sacrohysteropexy, and Manchester procedures can be appropriate for some patients. Sacrocolpopexy, which is described in more detail in

Figure 20.29 Uterine prolapse.

the Vaginal Vault Prolapse (Apical Prolapse after Hysterectomy) section, is the most durable surgery for apical prolapse but has more surgical risks than vaginal surgeries.

Transvaginal repair usually involves a vaginal hysterectomy followed by a vaginal vault suspension to the uterosacral or sacrospinous ligaments. The uterosacral ligaments can be sutured together so that the cul-de-sac is shortened or obliterated as in a McCall culdoplasty described previously, or the vaginal vault can be supported high up to the uterosacral or sacrospinous ligaments. High uterosacral ligament and sacrospinous ligament suspensions are described in the Vaginal Vault Prolapse (Apical Prolapse after Hysterectomy) section presented later in this chapter.

The American College of Obstetricians and Gynecologists' 2009 committee opinion and a Cochrane systematic review the same year suggest that vaginal hysterectomy is associated with better outcomes and fewer complications than laparoscopic or abdominal hysterectomy (ACOG, 2009). This is a general recommendation, and with POP, often there are many other considerations including concomitant procedures needed, concern about failure rates, and restoration of bowel, bladder, and sexual function. In some cases, a vaginal hysterectomy is not advisable, and the optimal route of hysterectomy depends on many factors, including the size and shape of the uterus, accessibility to the uterus, surgeon training and experience, and planned concurrent surgical procedures. In cases in which an abdominal, laparoscopically assisted vaginal, or total laparoscopic hysterectomy is preferable, an apical suspension can be performed vaginally or abdominally, and anterior and posterior colporrhaphy can be performed vaginally if needed.

In some women the cervix is hypertrophied and elongated to the area of the introitus, but the supports of the uterus itself are intact. A cystocele and rectocele may be present, and operative repair can consist of a **Manchester** (Donald or Fothergill) operation. This operation combines an anterior and posterior colporrhaphy with the amputation of the cervix and the use of the cardinal ligaments to support the anterior vaginal wall and bladder. Although it was suggested for repair in young women who wish to maintain their reproductive abilities, the loss of the cervix may interfere with fertility or lead to incompetence of the internal cervical os. The operation has value in elderly women with comorbid medical conditions who have an elongated cervix and well-supported uterus because it is technically easier and has a shorter operative time than the vaginal hysterectomy in such cases, and the entering of the peritoneal cavity is avoided.

In elderly women who are no longer sexually active, a simple and effective procedure for reducing prolapse is an obliterative procedure called a **colpocleisis**. The classic partial colpocleisis procedure was described by Le Fort in 1877 (Fig. 20.30) and involves the removal of a strip of anterior and posterior vaginal wall, with approximation of the anterior and posterior walls to each other. This procedure may be performed with or without the presence of a uterus and cervix, and when it is completed, the vaginal cavity is nearly completely closed, with small vaginal canals on either side of the opposed vaginal walls to allow drainage of any fluid from the cuff or uterus. Dissection of the vaginal wall is carried to the level of the bladder neck anteriorly and to the reflection of bladder onto the cervix at the upper margin of the vagina. Posteriorly the

dissection is carried from just inside the introitus to a position just posterior to the cervix. If a hysterectomy has been previously performed, the dissection may begin approximately 1 cm on either side of the vaginal scar. Canals are left on each lateral vaginal wall to allow drainage from the cervix or apex. If the cervix and uterus are still present and intrauterine pathology occurs, bleeding through these canals can alert the physician to a potential problem. In low-risk women, no evaluation for uterine pathology is necessary prior to colpocleisis. In women with risk factors, however, a cervical or endometrial evaluation should be completed prior to colpocleisis because colpocleisis makes access to these organs difficult. If there is cervical or uterine pathology, the uterus and cervix should not be left in situ. Cystoscopy should be performed to assess bladder and ureteral integrity after the procedure is completed.

A large perineorrhaphy is usually performed in association with the colpocleisis. Together, these procedures result in a short vagina of approximately 3 cm and a small genital hiatus of about 1 to 2 cm. The patient can be reassured that her external genitalia look completely normal and that her risk of prolapse recurrence is small. Cystoscopy and rectal examination are important to ensure no bladder, rectal, or ureteral injury after prolapse surgery. An anti-incontinence operation such as a midurethral synthetic sling may be carried out if the patient has stress urinary incontinence or stress urinary incontinence on prolapse reduction, either at the time of surgery or as an interval procedure.

The **Goodall-Power modification** of the Le Fort operation (Fig. 20.31) allows for the removal of a triangular piece of vaginal wall beginning at the cervical reflection or 1 cm above the vaginal scar at the base of the triangle, with the apex of the triangle just beneath the bladder neck anteriorly and just at the introitus posteriorly. The cut edge of vaginal wall making up the base of the triangle anteriorly is sutured to the similar wall posteriorly, and the vaginal incision is then closed with a row of interrupted sutures beginning beneath the bladder neck and carried side to side to the area of the introitus. This procedure works well for relatively small prolapses, whereas the Le Fort is best for larger ones.

Prognosis for a colpocleisis procedure to reduce the prolapse and prevent recurrence is generally excellent. Case series report 91% to 100% success rates. Careful counseling must be done preoperatively to be sure the woman will never desire coital activity because occasional regret over closure of the vagina has been reported. Overall, patient satisfaction is high, and regret is low (Vij, 2014).

In a comparison of 25 elderly women (average age 82 years) in poor health with uterovaginal prolapse treated by colpocleisis with 42 younger women with similar prolapse treated with vaginal hysterectomy, anterior colporrhaphy, and posterior colporrhaphy, the average operating time for the Le Fort procedure was 75 minutes compared with 150 minutes for the vaginal hysterectomy. There was one postoperative death in the Le Fort group, but 19 of the 20 remaining Le Fort patients had excellent results for a follow-up of an average of 25 months (range of 4 to 40 months) (Denehy, 1995).

A special circumstance involves the treatment of women who wish to maintain their fertility despite the fact that they have symptomatic uterine prolapse. As noted, pessary is preferable to surgery for these women. However, there are small

Figure 20.30 Le Fort Procedure. A, Incision of anterior vaginal wall strip. B, Incision of posterior wall strip. C, Removal of vaginal strip. D and E, Placement of sutures. F, Appearance of vagina after procedure is completed but before perineorrhaphy is performed.

studies suggesting surgical treatment may be an option. There was one small case series in which the authors sutured bilateral uterosacral ligaments to the sacrospinous ligaments to reduce the prolapse. Eighteen of the 19 women had good anatomic restoration, and five subsequently delivered babies (Kovac, 1993). An uncontrolled trial of laparoscopic uterosacral ligament uterine suspension versus vaginal hysterectomy and vault suspension reported excellent support as measured by POP-Q, and no laparoscopic uterine suspension patient had reoperation for recurrence (Diwan, 2006). Laparoscopic hysteropexy (sacrospinopexy with uterine preservation) has also been described. In a case series of 40 women who desired retention of fertility, 1 year after surgery the cervix was on average 4.84 cm above the hymenal ring (Rosenblatt, 2008). With only small studies and case series, it is unclear what the role of

uterine suspension should be in current practice and the longevity of such repairs. Young women with POP who desire further childbearing should be encouraged to try a pessary first.

VAGINAL VAULT PROLAPSE (APICAL PROLAPSE AFTER HYSTERECTOMY)

Prolapse of the vaginal apex at some time remote to the performance of either abdominal or vaginal hysterectomy has been reported as occurring in 0.1% to 18.2% of patients, with 5% of women having surgery for posthysterectomy POP (Blandon, 2007). Apical prolapse may be accompanied by a cystocele, a rectocele, an enterocele, or some combination thereof. Occasionally the prolapse involves only one of those entities and not the entire vaginal apex. In a study in Munich, Richter reported that of 97 posthysterectomy prolapses,

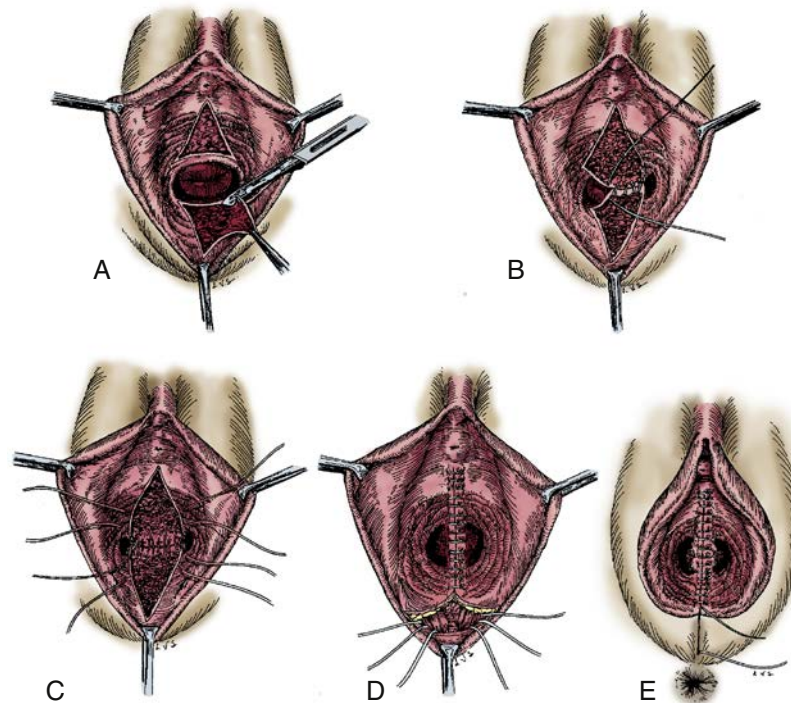

Figure 20.31 Goodall-Power modification of Le Fort operation. **A**, Representation of vaginal incision on anterior and posterior wall. **B**, Early placement of sutures. **C**, Later placement of sutures. **D**, Vaginal incision completely closed; perineorrhaphy being performed. **E**, Appearance at completion of procedure. (From Symmonds RE. Relaxation of pelvic supports. In: Benson RC, ed. *Current Obstetric and Gynecologic Diagnosis and Treatment*, 5th ed. Los Altos, CA: Lange Medical; 1984.)

6.2% were cystocele only, 5.1% rectocele only, 9.3% primarily an enterocele type, and 72.2% of mixed type (Richter, 1982). It is rare to find isolated support defects of the anterior or posterior vaginal walls or an isolated apical defect (Rooney, 2006). Vaginal vault prolapse is probably the result of continuing pelvic support defects in the connective tissues, namely, the cardinal and uterosacral ligaments attachments to the vaginal cuff. Multiple vaginal wall defects are usually found because the connective tissue defects, the pelvic floor muscles, and innervation are globally affected and usually not isolated damage to one site.

Symptoms and Signs

Symptoms and signs of vaginal apex prolapse are similar to those delineated for uterine prolapse. They include pelvic heaviness, backache, a mass protruding through the introitus, vaginal bleeding or discharge, and discomfort sitting or walking. Bladder and rectal symptoms can include stress incontinence, urinary urgency, urinary frequency, incomplete bladder emptying, difficult bowel movements, and splinting to void or defecate.

Diagnosis

POP-Q or other quantitative measurements should be performed, as with other forms of prolapse, to ensure that all three compartments are considered: anterior, apical, and posterior. Examination may help determine the contents of the herniation depending on where the vaginal scar is located in relation to the protruding mass and the extent to which the supports of the pelvis are lost. Rectovaginal examination is often helpful in delineating an enterocele from a rectocele.

Management

As with other POP, if not bothersome and not causing excessive kinking of the urethra or ureters, vaginal vault prolapse can be managed expectantly or with pelvic floor muscle strengthening. Vaginal estrogen can be used to treat ulcerations. Pessaries should be offered and attempted if preferable to the patient; unfortunately, however, prior hysterectomy makes successful pessary fitting difficult because the pessaries are more likely to fall out.

For operative management, the first guiding principle is that the normal position of the vagina in the standing position is against the rectum and no more than 30 degrees from the horizontal (Fig. 20.32). The second principle is that pelvic relaxation is a part of the problem and dictates that an existing cystocele, rectocele, or enterocele may need to be repaired as part of the procedure, particularly if correction of the apical defect does not reduce all the prolapsed compartments. The third principle acknowledges that the perineal body is almost always severely weakened in such patients and must therefore be reconstructed as well. The choices of operative procedures are many and may be approached abdominally, vaginally, laparoscopically, robotically, or some combination thereof. Benefits of vaginal surgery are generally shorter operative times, fewer complications, and quicker return to daily activities. Benefits of abdominal (whether open, laparoscopic, or robotic-assisted laparoscopic) include improved durability but with increased operative time and risks. Randomized, controlled trials are few, but a systematic review suggests that abdominal sacrocolpopexy for apical prolapse has higher success rates than sacrospinous colpopexy with less stress

Figure 20.32 Normal vaginal axis of nulliparous woman in the standing position. Note that the upper third of the vagina is nearly horizontal and is directed toward the S3 and S4 sacral vertebrae. (From Funt MI, Thompson JD, Birch H. Normal vaginal axis. *South Med J.* 1978;71[12]:1534.)

incontinence and less dyspareunia. However, it has greater morbidity, including operating time, length of hospital stay, and time to return to normal activity, and it is also associated with higher cost (Barber, 2013). The material of choice for sacrocolpopexies is type 1 wide pore, monofilament polypropylene mesh.

For transvaginal procedures, goals include maintaining adequate vaginal length and supporting the vagina nearly parallel to the horizontal. A randomized controlled trial of 374 women assigned to transvaginal fixation to the uterosacral ligaments or the sacrospinous ligaments found comparably good success rates: 15% of women in the trial had prolapse beyond the hymen 2 years after surgery, and only 5% required treatment for recurrent prolapse with pessary or surgery (Barber, 2014). The overall rate of perioperative adverse events was comparable between the procedures, including less than 1% risk of urethral, major vascular, or rectal injury, and a 3% risk of blood transfusion. Vaginal granulation and suture exposures were seen in approximately 15% of patients. Neurologic pain was higher in the sacrospinous ligament group (12%) than in the uterosacral group (7%). Ureteral obstruction was only seen in the uterosacral group (3%), and all but one was recognized and successfully managed intraoperatively. Mesh augmentation for vaginal vault prolapse is an alternative with some evidence to support it in terms of anatomic outcomes; however, as noted previously, it has higher complication rates and should only be placed by surgeons with adequate training to minimize complications.

Sacrospinous ligament suspension is performed by dissecting the vaginal epithelium off the underlying fibromuscular tissue all the way down through the perirectal space to the right ischial spine and then clearing off the sacrospinous ligament medial to the ischial spine. The surgeon must first identify the apex of the vagina and ensure that it will reach the ligament without tension. The vaginal incision can be in the anterior, apical, or posterior vaginal wall. After the dissection is complete, sutures are placed through the sacrospinous ligament 2 fingerbreadths medial to the ischial spine while the rectum is manually deflected medially. Figure 20.33 depicts the fixation of the vaginal vault to the sacrospinous ligament and

Figure 20.33 Sutures tied to bring the vaginal apex into contact with the sacrospinous ligament. The apex should approximate the ligament such that there is no “suture bridge.” (Modified from Morley GW, DeLancey JOL. Sacrospinous ligament fixation for eversion of the vagina. *Am J Obstet Gynecol.* 1988;158:872.)

Figure 20.34 The Miyazaki hook ligature carrier. (From Miyazaki FS. Miya hook ligature carrier for sacrospinous ligament suspension. *Obstet Gynecol.* 1987;70:286.)

the direction of the vagina after the procedure. Care must be taken to place the sutures sufficiently medially to avoid pudendal nerve injury. This space is deep and tight, and several techniques and devices have been designed to assist with passage of the sutures through the sacrospinous ligament, including the Miyazaki hook ligature carrier (Fig. 20.34) and Deschamps ligature carrier with nerve hook, both of which require direct visualization of the ligament using Breisky-Navratil retractors. Other systems have been adopted from other fields such as the Shutt suture punch system from orthopedics (Sharp, 1993), and the Endo Stitch (Covidien) autosuturing device from laparoscopic surgery. The Capiro (Boston Scientific) was specifically designed for prolapse surgery. Mesh kits for apical support procedures often have their own methods of attachment to the sacrospinous ligaments (Fig. 20.35).

Operative risks of sacrospinous colpopexy include injury to the pudendal and inferior gluteal arteries and the pudendal and sciatic nerves. Rectal injury is rare, although care must be taken when dissecting the rectal pillars to reach the ligament and to retract the bowel away when placing the sutures. The iliococcygeal ligament can be used in cases in which the vagina is not

Figure 20.35 Trocarless Mesh Delivery Systems. *Upper left*, Elevate tined delivery system by American Medical Systems. *Lower left*, Capio needle driver for Boston Scientific products. *Upper right*, Pinnacle mesh system by Boston Scientific. *Lower right*, Uphold anterior mesh system by Boston Scientific. long enough to reach the sacrospinous ligament without excessive tension. It has a similar risk profile with respect to recurrent cystocele, buttock pain, and hemorrhage and only slightly inferior subjective success rates (91% compared with 94%) and patient satisfaction (71% compared with 91% on a visual analog scale 0-100) (Maher, 2001).

Uterosacral ligament suspension offers theoretic advantages for apical support because, unlike the sacrospinous ligaments, these units are support structures in normal anatomy and replace the vagina in its normal anatomic position. However, as noted earlier, clinical trials do not suggest any advantage over sacrospinous ligament suspension (Barber, 2014). To perform this procedure, the anterior and posterior vaginal walls are opened in the midline, and the enterocele sac is opened to enter the peritoneal cavity (Shull, 2000). It is commonly performed after vaginal hysterectomy, when the peritoneal cavity is already open, or it can be performed open or laparoscopically at the time of other abdominal or laparoscopic procedures. After packing the bowel out of the field, the uterosacral ligaments can be identified and grasped with a long Allis clamp, taking care to avoid the ureter. A series of two or three sutures are placed high in each uterosacral ligament near the level of the ischial spine and then used to resupport the vaginal apex with the anterior vaginal endopelvic connective tissue and the posterior vaginal rectovaginal septum closed together. Any enterocele defect is closed with this technique, and any residual anterior or posterior vaginal wall prolapse can be further reduced with colporrhaphy.

Cystoscopy must be performed at the end of the procedure to ensure ureteral patency by looking for brisk efflux of urine from each ureteral orifice because there is as high as 11% rate of intraoperative ureteral kinking that requires removal and

replacement of the offending sutures (3% in the trial described earlier). Some surgeons prefer to perform cystoscopy mid-procedure with the uterosacral sutures on tension before they are placed through the vaginal apex because they are easier to remove and replace at that time. They must repeat cystoscopy to ensure ureteral patency at the end of the procedure as well. Injury to the sacral nerves from sutures that are placed too deeply in the sidewall has also been reported and usually presents as pain.

For the abdominal surgical treatment of vaginal vault prolapse, a variety of procedures have been tried, and sacrocolpopexy appears to be the most successful. Other methods of transabdominal apical support include fixation of the vaginal vault to the anterior abdominal wall, to the lumbar spine, to the sacral promontory, to various tendinous lines in the musculature of the true pelvis (e.g., paravaginal repair to the arcus tendineus), and to the sacrospinous ligament. The anterior abdominal wall fixation increases the diameters of the pouch of Douglas and frequently adds to the risk of subsequent enterocele development, often creating a recurrence in short order. Fixation to the lumbar spine or the sacral promontory is often difficult to achieve directly and requires the interposition of a graft to perform a sacrocolpopexy. Wide-pore, monofilament polypropylene mesh is what is most commonly used today due to decrease complications compared to braided mesh with small pores and due to reduced recurrence rates compared to biologic materials such as cadaveric fascia and fascial aponeurosis from the patient (Culligan, 2005).

The technique for performing a **sacrocolpopexy** is essentially the same whether it is performed through a laparotomy, with laparoscopy, or with robotic-assisted laparoscopy. The vagina is

Figure 20.36 Exposed presacral space in two unembalmed cadavers. These exposed presacral space illustrate the average distances (in centimeters) and range from midsacral promontory (yellow arrowhead) to (A) the vascular structures and to (B) the right ureter. Note the proximity of LCIV to the midsacral promontory in the cadaver on A (left panel). IIA, Internal iliac artery; LCIV, the left common iliac vein; RCIA, right common iliac artery; U, ureter. (From Good MM, Abele TA, Balgobin S, et al. Vascular and ureteral anatomy relative to the midsacral promontory. *Am J Obstet Gynecol.* 2013;208[6]:486.e1-486.e7.)

dissected away from the bladder and rectum, and then the mesh graft is sutured to the anterior and posterior vaginal walls. A bridge of mesh extends to sacrum, where it is affixed to the anterior longitudinal ligament over first sacral vertebral body (S1) in a tension-free manner. Care must be taken when performing the dissection to access the anterior longitudinal ligament to avoid the middle sacral artery and the plexus of veins in its vicinity. The mesh graft should be made retroperitoneal by closing the peritoneum over it, theoretically to reduce internal hernias and adhesions that could result in small bowel obstruction, which nonetheless can occur in one in 400 of cases. After sacrocolpopexy, the pouch of Douglas may still be large enough to allow an enterocele to develop. Therefore some surgeons also perform a culdoplasty to obliterate the cul-de-sac.

Operative complications from abdominal sacrocolpopexy include cystotomy (3.1%), enterotomy (1.6%), wound problems (4.6%), ileus (3.6%), thromboembolic event (3.3%), ureteral injury (1%), hemorrhage or transfusion (4.4%), and small bowel obstruction (1% to 5%) (Nygaard, 2004). As with vaginally placed mesh, synthetic mesh for sacrocolpopexies can result in vaginal exposures or bladder or bowel erosions, although the rates of mesh complications for mesh placed abdominally is less than that for mesh placed vaginally. Some operative risks are decreased with minimally invasive techniques (laparoscopy, robot) compared to laparotomy. One of the most dreaded operative complications is presacral hemorrhage when dissecting or placing sutures over the sacrum due to the proximity of large vessels and presacral plexuses (Fig. 20.36). Care must be taken to visualize the blood vessels and be prepared in the event of hemorrhage.

As with other POP surgeries, abdominal sacrocolpopexy can unmask stress urinary incontinence. A multicenter study

of 322 women with no preoperative stress incontinence symptoms were randomized to have a concomitant Burch colposuspension or not (controls). Three months after surgery, 24% of women in the Burch group and 44% of controls had stress incontinence, even though none reported stress incontinence preoperatively. Burch colposuspension significantly reduced postoperative stress incontinence when performed at the time of abdominal sacrocolpopexy, without an increase in other urinary problems (Brubaker, 2006). Now that Burch colposuspensions have largely been replaced by midurethral slings, it is less imperative to preemptively treat stress incontinence at the time of a sacrocolpopexy. Surgeons and patients have the option of concomitant anti-incontinence surgery in the form of a midurethral sling or Burch at the time of sacrocolpopexy or performing an interval midurethral sling surgery if indicated postoperatively.

In elderly women who are no longer sexually active, and particularly in those who have medical reasons to avoid a longer procedure, a Le Fort-type **colpocleisis** operation may be performed with an excellent result, low complication rate, and low recurrence rate. This procedure was discussed in detail in the uterine prolapse section of this chapter.

The question of continuing sexual activity after POP repairs is obviously an important one. With an adequate vaginal operation (with the exception of colpocleisis) or abdominal operation, intercourse is achievable in most patients who wish to maintain this activity.

RECTAL PROLAPSE

Rectal prolapse is covered in Chapter 22.

CONCLUSION

In all women with symptomatic pelvic organ prolapse, several areas of function must be discussed and potentially addressed, including urinary, bowel, sexual, and other pelvic complaints. Nonsurgical treatments are often effective, and women do not need any treatment if they have no symptoms or bother. Symptomatic women with mild prolapse should be offered pelvic floor

physical therapy if available. Symptomatic women with any stage of prolapse should be offered a pessary fitting.

If surgical treatment is desired, there are many factors to consider, including patient characteristics and desires as well as the surgeon's skills. Recurrent pelvic organ prolapse is a substantial problem, and little is known about the prevention of pelvic organ prolapse, so much research is still needed in this field.

KEY POINTS

- In the female, large hernias, hernias that continuously have intraabdominal contents, hernias that cause continuing discomfort, and hernias that have been incarcerated should be operatively repaired.
- Pelvic organ prolapse is defined as the descent of one or more compartments of the vagina: the anterior vaginal wall, posterior vaginal wall, uterus (cervix), or apex (vaginal vault or cuff scar after hysterectomy).
- Pelvic organ prolapse is more likely to be symptomatic when the leading edge protrudes past the hymen; it can be managed expectantly if asymptomatic.
- Renal function should be evaluated in women with advanced pelvic organ prolapse if the patient declines treatment to reduce the prolapse.
- Vaginal delivery is a major risk factor for the development of pelvic organ prolapse.
- The cardinal and uterosacral ligaments hold the uterus and upper vagina in the proper location.
- Pessaries should be offered to all women with symptomatic pelvic organ prolapse.
- Pelvic organ prolapse often includes a mixture of anterior, posterior, and apical prolapse, and each compartment should be evaluated under strain prior to determining the appropriate operative treatment.
- Surgery for pelvic organ prolapse is usually effective at decreasing a vaginal bulge, but the effects on urinary, bowel, and sexual function can vary. It is important to elicit a patient's goals before surgery.
- Vaginal vault prolapse can be repaired abdominally or vaginally. An abdominal sacral colpopexy with synthetic mesh appears to have a higher long-term success rate for the vaginal apex, but at the risk of more surgical complications.

Lower Urinary Tract Function and Disorders Physiology of Micturition, Voiding Dysfunction, Urinary Incontinence, Urinary Tract Infections, and Painful Bladder Syndrome

Anna C. Kirby, Gretchen M. Lentz

The gynecologist frequently consults on and treats urologic problems in the female patient. Perhaps the most commonly seen of these problems involves infection and inflammation of the lower tract. Urinary tract infections (UTIs) occur in up to 50% of women over their lifetime. Painful bladder syndrome affects fewer women, but they often have chronic pain and may make frequent visits to the gynecologist's office before a diagnosis is made. Furthermore, there is considerable overlap of symptoms with other gynecologic problems such as UTIs, overactive bladder (OAB), endometriosis, and dyspareunia, so a gynecologist should be familiar with these conditions.

Many women suffer from some degree of urinary incontinence. Various prevalence studies have reported that approximately 30% of women noted some degree of incontinence during the preceding 12 months. Ten percent of women suffer from weekly incontinence, and 5% have daily incontinence. Urinary incontinence problems increase in incidence with age and, because the number of older women in our population is increasing, this problem is growing in magnitude. A survey of pelvic floor disorders by (Nygaard, 2008) found at least one pelvic floor disorder in 24% of women. At least monthly urine leakage was reported by 7% of women ages 20 to 39, 17% ages 40 to 59, 23% ages 60 to 79, and 32% 80 years of age and older. This study may actually underpredict the prevalence of these disorders because women in the survey may have been successfully treated and not counted. Overweight and obese women were more likely to report urinary incontinence than women of normal weight.

Continence depends on a number of factors, including the neurologic control of micturition, the anatomic relationships of the urinary tract, and the specific effects of a number of systemic, infectious, and neoplastic conditions. Older women have additional challenges to the urinary system with comorbid medical conditions, ambulatory difficulties, and cognitive impairments. Not only does the prevalence of urinary incontinence increase with age, but so does the severity. Incontinence has been associated with depression, increased social isolation, falls, hip fractures, and admission to nursing homes, which has additional morbidity. Furthermore, incontinence decreases quality of life

and increases costs to society. This chapter discusses the physiology of normal micturition as well as the evaluation and treatment of female lower urinary tract conditions.

PHYSIOLOGY OF MICTURITION

A number of factors are involved in maintaining continence. The central nervous system (CNS) and peripheral ganglia coordinate function of the lower urinary system through complex neural pathways—those that maintain a urethral closure mechanism and those that affect detrusor function. It is a balance between bladder storage, which is organized primarily in the spinal cord and coordinates urethral closure and detrusor relaxation, and micturition, which is controlled by reflex mechanisms mediated by the brain. Voluntary voiding is a learned function and is not automatic, like heart rate control.

Bladder detrusor contractility is stimulated by the activity of the parasympathetic nervous system, mediated primarily through the neurotransmitter acetylcholine. This stimulates muscarinic (primarily M_3) receptors in the bladder wall, which then activate detrusor contraction. Sympathetic nerve α receptors within the bladder cause bladder relaxation when stimulated. Bladder contraction may also be affected by irritation and inflammation of the bladder wall lining, causing uninhibited contractions. Inhibitory input to the urethral smooth muscle is conveyed by nitric oxide via parasympathetic nerves. Somatic cholinergic motor nerves supply the striated muscles of the external urethral sphincter from the sacral spinal cord.

The act of voiding is under the control of four basic autonomic and somatic nervous system feedback loops. The first loop (loop I) involves a circuit from the cerebral cortex to the brain stem, which inhibits micturition by modifying sensory stimuli emanating from loop II. Loop II, which originates in the sacral micturition center (S2 through S4) and the detrusor muscle wall itself, represents sensory fibers to the brain stem, where modulation of the stimuli by loop I takes place. If cerebral inhibition is not imposed (loop I), the stimuli are returned to the sacral micturition center as a response to the bladder filling, allowing

activation of loop III. Loop III involves sensory flow from the bladder wall to the sacral micturition center with returning motor fibers to the urethral sphincter striated muscle, which allows the voluntary relaxation of the urethral sphincter as the detrusor contracts. Loop IV originates in the frontal lobe of the cerebral cortex and runs to the sacral micturition center and then to the urethral striated muscle, allowing urethral voluntary muscles to relax, thus leading to the initiation of voiding. Figure 21.1 demonstrates these four loops. Table 21.1 summarizes the important aspects of each loop (Ostergard, 1979).

Figure 21.1 Central nervous system feedback loops. (From Williams ME, Pannill FC 3rd. Urinary incontinence in the elderly: physiology, pathophysiology, diagnosis, and treatment. *Ann Intern Med.* 1982;97: 895-907.)

Both the parasympathetic and sympathetic nervous systems function with the CNS in these feedback loops via the pontine micturition center. The parasympathetic system is involved in the act of voiding via nuclei in S2 through S4 (micturition center) and mediates its activity through the neurotransmitter acetylcholine, directly stimulating muscarinic receptors in the bladder wall. This signal is transmitted via the pelvic nerve and causes the detrusor to contract. At the same time, the pontine micturition center (PMC) in the brain inhibits the sympathetic pathway as well as the somatic pathway to the urethra. This allows the urethra to relax so that coordinated voiding can occur. Functional brain imaging studies (e.g., positron emission tomography [PET]) during voiding show activation of the cortex, insula, and PMC. The sympathetic system, on the other hand, acts to prevent micturition. Norepinephrine is secreted via this system, stimulating both α - and β -adrenergic receptors. The bladder contains primarily β receptors, stimulation of which causes relaxation of the detrusor muscle. The urethra contains primarily α receptors. Stimulation of these α receptors causes contraction of the urethral sphincter. Thus the overall effect is to prevent micturition (Fig. 21.2). Estrogen and progesterone receptors are present in the bladder and urethra, although their role in affecting continence has not been fully elucidated. Many other neurotransmitters, neuropeptides, and receptors have been identified in the lower urinary tract, including dopamine, serotonin, nitric oxide, γ -aminobutyric acid (GABA), glutamine, neurokinin A, nerve growth factor, and adenosine triphosphate (ATP).

Because the neurogenic control of micturition is so complex and depends on the interaction of so many factors, it is understandable that a host of general systemic diseases or diseases involving the nervous system may affect bladder control. These include, but are not limited to, diabetes mellitus, vascular diseases, obesity, cognitive disorders, normal pressure hydrocephalus, demyelinating diseases (e.g., multiple sclerosis), CNS trauma, and tumors. The system can be disrupted by a stroke, which is a suprapontine lesions leading to loss of central inhibition, resulting in detrusor overactivity and reemergence of reflex micturition. A spinal cord injury above the lumbosacral level eliminates voluntary control of voiding, leading to acute urinary retention. Later, neurogenic detrusor overactivity occurs from spinal reflex pathways, which are uncoordinated, so the urethral sphincter may not relax simultaneously, leading to detrusor-sphincter dyssynergia. A lumbosacral burst fracture can result

Table 21.1 Neurologic Control of Micturition: Clinical Considerations on Central Nervous System Reflex Loops

Loop	Origin	Termination	Function	Associated Conditions
I	Frontal lobe	Brain stem	Coordinates volitional control of micturition	Parkinson disease, brain tumors, trauma, micturition
II	Brain stem Bladder wall	Brain stem	Detrusor muscle contraction to empty bladder	Spinal cord trauma, multiple sclerosis (MS), spinal cord tumors, neuropathy, local urinary tract disease
III	Sensory afferents of tumors, diabetic detrusor muscle disease	Striated muscle of urethral sphincter via pudendal motor neurons and sacral micturition center	Allows relaxation of urethral sphincter in synchrony with detrusor contraction	MS, spinal cord trauma or neuropathy, local urinary tract
IV	Frontal lobe	Pudendal nucleus	Volitional control of striated external urethral sphincter	Cerebral or spinal trauma or tumor, MS, cerebrovascular disease, lower urinary tract disease

Modified from Ostergard DR. The neurological control of micturition and integral voiding reflexes. *Obstet Gynecol Surv.* 1979;34:417-423.

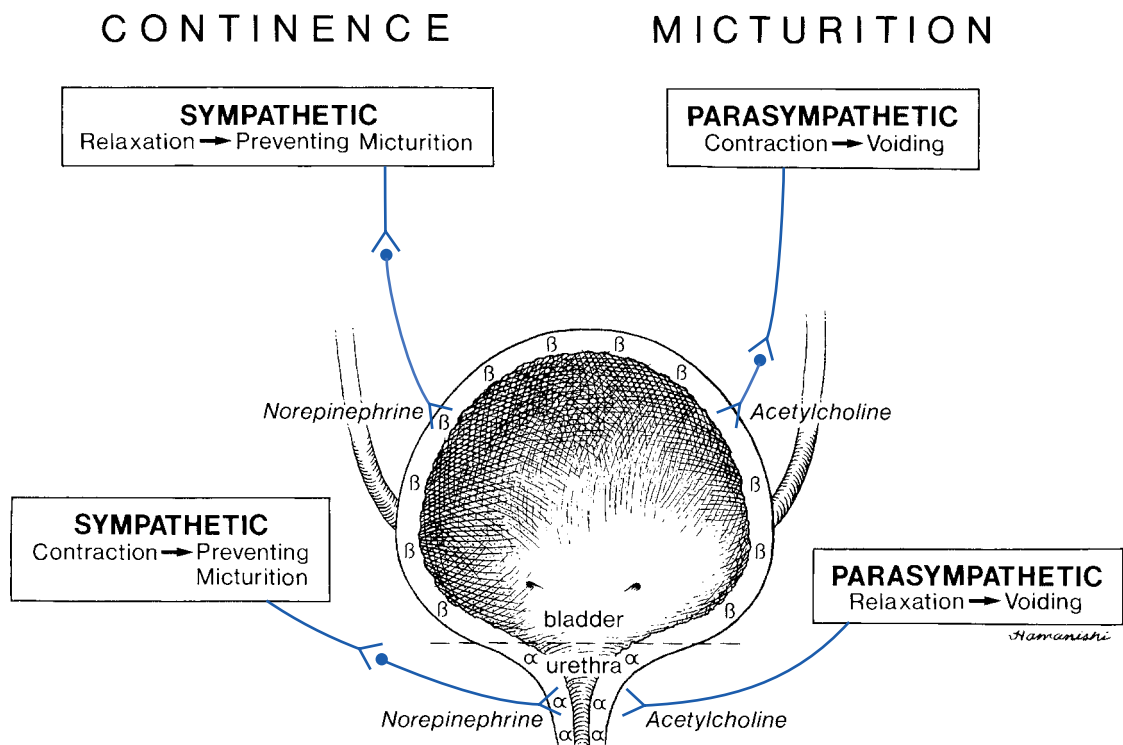

Figure 21.2 Innervation of the Bladder and Urethra. Parasympathetic fibers arising in S2-S4 have long preganglionic fibers and pelvic ganglia close to the bladder and urethra. These parasympathetic fibers excrete acetylcholine. Sympathetic fibers that have long postganglionic fibers discharge norepinephrine to β receptors, primarily in the bladder, and α receptors, primarily in the urethra. (Modified from Raz S. Pharmacological treatment of lower urinary tract dysfunction. *Urol Clin North Am.* 1978;5:323-324.)

Table 21.2 Drugs That Affect Continence and Micturition

Drug	Action
Sympathetic (Relaxes Bladder; Controls Urethral Sphincter)	
Dopamine	α -Adrenergic stimulator
Methamphetamine	α -Adrenergic stimulator
Norepinephrine	α -Adrenergic stimulator
Phenylephrine	α -Adrenergic stimulator
Albuterol	β -Adrenergic stimulator
Isoproterenol	β -Adrenergic stimulator
Terbutaline	β -Adrenergic stimulator
Parasympathetic (Stimulates Bladder Contraction; Relaxes Urethral Sphincter)	
Pilocarpine	Stimulates acetylcholine, incontinence
Pyridostigmine	Stimulates acetylcholine, incontinence
Sympathetic Blockers	
Hydralazine	Adrenergic blocker, stress incontinence
Methyldopa	Adrenergic blocker, stress incontinence
Reserpine	Adrenergic blocker, stress incontinence
Parasympathetic Blockers	
Atropine	Parasympathetic inhibitor, impaired emptying
Papaverine	Parasympathetic inhibitor, impaired emptying
Scopolamine	Parasympathetic inhibitor, impaired emptying

in detrusor overactivity with urethral sphincter hyporeflexia or sphincter hyperreflexia. A radical hysterectomy or subsacral cauda equine lesion might disrupt the local reflexes and lead to overflow incontinence because of detrusor and sphincter hyporeflexia. If the pudendal nerve is intact, the sphincter function will be normal.

In addition, medications that have an effect on the CNS or autonomic nervous system may affect bladder control. Compounds with atropine-like effects may interfere with the initiation of micturition, whereas those with cholinergic effects may cause bladder overactivity (Table 21.2).

In summary, bladder control depends on the ability of the bladder to store urine under low pressure, which involves inhibition of the detrusor muscle and contraction of the smooth and striated urethral sphincters. Emptying the bladder requires coordination with pelvic floor and urethral sphincter relaxation and detrusor contraction. Local reflexes and central inhibitory influences are involved.

BLADDER AND URETHRAL ANATOMY AND FUNCTION

With the neurologic principles of micturition in mind, it is appropriate to assess other factors that may influence continence. The bladder and urethra are essentially a functional

unit (Asmussen, 1976) with the bladder's subfunction being to store urine and the urethra's to allow it to pass. For urine to pass through the urethra, the maximum urethral pressure must be lower than the intravesical pressure. Intravesical pressure depends on the following: (1) the volume of fluid in the bladder, (2) the part of the intraabdominal pressure transmitted to the bladder, and (3) the tension in the bladder wall related to muscular and nervous system activity and elastic properties. The resting pressure in the bladder is between 20 and 30 cm H₂O due to surrounding intraabdominal pressure with little or no pressure added from tension in the bladder wall in normal bladders (i.e., the detrusor pressure, which is further described in the Urodynamics section of this chapter) is 0 cm H₂O.

The intraurethral pressure depends on the following: (1) striated muscle fibers of the urethral wall, (2) smooth muscle fibers of the urethral wall (a circular and longitudinal layer), (3) vascular content of the urethral submucosal cavernous plexus, (4) passive elasticity of the urethral wall, and (5) the part of the intraabdominal pressure transmitted to the urethra. The urethra has primarily receptors from the sympathetic nervous system, which, when stimulated, cause contraction of the urethral sphincter. The urethral smooth and striated (skeletal) muscles add to the resting urethral tone, whereas the skeletal fibers react when intraabdominal pressure rises, such as with a cough.

Anatomically, the exact border between the bladder and urethra is difficult to determine. The functional length of the urethra, however, is that part in which the urethral pressure exceeds the bladder pressure. The urethral closure pressure (UCP) is defined as the maximum urethral pressure minus the bladder pressure (Asmussen, 1976). For continence to be present, the UCP must be higher than the bladder pressure. Urethral pressure varies with age, increasing up to the age of 20 years and then gradually decreasing until menopause. However, after menopause, the fall of this pressure is more rapid. Asmussen and Ulmsten (1976) have demonstrated that the highest pressure zone in the urethra is approximately at the midpoint of the functional urethral length. The anatomic urethral length is approximately 3 to 4 cm. This high-pressure zone is located at approximately 0.5 cm proximal to the urogenital diaphragm (Westby, 1982). Most of the functional urethral length is actually above the urogenital diaphragm (Fig. 21.3). The submucosal cavernous plexus of vessels, the bulk of the smooth and striated muscle, and the bulk of the autonomic nerve supply are most prominent in the area in which they record the maximum urethral pressure. Because the urethral pressure displays high-pressure zone oscillations that are synchronous with the heartbeat, the submucosal cavernous plexus is probably important in helping to maintain continence (Fig. 21.4). Estrogen receptors are found in the bladder and urethra. Urethral pressure can oscillate as much as 25 cm H₂O in young women but seldom more than 5 cm H₂O in postmenopausal women (Enhörning, 1961). The cavernous plexus is thicker walled and less elastic in older women. Thus not only is the epithelium of the bladder and bladder neck dependent on hormone stimulation, but probably so is the vascular system of these areas.

DeLancey made some interesting observations on functioning periurethral anatomy by studying serial histologic sections of intact pelvic viscera and surrounding tissue and by dissecting 22 fresh and embalmed cadavers (DeLancey, 1986). Because the length of the urethra varies among women, the topography of urethral and paraurethral structures was expressed in terms

of the location along the urethra, as a percentage of the total urethra. DeLancey considered the zero location as that point at which the urethra leaves the bladder lumen and the 100th percentile as that point at which the urethra terminates on the perineum. From the standpoint of functional anatomy, there is excellent agreement among the measurements made from each of his specimens when percentiles are used; Table 21.3 depicts these anatomic relationships. It can be seen that the intramural urethra represents approximately 20% of the length of the urethra. The portion of the urethra encircled by striated urethral sphincter muscle and associated with the pubourethral ligament and vaginal levator attachment concerns the midurethra—that is, that portion from the 20th to 60th percentile along the total length. The 60th to 80th percentile of the urethral length passes through the urogenital diaphragm and is under the influence of the urethrovaginal sphincter muscles. Finally, the last 20%, or distal urethra, traverses the bulbocavernosus muscles. These urethral landmarks are depicted in Figure 21.5, which highlights the actual ranges and values. The actual anatomic relationships

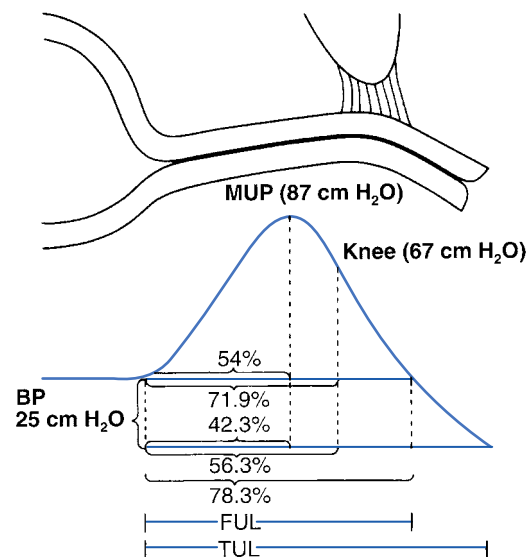

Figure 21.3 Location of maximum urethral pressure in relation to the urogenital diaphragm (average value of 25 normal women). Knee indicates the location of the urogenital diaphragm seen on x-ray film and transformed to the pressure curve. BP, Blood pressure; MUP, maximal urethral pressure. (From Asmussen M, Ulmsten U. On the physiology of continence and pathophysiology of stress incontinence in the female. *Contrib Gynecol Obstet.* 1983;10:32-50.)

Figure 21.4 Maximum urethral pressure shows great variation synchronously with the heartbeat. Variations of 20 cm H₂O as shown in the curve are not uncommon. (From Asmussen M, Ulmsten U. On the physiology of continence and pathophysiology of stress incontinence in the female. *Contrib Gynecol Obstet.* 1983;10:32-50.)

are depicted in Figure 21.6. DeLancey’s observations help correlate the anatomic relationships with the physiologic observations that others have made.

In a subsequent paper, DeLancey (1994) noted that additional anatomic factors might influence continence. Using serial histologic sections from eight female cadavers and the dissections of 34 other cadavers, he noted that the proximal urethra gets added support because the anterior vagina is attached to the muscles of the pelvic diaphragm and to the arcus tendineus fasciae pelvis. Contraction of the pelvic diaphragm thus pulls the vagina against the posterior surface of the urethra, helping to close it. At rest, the urethra is supported by its attachment

to the arcus tendineus fasciae pelvis and the tone of the pelvic diaphragm muscles. Two striated muscle arches, the compressor urethrae and urethrovaginal sphincter, support the distal urethra in the region of the urogenital diaphragm. These muscles help compress the distal urethra, helping to maintain continence during a cough.

In summary, continence depends on the bladder, urethra, pelvic muscles, the surrounding connective tissue supports, and the nervous system.

DIAGNOSTIC PROCEDURES

The clinical history is useful in the diagnosis of urinary incontinence. Several validated scales are available, such as the Urogenital Distress Inventory (UDI), Incontinence Impact Questionnaire (IIQ), Bristol Female Lower Urinary Tract Questionnaire, and King’s Health Questionnaire, although not one has become the preferred instrument. Useful testing can be done in the gynecologist’s office without the need for sophisticated equipment. These procedures are described and their benefits noted. The description is followed by a discussion of more sophisticated diagnostic techniques requiring specialized equipment.

URINALYSIS AND CULTURE

A simple urinalysis and urine culture may provide much information. The presence of white or red blood cells (RBCs) and bacteria in a catheterized or clean voided sample, in which the perineum around the urethra has been appropriately prepared with an antiseptic solution, may suggest a UTI, nephrolithiasis,

Table 21.3 Topography of Urethral and Paraurethral Structures*

Approximate Location†	Region of the Urethra	Paraurethral Structures
0-20	Intramural urethra	Urethral lumen traverses bladder wall
20-60	Midurethra	Striated urethral sphincter muscle Pubourethral ligament Vaginolevator attachment
60-80	Urogenital diaphragm	Compressor urethrae muscle Urethrovaginal sphincter muscle
80-100	Distal urethra	Bulbocavernosus muscle

kidney disease, or even urinary tract malignancy in rare cases. UTI may be associated with urgency, frequency, dysuria, and even incontinence. In such cases, the urinalysis and urine culture may be diagnostic. Several dipstick methods are available to detect bacteriuria, pyuria, and the presence of nitrites and leukocyte esterase. The accuracy of these methods is variable, but they do have some use in screening patients who are incontinent or have symptoms suggestive of infection. In some cases, a culture should be obtained to identify the specific organism involved and verify the presence of an infection. Urinalysis is also useful to screen for microscopic hematuria (RBCs) in women with new-onset urgency and frequency because underlying urinary tract pathology may be present. A formal microscopic urinalysis should be carried out to confirm screening results because urine dipstick tests can often yield a false-positive result and actual RBCs need to be identified. A catheterized specimen should be obtained if abnormal results are questioned because of vaginal contamination. This is common in women with pelvic organ prolapse, obesity, postmenopausal bleeding, menses, or in older women with arthritis and poor hand function. Screening for asymptomatic bacteriuria should only be done for pregnant women and for women planning to undergo urologic procedures.

TEST FOR RESIDUAL URINE

This simple procedure can be extremely helpful in the evaluation of a woman with incontinence with pelvic organ prolapse, voiding symptoms such as frequency or incomplete bladder emptying, or recurrent UTIs. The woman is asked to void, and a catheter is inserted into the bladder no more than 10 to 15 minutes later.

Figure 21.6 Interrelationships of approximate location of paraurethral structures. Levator ani muscles are shown as light lines running deep to the pelvic viscera. The vaginal levator attachment is shown as a darker area. AT, Arcus tendineus fasciae pelvis; BC, bulbocavernosus muscle; CU, compressor urethrae; D, detrusor muscle; IC, ischio cavernosus muscle; LA, levator ani muscles; PUL, pubourethral ligament; US, urethral sphincter; UVS, urethrovaginal sphincter; VLA, vaginal levator attachment. (Modified from DeLancey JO. Correlative study of paraurethral anatomy. *Obstet Gynecol.* 1986;68:91-97.)

The urine remaining in the bladder is measured and may be sent for urinalysis and culture. Definitions of normal postvoid residual volumes vary, but under normal circumstances, the amount of residual urine should be less than 150 mL or less than one third of the bladder volume (e.g., 100 mL after voiding 200 mL). Large amounts of residual urine suggest urinary retention resulting from inadequate bladder emptying. A reasonably accurate measure of residual urine volume can also be obtained noninvasively by ultrasound. Bladder scan ultrasound units are available and patients prefer to avoid urethral catheterization. Postvoid residual urine volume by ultrasound may be falsely elevated in women with large uterine fibroids or a large adnexal mass. Confirmation is necessary with catheterization if this is suspected.

BLADDER DIARY

In many cases, stress urinary incontinence can be correctly diagnosed in a primary care setting from the clinical history alone. The bladder diary appears to be a cost-effective adjunct to clinical history for diagnosing detrusor overactivity. Asking the woman to complete a bladder diary is a simple, inexpensive way to obtain information about her fluid intake, voiding habits, voided volumes, and incontinent episodes. An example diary form is shown in [Figure 21.7](#).

OFFICE CYSTOMETRICS

It is possible to gain a great deal of information about bladder capacity and bladder function with relatively simple tools. Once a catheter is inserted to check for residual urine, the catheter is left in place and attached to a graduated Asepto syringe without a bulb. It is possible to pour sterile saline (or sterile water) into the syringe by gravity and measure the amount of saline that first causes the woman to have the urge to void. This first urge should normally occur after 150 to 200 mL of saline has been infused. Women with normal bladder function should be able to continue to maintain continence at that level. Similarly, a strong, normally controllable urge to void usually occurs when 400 to 500 mL has been instilled. Thus a normal bladder first transmits an urge to void at 150 to 200 mL, and functional capacity is reached at 400 to 600 mL. Larger volumes can be reached without incontinence, but this is usually accomplished with a great deal of conscious effort. If, during filling, the woman reports urgency and the column of fluid in the Asepto syringe rises, leakage may be seen around the catheter and detrusor overactivity confirmed.

COUGH STRESS TEST AND PAD WEIGHT TEST

If a bladder has been previously filled to measure capacity, it should then be emptied to approximately 250 to 300 mL of saline, or if the bladder is empty, 250 to 300 mL of saline should be instilled. The catheter is then removed and the woman is asked to cough while in the recumbent position. If urine spurts from the urethral meatus, stress incontinence may be present and a positive cough stress test (CST) is noted. After the stress test is performed in a recumbent woman, it should be repeated with the woman standing if no leakage is seen. Frequently, she will appear to be continent with stress while lying down but may demonstrate incontinence when the influence of gravity on the

Your Daily Bladder Diary

This diary will help you and your health care team. Bladder diaries help show the causes of bladder control trouble. The “Example” line (below) will show you how to use the diary.

Your name: _____ Date: _____

Figure 21.7 Daily bladder diary. (From Vasavada SP, Appell R, Sand PK, et al, eds. *Female Urology, Urogynecology, and Voiding Dysfunction*. New York: Marcel Dekker; 2005:127.)

pelvic organs is brought into play in the standing position. For research studies, 250 or 300 mL of saline is instilled, the woman is asked to cough 10 times, and any leakage is considered a positive CST. In clinical practice, it is also reasonable to perform the standing cough stress test if the patient has a comfortably full bladder and then calculate the volume in the bladder afterward by adding the voided volume and the postvoid residual. If around 250 mL, the volume was adequate. If the volume in the bladder was low during a negative cough stress test, it should be repeated with around 250 mL. The clinical stress test is effective in diagnosing stress incontinence.

Because urine loss with cough should be immediate if stress incontinence is the problem, it may be possible to detect evidence of detrusor overactivity by observing the time of the spurt of urine in the stress test. Typically, the detrusor reacts a few seconds after the stimulus; therefore a spurt that occurs after a delay after a cough suggests the presence of a cough-induced involuntary detrusor contraction.

If no leakage is seen and anterior vaginal wall prolapse is present, occult stress incontinence is possible. It can be challenging to determine whether a woman with anterior vaginal wall relaxation is likely to develop overt stress incontinence after a pelvic organ prolapse repair. The cough stress test is repeated with

the prolapse reduced manually or with a pessary, either in the clinic or during urodynamic testing; a positive prolapse reduction cough stress test is associated with increased risk of de novo stress incontinence than a negative test, but it is not a perfectly accurate predictor.

A 1-hour pad weight test is another research tool for documenting pre- and postintervention urinary leakage volumes. Again, with a 250-mL bladder volume, a pad is given to the woman and she is asked to complete a series of activities over the hour, including walking, climbing stairs, coughing, and other events. If the pad weighs more than 2 to 3 g, the test is considered positive. Both this test and the CST are commonly used as objective measures of outcome for surgical incontinence trials.

Thus with urinalysis, urine culture, measuring postvoid residual urine, bladder diary, documented first urge to void, bladder capacity, and the cough stress test, the physician will have a great deal of information concerning the cause of the woman’s urinary complaint. More sophisticated urodynamic evaluations using specific and often costly equipment should be performed by those who are trained and experienced in these tests. A short discussion of these procedures and the equipment involved follows.

URODYNAMICS

Urodynamic investigation attempts to measure bladder and urethral function and voiding function. Cystometry, part of the urodynamic test, measures bladder pressure during the filling phase of the micturition cycle. First urge to void, normal desire to void, and bladder capacity are noted. The woman can cough or perform the Valsalva maneuver to detect stress incontinence in the absence of a detrusor contraction. Detrusor overactivity may be noted with the symptom of urgency, with or without leakage, in association with a detrusor pressure rise. Poor compliance from a nonelastic bladder is noted with a gradual pressure rise of more than 15 cm H₂O from baseline rather than phasic contractions of detrusor overactivity. Pressure flow studies measure voiding in terms of detrusor and urethral function. In attempting to understand the basis of urinary stress incontinence, the practitioner must realize that what must be determined is the relationship between the simultaneous intraurethral and intravesical pressures (Fig. 21.8). For greatest accuracy, these should be measured with the woman in the sitting position as well as standing, at rest, and with straining. The ideal means of evaluating a woman for incontinence is to use a multichannel recorder that permits pressure determinations at two points within the urethra (proximal and midpoint to distal), one within the bladder, and one intraabdominally as recorded by an intra-rectal sensor or by a sensor within the vagina if the vagina is in a relatively normal position (not prolapsed). Figure 21.9 shows a multichannel urodynamic study during the pressure/flow or voiding phase and highlights a woman with a voiding disorder, which was the main reason the study was ordered.

Several authors have described the concept of leak point pressure tests for evaluating urethral function in stress incontinence. Instead of measuring the intravesical pressure needed to overcome passive urethral resistance, this test measures the intravesical pressure necessary to overcome urethral resistance under stress (cough or strain). Studies have reported many variations in techniques to measure leak point pressures. The International Continence Society defines an abdominal leak point pressure (ALPP) as the lowest of the intentional or actively increased intravesical pressure that provokes urinary leakage in the absence of a detrusor contraction. This increased pressure can result from a Valsalva maneuver (VLPP) or coughing. The ALPP has been used to separate urinary stress incontinence as either related to an anatomic defect (hypermobility of the urethra) or intrinsic sphincter deficiency. However, it has become clear there is significant overlap in these conditions and using a simple cutoff of less than 60 cm H₂O to define intrinsic sphincter deficiency is too simplistic. The woman's history and clinical picture must be considered carefully and not just an arbitrary cutoff point.

Maximal urethral closure pressure (MUCP) is another measure of urethral function in stress incontinence. Below 20 cm H₂O is the criteria used to define intrinsic sphincter deficiency. Using the MUCP for choosing therapy in subtypes of stress incontinence or for outcome results in surgical trials has been criticized because unlike the VLPP, the test is not performed during stress. A 2010 randomized, controlled trial by Nager and colleagues studied the relationship between various measurements of urethral function and subjective scores of urinary incontinence (Nager, 2010). They found that VLPP and MUCP have moderate correlation with each other, but each had little or no correlation with the woman's subjective scores of

Figure 21.8 Simultaneous recordings of urethra and intravesical pressures during coughing. Stress produces a parallel increase of bladder and urethral pressure because the intraabdominal position of the bladder and proximal two thirds of the urethra are displayed. U.P.P., Urethral pressure profile. (From Raz S. Pharmacological treatment of lower urinary tract dysfunction. *Urol Clin North Am.* 1978;5:323-324.)

incontinence severity or objective tests such as the supine empty bladder stress test. These data call into question the use of urodynamic measures of urethral function when they do not correlate with urinary incontinence severity. However, many stress incontinence surgical trials use the MUCP and leak point pressures to categorize incontinence and to predict risk of surgical failure, so being familiar with the tests is useful.

Other studies have called into question the usefulness of urodynamics for stress or urge incontinence symptoms in uncomplicated cases. The test correlates poorly with symptoms and often does not affect the outcome of treatment, even with stress incontinence surgery (Nager, 2008). When urodynamic testing is done, it must be correlated with the woman's symptoms and exam, as those factors may be more revealing than the test.

Multichannel devices involve more expensive equipment and require continuous maintenance. It is possible to add a video urodynamic system to the multichannel recorders, making it possible via fluoroscopy to identify reflux into the ureters in high-risk patients. The video system also makes it possible to actually observe the act of micturition, any anatomic changes, and the effect of stress. Because the data obtained by multichannel pressure recordings plus the ability to actually visualize the woman voiding offers the most accurate diagnostic information that the clinician can obtain, this technique is considered the standard against which other tests are measured.

Urodynamic testing is not necessary for beginning a conservative treatment program for stress, urge, or mixed incontinence

Figure 21.9 Multichannel urodynamic study of a 44-year-old woman, G5 P1, with complaints of mixed incontinence and difficulty emptying her bladder. She had some minor neurologic symptoms suggestive of multiple sclerosis, but her evaluation had not proved a definite diagnosis. Her voiding study revealed an acontractile bladder and abdominal straining to void, with poor urine flow.

symptoms or for routine evaluation. However, if the diagnosis is unclear, the woman has failed conservative therapy, has had prior incontinence surgery, has voiding complaints, has pelvic organ prolapse beyond the hymen, or has a complicated medical history (such as neurologic disease), then urodynamic testing may provide useful information.

CYSTOURETHROSCOPY

Cystourethroscopy, or simply cystoscopy, may be performed with a flexible or rigid telescope that allows visualization of the urethra, bladder, and ureteral orifices in an office setting (Box 21.1). Generally, saline or sterile water is used for the infusion fluid to expand the bladder. Local lidocaine jelly is inserted into the urethra for analgesia in the office. A small 17 Fr sheath is commonly used for routine inspection and a larger sheath for operative procedures. Examination of the bladder is best accomplished using a 30- or 70-degree lens, which offers the angles needed to examine the bladder in its entirety. A 0- or 12-degree lens is best for examining the urethra. The bladder may have to be flushed for optimal viewing if blood obscures the view; this can easily be done by filling, emptying, and refilling the bladder. A systematic survey should be done inspecting the bladder base and trigone, ureteral orifices, dome, and all other surfaces all the way back to the bladder neck. The bladder may be visualized and the presence of inflammation, foreign bodies, urinary tract stones, anatomic abnormalities such as a duplicated ureter (Fig. 21.10), or benign or malignant lesions noted. Urethroscopy, using the same cystoscopy equipment, is excellent for visualizing the

Box 21.1 Common Findings on Urethroscopy

Normal Urothelium—Pale, Fine Blood Vessels

- Normal—squamous metaplasia in trigone (benign overgrowth)
- Abnormal—hypervascularity
- Abnormal—cystic lesions in the trigone; could be benign cystitis (UTI)
- Abnormal—stitch or mesh from incontinence surgery
- Abnormal—bladder stone or kidney stone that has passed
- Abnormal—lesion growing from wall; biopsy, could be carcinoma
- Abnormal—grapelike clusters; biopsy, could be transitional cell carcinoma
- Abnormal—trabeculations (hypertrophied detrusor muscle), benign; seen in OAB or outlet obstruction
- Abnormal—Hunner ulcer; pathognomonic for interstitial cystitis

Normal Urethra—Collapsed in Absence of Fluid Flow

- Abnormal—fronds or pseudopolyps, benign response to inflammation
- Abnormal—stricture; prior surgery, especially urethral diverticulum excision

Ureteral Orifices with Bilateral Jets of Urine Flow

- Abnormal—sluggish flow, could mean partial obstruction
- Abnormal—no flow, could mean obstruction from current or past surgery, stone, or stricture

urethra and provides information about inflammatory processes within the urethra, urethral diverticula, and other anatomic defects such as a urethral stricture or foreign body (e.g., mesh from an midurethral tape sling), and it permits some estimate of urethral tone.

Figure 21.10 Cystoscopy after indigo carmine was infused intravenously to confirm the duplicated ureters on the left side and that both were functioning.

INFECTIONS OF THE LOWER URINARY TRACT

CYSTITIS

A UTI (cystitis) is the most common bacterial infection seen in an outpatient setting. Infections of the urethra and bladder are almost always associated with some combination of the following: frequency, urgency, dysuria, pyuria, hematuria, acute or chronic pelvic pain, backache, and, at times, fever. As many as 50% of all women develop UTIs at some time during their life and, by age 70, as many as 10% of women will have recurrent UTIs. At times, incontinence is associated with acute and recurrent infections. Although *Escherichia coli* is the cause of most UTIs (80% to 85%), a myriad of organisms, including *Enterobacter*, *Klebsiella*, *Pseudomonas*, *Proteus*, *Streptococcus faecalis*, *Staphylococcus saprophyticus*, *Enterococcus*, and *Chlamydia*, can be found. The presence of bacteria in the urine (bacteriuria) does not necessarily prove clinical infection. Bacteriuria is fairly common in women, especially older women. For example, cumulative data from several studies have suggested that 20% of women older than 65 years will demonstrate bacteriuria, but the percentage increases from approximately 15% in the 65- to 70-year group to 20% to 50% for women older than 80 years. Bacteriuria is present in women who are on chronic catheterization and common in women in nursing homes who are chronically incontinent. Asymptomatic bacteriuria is not treated, even in older women or people with diabetes, with no change in their morbidity or mortality (Mody, 2014). Exceptions exist to this recommendation if the woman is undergoing an invasive procedure, is pregnant, has had a renal transplant, or is incontinent and her incontinence resolves with treatment. If a woman with asymptomatic bacteriuria becomes symptomatic, treatment is appropriate.

Many explanations have been offered as to why the female urinary tract is vulnerable to infection. These include the following: short female urethra, thereby allowing easier access of bacteria to the bladder; proximity of the vulva, vagina, and rectum to the opening of the urethra; effects of sexual intercourse on

the entrance of bacteria into the urethra and lower urinary tract; and effect of loss of estrogen on the reproductive tract of older women. After menopause, the vaginal pH rises and may alter the vaginal flora, allowing for colonization of uropathogenic species, especially *E. coli*; it is probably appropriate to add personal immunologic and genetic variations to this list, which may make one woman more susceptible than another to certain bacteria. Genetic factors also explain why some UTIs as nonsecretors of certain blood group antigens are at increased risk.

The definition of a symptomatic UTI is a woman with dysuria, frequency, urgency, or suprapubic pain with pyuria. Uncomplicated UTIs occur in healthy women with normal urinary function. UTIs are classified as complicated when there are comorbid conditions that require longer treatment courses, such as underlying urologic abnormalities, presence of a foreign body (e.g., catheter), urinary calculi, obstruction of urine flow, diabetes mellitus, spinal cord injury, pregnancy, renal transplantation, or other illnesses. Acute uncomplicated cystitis (AUC) can often be diagnosed successfully with symptom assessment. In outpatient settings, women with at least two of three acute symptoms (dysuria, urgency, frequency) in the absence of vaginal discharge (or risk for sexually transmitted infection) have a greater than 90% probability of having AUC. Additional urine testing does not aid in the diagnostic accuracy. However, outside of those criteria, a clean-catch midstream urine sample for dipstick testing for leukocyte esterase and nitrites or a microscopic unspun urine evaluation for white blood cells (pyuria) can be helpful. Pyuria should always be seen in the urine when UTI occurs and is the most valuable test. RBCs may be present in microscopic or macroscopic numbers. Hematuria is common in acute infections, and infection is the most common cause of hematuria. Gross hematuria may occur as a result of the extravasation of blood across dilated and inflamed capillaries. If microscopic or macroscopic hematuria persists after UTI treatment, it must be evaluated. The pathogens are predictable in AUC, so culture is unnecessary and can be reserved for recurrent UTIs (≥ 2 in 6 months) or complicated UTIs. If a culture is done, it usually grows a single organism. The number of organisms per milliliter is not important. In cases of urethritis, the presence of as few as 100 organisms/mL may indicate an infection because of the dilution of the urine.

In 2009, the Infectious Diseases Society of America (IDSA) developed evidence-based guidelines for the treatment of acute uncomplicated cystitis (AUC). These are UTIs in nonpregnant, premenopausal women without pyelonephritis. If local *E. coli* bacterial resistance rates are less than 20%, trimethoprim-sulfamethoxazole (TMP-SMX) is recommended. Three-day therapy is adequate for AUC. The resistance of *E. coli* to TMP-SMX has increased over time. Short-course (3-day) therapy improves patient tolerability and compliance and reduces cost. This treatment strategy results in more than a 90% cure rate. Nitrofurantoin monohydrate/macrocrystals are an appropriate alternative. At least 5 days of drug treatment is recommended. Resistance rates of *E. coli* to nitrofurantoin have remained low. This should be avoided if early pyelonephritis is even suspected. The third alternative recommended is fosfomycin trometamol, 3 grams given as a single dose. This may have slightly lower efficacy than the other two options. Fluoroquinolones are not on the list, although highly efficacious, as resistance is rising, and it is recommended that these medications be reserved for

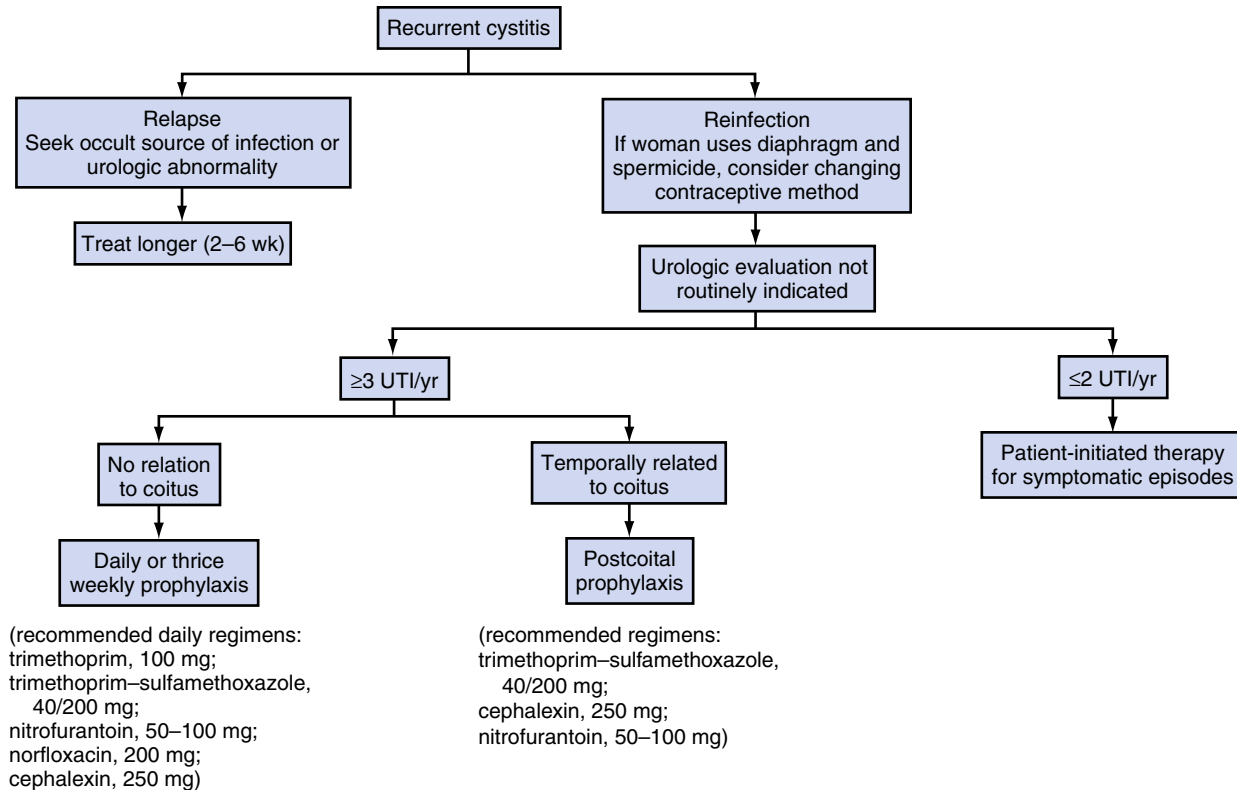

Figure 21.11 Strategies for managing recurrent cystitis in women. (From Stamm WE, Hooton TM. Management of urinary tract infections in adults. *N Engl J Med*. 1993;329:1328-1334.)

more serious infections. With uncomplicated UTIs, progression to pyelonephritis is extremely rare. The woman should remain adequately hydrated and be encouraged to continue treatment, even though symptoms generally disappear within 48 hours. Infections frequently recur because they are not adequately eradicated. This may result from physician error (treating with too low a dose of antibiotic, the wrong antibiotic, or for too short a period of time) or patient error (not taking the medication as prescribed). For complicated UTIs, a 7- to 10-day course of a fluoroquinolone is recommended. If a culture is obtained and results are reported, the antibiotic may be changed if the organisms noted are not sensitive to the antibiotic in use.

Persistent or recurrent cystitis following the initial infection presents in approximately 20% of women (Fig. 21.11). Frequent infections with the same organism (relapse) suggest the possibility that a nidus of infection exists. Recurrent infections of different organisms (reinfection) should alert the physician to the need for a more complete evaluation. However, radiographic imaging—seeking structural abnormalities of the bladder, kidney, or ureters—is rarely useful in otherwise healthy women. More than 90% of recurrences in young women are exogenous reinfection with new isolates arising from local flora. Behavioral modification has become popular for preventing recurrent acute cystitis. Possible modifications in lifestyle include discontinuing use of a diaphragm and spermicide for contraception. Nonoxynol 9 has been associated with an increased risk of UTIs in women (Fihn, 1996).

Recurrent UTI are defined by ≥ 2 episodes in the past 6 months or ≥ 3 episodes in the past 12 months. In primary care clinics, 53% of women over 55 years of age and 36% of younger women

report a recurrence within 1 year. There are several strategies for managing recurrent UTIs. One strategy is eliminating risk factors, such as use of Nonoxynol 9 or correcting vaginal atrophy. Postmenopausal women with recurrent UTIs often benefit from vaginal estrogen therapy because this restores the acidic environment of the vagina and allows normal bacteria and lactobacilli to repopulate the vagina (Raz, 1993). Many episodes of recurrent UTIs in young women occur within 24 hours of coitus. These women are excellent candidates to be treated with postcoital prophylactic antibiotics with a single dose. The antibiotics most commonly chosen for low-dose antibiotic prophylaxis include trimethoprim, TMP-SMX, nitrofurantoin, and a cephalosporin. Often women with recurrent UTIs at unpredictable times prefer self-initiated treatment with the onset of symptoms. Using the antibiotics presented here for AUC is reasonable. Continuous antibiotics are sometimes needed. Prophylaxis may be given for months without significant emergence of antibiotic-resistant bacteria. Personalized antibiotic prophylaxis remains the most effective method of managing recurrent UTIs. Non-antibiotic prevention strategies such as cranberry supplements, vitamin C, and methenamine salts lack strong evidence of benefit, but some women wish to try these options. The most evidence exists for cranberry supplements, but the correct dosage or formulation is unknown and studies are contradictory. D-Mannose also has little evidence of benefit but is being studied. Also under study are use of vaccinations, *Lactobacillus* and probiotics. Delaying treatment with antibiotics and trying ibuprofen has been studied. However, the majority of women needed antibiotics, and it just delayed the duration of symptoms (Grigoryan, 2014).

Frequent catheterizations or manipulation of the lower urinary tract will often cause UTIs. An indwelling catheter for 24 hours leads to bacteriuria in as many as 50% of patients. When left in place for 96 hours, an indwelling catheter causes bacteriuria in almost 100% of patients. There is no good evidence supporting the use of prophylactic antibiotics in patients who must continue catheter use. A woman with an indwelling catheter should be monitored for the possibility of a symptomatic UTI, be kept adequately hydrated, have a urine culture if symptoms occur, and be treated with the appropriate antibiotic. However, it is difficult to eradicate infection in the presence of an indwelling catheter. Removing the catheter or switching to clean intermittent self-catheterization would be optimal. Postoperative and debilitated patients are at greatest risk.

Although physicians commonly recommend measures to their patients for preventing UTIs, studies do not support these practices. These include wiping the rectum away from the urethra, voiding after intercourse, and drinking more fluid.

Additional circumstances that may be responsible for infections in women include the dilation of the urinary tract in pregnancy, urinary tract obstruction, urinary stones, urethral diverticulum, foreign bodies (e.g., mesh placed for a midurethral sling for incontinence), ureteral reflux, and pelvic organ prolapse. Other causes of UTIs in men and women include the need for frequent catheterization, instrumentation, and overdistention of the bladder in neurogenic conditions in which stasis becomes a problem.

URETHRITIS

Patients with acute urethritis generally have the typical findings of lower tract UTIs, which include dysuria, frequency, and urgency. They often have a urethra that is tender to palpation. Under certain circumstances, it may be possible to express pus from the urethra; this is particularly common in acute infections with gonococcal or *Chlamydia* organisms. In these situations, the infection involves not only the urethra but also the periurethral glands. Herpes simplex virus has also been associated with urethritis. *Trichomonas vaginalis* has been cultured in nongonococcal urethritis but is more established as a causative agent in men.

Pus expressed from the urethra should be submitted for culture and for smear with Gram stain. Intracellular diplococci are suggestive of gonorrhea. *Neisseria gonorrhoeae* and *Chlamydia* are well known for causing urethritis, and nucleic acid amplification tests (NAATs) of the urine enable detection of both organisms. It should be kept in mind that these are reportable diseases to the state health department. Frequently, significant pyuria is noted in a first void clean-catch urine sample, particularly when taken early in the voiding. Urine obtained by the clean-catch method should also be cultured. NAATs are available at major centers for *Mycoplasma genitalium*, although not approved by the U.S. Food and Drug Administration (FDA). This organism has been implicated in recurrent urethritis in men and cervicitis and pelvic inflammatory disease in women, so is worth consideration if no other causes of dysuria are identified.

If no specific organism is identified on smear, treating as for AUC is appropriate with 3 days of TMP/SMX or nitrofurantoin for 5 days. If *Chlamydia* is found on NAAT, doxycycline, 100 mg twice daily, should be prescribed for 7 days, or

azithromycin, 1 g orally, in a single dose, should be given. If gonorrhea is diagnosed, the current recommended treatment consists of dual therapy with ceftriaxone 250 mg IM (single dose), plus azithromycin 1 g (single dose). Alternative treatment is cefixime, 400 mg (single dose) with azithromycin 1 gram (single dose) (Centers for Disease Control and Prevention [CDC] 2015). Coinfections with *N. gonorrhoeae* and *C. trachomatis* are common. *Mycoplasma* and *ureaplasma* are treated with 7 days of doxycycline as for *Chlamydia*, but they have a cure rate of 31%. Azithromycin is more effective, but resistance is rising.

PAINFUL BLADDER SYNDROME AND INTERSTITIAL CYSTITIS

Painful bladder syndrome is a more global definition adopted by the International Continence Society to deal with patients with pain syndromes of the lower urinary tract without evidence of bladder pathology or infection. By definition, painful bladder syndrome (PBS) is the complaint of suprapubic pain related to bladder filling accompanied by other symptoms, such as daytime frequency and nocturia, in the absence of proven UTIs or other pathology. Interstitial cystitis (IC) is a complex, painful bladder condition that may be the same entity as PBS or may be at the far end on the severity spectrum. There is no consensus on how to define this condition. They will be referred to together as PBS-IC or individually, according to research study definition. The cause and pathophysiology are poorly understood but are most likely multifactorial. Theories regarding cause include an altered bladder epithelial permeability, mast cell activation, and an up-regulation of sensory afferent nerves. Studies have found that C fiber bladder afferent neurons have changes in their electrical and chemical properties affecting bladder sensitivity. It is a common syndrome, seen in women more often than men, but the actual incidence is unknown, although it has been estimated to be as high as 500/100,000 women.

The most common symptoms of PBS-IC are bladder-pelvic pain, urgency, daytime frequency, and nocturia, without evidence of infection or other causes. A common feature that may distinguish PBS-IC from other conditions is increase in pain with bladder filling and relief with voiding. The so-called *urethral syndrome* is poorly characterized and has largely been abandoned. The International Continence Society standardization report in 2002 added a new genitourinary pain syndrome category and defined urethral pain syndrome as the “occurrence of recurrent episodic urethral pain usually on voiding, with daytime frequency and nocturia, in the absence of proven infection or other obvious pathology.” This problem may be part of the PBS-IC group. Several symptom indices are useful for evaluating women with painful bladder complaints, although they were not developed for screening. The pain, urgency, frequency (PUF) scale (Table 21.4) and O’Leary-Sant scale are helpful in characterizing a woman’s complaints, especially in light of the lack of definitive diagnostic testing. There is much overlap in PBS-IC symptomatology. It is often confused with other bladder conditions such as UTIs, overactive bladder, and urethral syndrome (an outdated term, but it may be part of the spectrum of the syndrome). The differential diagnosis also includes several gynecologic conditions such as pelvic inflammatory disease, vulvodynia, and endometriosis. Dyspareunia is also a common

Table 21.4 Pelvic Pain, Urgency, Frequency (PUF) Patient Symptom Scale

Question	POINTS					Score
	0	1	2	3	4	
1. How many times do you go to the bathroom during the day?	3-6	7-10	11-14	15-19	20 +	
2. a. How many times do you go to the bathroom at night?	0	1	2	3	4 +	
b. If you get up at night to go to the bathroom, does it bother you?	Never	Occasionally	Moderate	Severe		
3. Are you currently sexually active? Yes/No						
4. a. If you are sexually active, do you now or have you ever had pain or symptoms during or after sexual intercourse?	Never	Occasionally	Usually	Always		
b. If you have pain, does it make you avoid sexual intercourse?	Never	Occasionally	Usually	Always		
5. Do you have pain associated with your bladder or in your pelvis (vagina, labia, lower abdomen, urethra, perineum)?	Never	Occasionally	Usually	Always		
6. Do you still have urgency after you go to the bathroom?	Never	Occasionally	Usually	Always		
7. a. If you have pain, is it usually mild, moderate, or severe?		Mild	Moderate	Severe		
b. Does your pain bother you?	Never	Occasionally	Usually	Always		
8. a. If you have urgency, is it usually mild, moderate, or severe?		Mild	Moderate	Severe		
b. Does your urgency bother you?	Never	Occasionally	Usually	Always		
Total Score:						

complaint in sexually active women and in women with PBS-IC. PBS-IC should be considered in the differential diagnosis of any woman with chronic pelvic pain.

A urinalysis, urine culture, and postvoid residual urine are recommended. A voiding diary will often demonstrate frequent small voids of less than 150 mL each and as many as 20 or more voids daily. Sleep can be disrupted by a frequent need to void. On examination, suprapubic and anterior vaginal wall tenderness may be found. Other assessments might include cytology (tobacco use), imaging, cystoscopy, and or laparoscopy. These are not needed to make the diagnosis. Cystoscopy may be needed to rule out other conditions. On cystoscopy, the bladder frequently appears normal during filling but, with distention under anesthesia, characteristic petechial hemorrhages resembling glomeruli usually appear. Oozing of blood is often seen. However, glomerulations may be a nonspecific finding because they can be seen in asymptomatic women. This cystoscopic finding is not diagnostic of IC, although it is used to differentiate IC from PBS in some studies. Hunner ulcers are diagnostic of IC but are infrequently seen in women with bladder pain. If a biopsy under anesthesia is taken, ulcers with granulation tissue, mucosal hemorrhage, monocytic infiltration, and mast cells in the lamina propria and detrusor muscle are often seen. Parsons has proposed that these changes are related to a defective or altered glycosaminoglycan mucus layer, which results in altered bladder permeability (Parsons, 1994). However, investigations to date have not shown whether this alteration is cause or effect. Some authors believe that these changes are the result of an autoimmune disease. The presence of immunoglobulins and complement in the bladder wall and the increase in interleukin-6 level in patients' urine may support this finding. Naturally occurring feline interstitial cystitis (FIC) shows changes in electrical currents that control neuronal excitability in sensory neurons.

To date, there is no laboratory test or urine test that is diagnostic of IC. Although urodynamic testing may reveal that these patients have early first sensation to void and low bladder

capacities, there is no range in volume that is specific for IC. The potassium sensitivity test (PST) involves inserting a catheter into the bladder and instilling a saline solution, followed by a potassium chloride solution. A positive PST result is noted if increased pain occurs with the potassium solution. Current recommendations do not support using the PST for diagnosis of PBS-IC (Hanno, 2015), and it can be very painful for women.

Many treatments are available, but few have been uniformly helpful. A multipronged treatment strategy is often necessary including behavioral changes, oral medications, bladder instillations, and other surgical treatments (Hanno, 2015). Women are encouraged to see this as a chronic problem that is not malignant and to try to reduce stress, work on general management strategies, encourage family support, and avail themselves of the writings and support of the Interstitial Cystitis Association. Women should be instructed to avoid acidic, alcoholic, and carbonated beverages, spicy foods, coffee, tea, chocolate, tomatoes, vinegar, and artificial sweeteners, all of which have been associated with increased pain in patients with PBS-IC. Tobacco should also be avoided. Bladder retraining to increase the interval between voiding may help. Pelvic floor physical therapy that emphasizes relaxation techniques also can be of benefit in woman with increased pelvic floor muscle tone and tenderness.

A heparin analogue, pentosan polysulfate sodium (PPS, Elmiron), has been given orally 100 mg three times daily, with some reported improvement. PPS is the only FDA-approved oral drug for IC and may help repair the glycosaminoglycan layer of the bladder epithelium. It can take 6 months to be effective and improvements are modest; 38% of patients have a more than 50% improvement at 12 weeks. Tricyclic antidepressants may also be helpful because they can inhibit the neural activation that leads to pain. Amitriptyline is not FDA-approved for IC, but doses of 10 to 75 mg nightly have produced pain relief in two thirds of women and decreases in urgency and frequency. Unfortunately, in another trial, when reviewing all randomized subjects, amitriptyline with education and behavioral modification

did not significantly improve symptoms. However, in this study, it was found that amitriptyline may benefit those who can tolerate a daily dose of 50 mg or more, although this subgroup comparison was not specified in advance. Women with PBS-IC often have trouble sleeping from the pain and nocturia and amitriptyline has anticholinergic effects to potentially reduce urgency/frequency, so taking amitriptyline at bedtime might be helpful for other reasons. The side effects of sedation, dry mouth, and constipation are often bothersome. Antihistamines such as hydroxyzine may be of benefit for patients with concurrent allergies and for decreasing mast cell degranulation, but most studies have not shown benefit. Depression treatments and antidepressants may be useful in depressed women. General chronic pain medication treatments might be of use.

Bladder instillations with various solutions have been tried. FDA-approved therapy includes dimethyl sulfoxide (DMSO) bladder instillation. DMSO is an anti-inflammatory agent that acts as a bladder anesthetic, relaxes muscles, causes mast cell inhibition, and may dissolve collagen. Many other drugs have been instilled, including heparin, lidocaine, steroids, and oxybutynin, but trials are insufficient to show a benefit. With pain flares, heparin and lidocaine may be of benefit (though not FDA approved).

Hydrodistention of the bladder under anesthesia is therapeutic in 20% to 30% of patients and is sometimes done at the initial evaluation when performing cystoscopy to rule out other pathology. However, most experts do not use hydrodistention as a diagnostic criterion any longer because the findings of glomerulations are nondiagnostic. If Hunner ulcerations are seen, they can be treated. Three to 6 months of symptom improvement occurs with distention in responders.

Hormonal suppression in premenopausal women with menstrual flares may provide benefit. There are additional fourth- and fifth-line therapies to be tried if the basic strategies have not been successful, including neuromodulation and intradetrusor Botox injections. Because PBS-IC is a complex disease, it is best treated by an experienced physician with the expertise and patience to deal with the woman and her needs over a prolonged period. Usually, multiple interventions are necessary, with a combination of behavioral changes, pelvic floor physical therapy, counseling, oral medications, and bladder instillations.

URETHRAL DIVERTICULUM

Causes

Urethral diverticulum is an outpouching of the urethral mucosa, usually into the vaginal tissues. Urethral diverticula occur in perhaps as many as 1% to 5% of all women at some time during their lifetime. Age distribution in published reports ranges from 19 to 76 years, but most diverticula seem to occur between the ages of 20 and 60 years. The disease occurs more frequently in black women than white women, with a ratio perhaps as high as 3:1.

A variety of causes have been suggested, including congenital, acute and chronic inflammatory, and traumatic. The congenital theory stems from the fact that rare cases have been reported in children and neonates. Most are likely acquired, however. Evidence for acute and chronic infection comes from observations noting infection and obstruction of the periurethral glands, which result in the formation of retention cysts that

when repeatedly infected, may rupture into the lumen of the urethra and remain as an outpouching, giving rise to the diverticulum. Several authors have suggested that the gonococcus is the cause of this condition, but *E. coli* and other organisms have been found in such processes. Urethral trauma from multiple catheterizations or from childbirth has also been suggested as a causative factor. However, many women with diverticula have neither been catheterized nor given birth.

Symptoms and Signs

The classic description of symptoms in a woman with urethral diverticula includes the three Ds: postvoid dribbling, dysuria, and dyspareunia. More common are complaints of postvoid dribbling and the finding of an anterior vaginal wall mass. Urinary frequency and urgency, dysuria, history of recurrent UTIs, dribbling, urethral or vaginal pain, and incontinence symptoms occur and more often will suggest other etiologies. Occasionally, hematuria occurs or stones are found in the diverticula or discharge or pus come from the urethra. Most occur in the middle or distal urethra posteriorly. There may be more than one present, and complex diverticula can even encircle the urethra or be horseshoe shaped.

Diagnosis

Diagnosis is generally suggested by physical examination. The distal anterior vaginal wall overlying the urethra or bladder neck may be tender, or a cystic mass may be found about the distal or midurethra. Pus, blood, or cloudy urine may be expressed as the urethra and mass are massaged. A normal examination and nonclassic symptoms are often typical of how a woman presents, which is why the diagnosis is often delayed. Historically, the double-catheter balloon technique, which essentially closes the urethra at each end and forces contrast medium into the diverticulum under pressure during cystography, has been the gold standard. Now, magnetic resonance imaging (MRI) with cross-sectional imaging offers the most detailed anatomic study; it can also image diverticula that do not communicate with the urethra, as well as multiple outpouchings. Other tests are sometimes useful, such as urethroscopy, voiding cystourethrography, urodynamics (because 35% to 50% will have incontinence), and transvaginal ultrasound.

Treatment

No treatment is indicated for asymptomatic urethral diverticula. Mild symptoms of frequency and urgency can be treated with anticholinergics and infections with antibiotics. Carcinoma has been reported in diverticula, so caution is needed if no surgical therapy is planned. A variety of procedures have been suggested for the management of urethral diverticula. Lapidus has suggested a technique for transurethral marsupialization that involves the resection of the roof of the diverticulum using transurethral electrocautery (Lapidus, 1978). Essentially, this technique enlarges the orifice of the diverticulum by incising its roof; however, the orifice can be challenging to identify or not found at all. Others have reported a marsupialization technique in which the diverticulum was opened and sutured to the vaginal epithelial surface. Generally, this leads to a fistula and requires secondary closure, making this technique useful in only rare circumstances and with distal diverticulum. Transvaginal diverticulectomy is the more common procedure.

Urethroscopy occasionally identifies the location of the diverticulum and careful inspection may show multiple diverticula. One study noted the diverticulum coming from the distal third of the urethra in only 10 of 85 patients, whereas 38 patients demonstrated an origin from the middle third and 13 from the proximal third, including the bladder neck (Lee, 1983). Lee noted multiple diverticula in 18 of 85 patients.

After the diverticulum is identified and evaluated, an incision is made in the anterior vaginal wall and the diverticulum is dissected free of the pubocervical connective tissue. The diverticulum's neck is noted and excised by sharp dissection, and the urethral wall is closed with a row of interrupted 4-0 polyglycol sutures. The closure line is generally in the longitudinal axis. Occasionally, however, a transverse closure is necessary because of the nature of the attachment. The pubocervical connective tissue is then reinforced with a row of 3-0 polyglycol reabsorbable interrupted sutures with attempt to avoid overlapping suture lines. Hemostasis is scrupulously secured with electrocautery, and the vaginal incision is closed with polyglycol sutures (Fig. 21.12).

Most diverticula emanate from the ventral wall of the urethra. Occasionally, however, the diverticulum is noted to be arising from the lateral wall of the urethra or even from the anterior wall. In these cases, the dissection must be carefully carried to

the base of the diverticulum and the procedure carried out as stated. In all cases, a 16 French Foley or suprapubic catheter is left in place for 7 to 14 days. Postoperative voiding cystourethrogram can be performed to ensure that there are no urethrovesical fistulas before discontinuing use of the catheter.

Several nuances have been offered to make dissection and subsequent repair easier. One involves placing a ureteral catheter into the diverticulum and allowing it to coil so that the diverticulum is more easily observable during dissection. Some surgeons have attempted to dilate the neck of the diverticulum before beginning the excision and, occasionally, have even tried to pack foreign substances such as gauze through the neck to make the dissection easier. Sometimes, a Martius flap is brought into the field between the periurethral connective tissue closure and vaginal wall. This is thought to prevent fistula formation and is more commonly done with recurrent diverticulum.

Complications

Major complications of this procedure include urethrovaginal fistula formation, development of stress urinary incontinence, recurrence of the diverticulum, missing diverticula when multiple diverticula are present, and stricture of the urethra. Reported urethrovaginal fistula rates are 5% to 8.3%. If the diverticulum recurs

Figure 21.12 Resection of Urethral Diverticulum. **A**, Diverticulum exposed with vaginal lining and endopelvic fascia retracted. **B**, Fingers hold diverticulum on traction, which aids in dissection and identification of ostium. **C**, After complete resection of the diverticulum, the urethra is closed with fine, interrupted extramucosal sutures. (Modified from Lee RA. Diverticulum of the female urethra: postoperative complications and results. *Obstet Gynecol.* 1983;61:52-58.)

within the first few months after operation, it may represent a second diverticulum that was overlooked or an inappropriate repair of the diagnosed diverticulum. If the diverticulum occurs after 1 year, it is probably a new lesion. Stricture of the urethra has been reported less than 5% of the time. After diverticulectomy, recurrence that requires repeat excision occurs about 10% of the time. Risk factors for recurrence included proximal diverticulum, multiple diverticula, and previous pelvic or vaginal surgery, excluding previous diverticulectomy. Some with recurrent diverticulum will have persistent pain or discomfort with urination and even with complete excision those symptoms can remain.

Stress incontinence development may be related to the dissection of the bladder neck and proximal urethra with injury to the urethral sphincter mechanism. If intrinsic sphincter deficiency results, the incontinence can be difficult to treat because of tissue compromise from repair.

UROLITHIASIS

Urinary tract stones, renal or ureteral, may occur in patients of both genders and at any age. Approximately 5% of women will develop a symptomatic stone by the age of 70 years. These may be related to metabolic abnormalities, such as gout or errors of calcium metabolism, but usually relate to chronic infection and stasis of urine. The leading risk factor for stones is genetic. Other risk factors for calculi in women include pregnancy, during which time the urinary tract becomes dilated and stasis is more common, a history of kidney stones or family history, certain medications, excessive vitamin C intake, low calcium intake, chronic diarrhea, and dehydration.

Symptoms occur most often when a stone passes from the kidney to the ureter. Pain occurs on the side of the stone and varies from a dull ache to severe paroxysms of pain, called *renal colic*. Flank pain, lower abdominal pain, and groin pain can occur; the location can vary as the stone moves down the ureter with radiation of pain to the groin. Gross or microscopic hematuria is usually present. Noncontrast CT scanning has become the gold standard for diagnosis, particularly if the abdominal radiograph is normal. Ultrasound misses small stones but is recommended for pregnant women and is increasingly recommended for initial screening as no radiation is used.

Various treatment modalities are available, including observation with pain medications and fluids awaiting spontaneous passage, endoscopic removal, surgical removal, and destruction of the stone with laser or shockwave lithotripsy. Although not FDA-approved, alpha-blockers may aid in passage of the stone. The principal consideration, however, should be correction of the basic problem that caused the stone. Urgent intervention is necessary if the woman has fever, chills, nausea and vomiting, and pain uncontrolled by narcotics. An obstructing stone in the presence of infection can be life threatening.

URINARY INCONTINENCE

RISK FACTORS

Box 21.2 lists the currently known risk factors associated with incontinence, summarizing the work of several authors. Some of the factors will be highlighted in this section. The

prevalence of urinary incontinence increases until approximately 50 years of age and then stabilizes before increasing again after age 65. Prevalence estimates were presented earlier in this chapter. One study compared risk factors and determinants of urodynamic stress incontinence between smokers and nonsmokers using a case-control method (Bump, 1994). In this study, 71 smokers and 118 nonsmokers were compared following a complete urogynecologic evaluation. Smokers were found to have stronger urethral sphincters and generated a greater increase in bladder pressure with coughing, but similar findings with respect to urethral mobility and pressure transmission ratios were found when compared with nonsmokers. Urodynamic stress incontinence developed in smokers despite their stronger urethral sphincter findings,

Box 21.2 Factors Independently Associated with Urinary Incontinence in Women

MODIFIABLE FACTORS	
Gynecologic	Medications
Cystocele	Diuretics
Uterine prolapse	Estrogen
Non-normal gynecologic examination	Benzodiazepines
Poor pelvic floor muscle contraction	Tranquilizers
	Antidepressants
	Hypnotics
	Laxatives
Urologic and Gastrointestinal	Other Factors
Antibiotics	Smoking
Recurrent urinary tract infections	High caffeine intake
Dysuria	Higher body mass index
Fecal incontinence	Functional impairment
Constipation	
Bowel problems	
Comorbid Diseases	
Diabetes	
Stroke	
Elevated systolic blood pressure	
Cognitive impairment	
Parkinsonism	
Arthritis	
Back problems	
Hearing and visual impairment	
NONMODIFIABLE FACTORS	
Gynecologic Factors	Other Factors
Hysterectomy in older women	Age
Prolapse surgery	White race
	Higher education
	Childhood enuresis
	Presence of two or more comorbid diseases
Pregnancy-Related Factors	
Vaginal delivery	
Forceps delivery	
Cesarean section	
Increased parity	
Fetal birth weight	

From Holroyd-Leduc JM, Straus SE. Management of urinary incontinence in women: clinical applications. *JAMA*. 2004;291(8):996-999.

probably because of more violent coughing leading to earlier development of anatomic defects.

Another area of interest involves racial and ethnic differences with respect to the presence of urinary incontinence. Black women with urinary incontinence have a different distribution of symptoms and different reasons for their incontinence than white women. Black women had a significantly lower prevalence of pure urodynamic stress incontinence than white women. The findings may possibly relate to differences in collagen and connective tissue. Several other studies have found a higher prevalence of urinary incontinence in non-Hispanic white women and Mexican-American women compared with rates in Asian and black women, although at least two studies have found no difference between racial or ethnic groups.

Obesity has a strong association with incontinence and, for every five-unit increase in body mass index, the risk increases. Depression and anxiety are associated with incontinence. This has been further evaluated in overweight and obese women. These women reported a higher number of weekly incontinence episodes than women without depressive symptoms, as well as more bothersome symptoms and poorer quality of life (Melville, 2009).

Epidemiologic studies have suggested increased risk with hysterectomy but short-term clinical studies have not, so more research is needed to clarify this issue. Vaginal childbirth and higher fetal weight are risk factors in younger women, but the effect diminishes in older women, possibly because the neuromuscular decline with aging becomes a more important factor. The prevalence of incontinence is significantly higher for women in nursing homes and women with cognitive impairment and poor mobility.

STRESS URINARY INCONTINENCE

Stress urinary incontinence is the involuntary loss of urine with physical exertion such as exercise, cough, or sneeze. When urine leakage is observed during a urodynamic study, with an increase in intraabdominal pressure and without a detrusor contraction, it is called *urodynamic stress incontinence* (Haylen, 2010). Stress urinary incontinence is a common condition for which nearly 14% of women in the United States will undergo surgery at some point (Wu, 2014).

Injury, particularly trauma from obstetric delivery, has been implicated in stress incontinence. The odds ratio of stress urinary incontinence in parous compared with nulliparous women is threefold (Hansen, 2012); the odds ratio after vaginal compared with cesarean delivery is twofold (Lukacz, 2006). Meyer and colleagues studied 149 patients during pregnancy and 9 weeks postpartum. They found that 36% of women who were delivered by forceps and 21% who delivered spontaneously suffered from urinary incontinence (Meyer, 1998). Bladder neck mobility was significantly increased after all vaginal births, but bladder neck position at rest was only lowered in the forceps group. Women who underwent cesarean delivery were unaffected. DeLancey and coworkers have reported MRI images showing levator ani injuries in 10% to 15% of primiparous women (DeLancey, 2003). These injuries may lead to later pelvic floor dysfunction and incontinence, although long-term follow-up studies are needed (Fig. 21.13). Considering other forms of pelvic floor trauma, Nygaard studied female American Olympic athletes and could not find a difference between the low-impact (swimmers) and high-impact (gymnasts, track and field performers) athletes with respect to the development of stress incontinence later in life (Nygaard, 1997).

Figure 21.13 Axial magnetic resonance imaging scan at the level of the midurethra in a normal nullipara (*left*) and a woman 9 months after vaginal birth (*right*) in whom the pubovisceral portion of the levator ani muscle has been lost. The pubovisceral muscle (*) is seen between the urethra (U) and obturator internus (OI) muscle in the normal woman but is missing in the woman on the right. R, Rectum; V, vagina. (From DeLancey JO, Ashton-Miller JA. Pathophysiology of adult urinary incontinence. *Gastroenterology*. 2004;126[Suppl 1]:S23-S32.)

Evaluation

Urethral support and coaptation are both important for maintaining continence. DeLancey's hammock theory suggests that the urethra is supported by the endopelvic fascia and anterior vaginal wall (DeLancey, 1994). Because that support layer is attached to the pelvic wall via the arcus tendineus fascia pelvis and levator ani, the urethra is compressed by increases in abdominal pressure. This maintains urethral pressure above bladder pressure and prevents urinary leakage (Fig. 21.14). Urethral hypermobility, which can be measured using a "Q-tip test," corresponds to the loss of the backstop support at the bladder neck. The Q-tip test involves placing a cotton swab into the urethra to the bladder neck and observing the angle that the urethra makes with the horizontal during a strain maneuver. A large excursion from the horizontal suggests defects in the supports of the urethra but not a specific urologic diagnosis. However, this angle is useful for deciding on an appropriate anti-incontinence procedure because midurethral slings act by providing resistance to a hypermobile urethra during increases in intraabdominal pressure, whereas urethral bulking agents are not affected by urethral movement and may be more appropriate for some women with stress incontinence. These are discussed in the "Intrinsic Sphincter Deficiency" section of the chapter. A maximum Q-tip excursion angle greater than 30 degrees suggests hypermobility and is associated with higher success rates after midurethral sling surgery. Women with stress incontinence without urethral hypermobility have a 1.9-fold risk of failure after midurethral sling and may be better served by a urethral bulking agent, which improves urethral coaptation at rest and during strain (Richter, 2011). Urethral mobility can also be evaluated using the prolapse quantification system, visualization, palpation, or ultrasonography.

Figure 21.14 Lateral view of the components of the urethral support system. Note how the levator ani muscles support the rectum, vagina, and urethrovesical neck. Also note how the endopelvic fascia next to the urethra attaches to the levator ani muscle; contraction of the levator muscle leads to elevation of the urethrovesical neck. (From DeLancey JO, Ashton-Miller JA. Pathophysiology of adult urinary incontinence. *Gastroenterology*. 2004;126[Suppl 1]:S23-S32.)

Urethral coaptation is affected by the urethral mucosa and vasculature, adjacent connective tissue structures, striated and smooth muscles, and involuntary and voluntary muscles that contract in response to stress. Midurethral sling and urethral bulking agents will be discussed in more detail in the Surgical Management section.

Stress incontinence may occur with injury to or degeneration of the urethral support system or urethral sphincter mechanism, and it is likely that most women with incontinence have elements of both problems. Although we try to classify women with stress incontinence as having urethral hypermobility or the more severe leakage associated with urethral musculature damage, termed *low-pressure urethra* or *intrinsic sphincter deficiency* (ISD), there is actually great overlap. The diagnosis of ISD is somewhat debatable but is given to women with low Valsalva leak point pressures or low maximum urethral closure pressures measured during urodynamics. These women may have more severe continence, and the diagnosis of ISD is also associated with higher failure rates after midurethral sling surgery as well (Nager, 2011).

Bladder neck funneling, position, and hypermobility can be evaluated by perineal ultrasound. Although the clinical uses to date are limited, it is useful in studying the pelvic structures in continent and incontinent women, and it may have clinical applications in the future. Ultrasound examination of the urethral sphincter may also be helpful in measuring length, thickness, and striated muscle volume. Athanasiou and associates, using three-dimensional ultrasound, have shown that women with stress urinary incontinence have significantly shorter, thinner, and smaller volumes of striated muscle in their urethras than continent women of comparable ages and parity (Athanasiou, 1999).

Women with anterior vaginal wall prolapse often have urethral hypermobility but may or may not have stress incontinence. If they have stress incontinence, they must have some urethral sphincter compromise along with the hypermobility. It is also possible that the prolapse kinks off the urethra, thus maintaining continence, and that reduction of the prolapse will unmask occult stress incontinence. Prolapse reduction stress testing, in which the patient is asked to cough with a comfortably full bladder while the prolapse is reduced, can help predict which women are likely to have stress incontinence after prolapse surgery. A concurrent anti-incontinence procedure can be considered in these women.

Prior to performing surgery for stress urinary incontinence, the minimum evaluation includes complete history (including urologic history, medical history, medications), urinalysis (to exclude urinary tract infection), physical examination that includes vaginal inspection and prolapse evaluation), demonstrable urinary leakage with a cough stress test, an evaluation of urethral mobility, measurement of postvoid residual volume (it should be less than 150 mL) (ACOG, 2014). This is sufficient for patients with uncomplicated stress incontinence. Multichannel urodynamic testing should be reserved for women with complicated stress incontinence, such as unclear diagnosis, large urge component, or prior anti-incontinence surgery. Inquiring about a woman's goals for treatment of stress incontinence is useful, as is identifying the most bothersome aspects of her complaints. All women should be offered conservative treatments first, and then surgery can be pursued if she fails or declines nonoperative treatments.

Treatment

Conservative Management: Pelvic Floor Muscle Strengthening

Conservative measure should be discussed and offered to all women with stress incontinence (Box 21.3). The first-line treatment is pelvic floor muscle training directed toward the strengthening of the levator ani and pubococcygeal muscles, which affect the urethral closure mechanism. This can be affected by isometric exercises, as described by Kegel. The woman can be instructed on how to contract these muscles by being told to attempt to stop the urinary stream while she is voiding. Importantly, after she learns which muscles to contract, she should perform the exercises at other times without any relationship to voiding because contracting her pelvic floor muscles during voiding could lead to voiding dysfunction. Pelvic muscle exercise success is improved with specific training by a health professional or physical therapist. Improvement in the muscular supports may be enough to overcome the anatomic weakness that originally led to the stress incontinence.

Although these exercises have a number of modifications, one useful application is to teach the woman to contract these muscles slowly, 8 to 12 times, for a count of 6 to 8 seconds each, and to repeat this series for three sets daily. A meta-analysis of 12 randomized controlled trials found that at least 24 contractions a day for 6 weeks resulted in decreased incontinence episodes; more contractions did not result in additional improvement (Choi, 2007). Better efficacy was noted in younger women with stress incontinence than older women and women with mixed or urgency incontinence.

A Cochrane Database review of pelvic floor muscle training analyzed 21 trials involving 1281 women (Dumoulin, 2015). Women who did pelvic floor muscle training were 8 times more likely to be cured and 17 times more likely to be cured or improved compared with the control group. These exercises helped women with all types of incontinence. Again, the women with stress incontinence enjoyed more benefit. With no serious adverse effects, pelvic floor muscle training should be offered as a first-line conservative management program for women with urinary incontinence.

Many patients enjoy prolonged relief, even after stopping pelvic floor muscle exercises. Bø and Talseth studied 23 women who participated in a 6-month intensive pelvic floor muscle exercise routine and noted that 5 years later, 75% demonstrated no leakage during a stress test and 70% were satisfied with their continence (Bø, 1996). Of these patients, 70% were still exercising their pelvic muscles at least once weekly and demonstrated pelvic floor muscle strength. Nygaard noted similar findings (Nygaard, 1996). These authors noted improvement of incontinence, not only in patients with stress incontinence but also in those with urge and mixed urinary incontinence.

It is important to ensure that the woman is aware of how to perform the exercises correctly. In a study by Bump and

coworkers in which 47 women were given simple verbal or written instructions, 23 (49%) had an ideal Kegel effort signified by an increase in force of the urethral closure. However, 12 subjects (25%) were performing the technique poorly and in such a way that incontinence might be promoted (Bump, 1991). The authors recommended a demonstration approach rather than a written or verbal approach.

A variation in pelvic muscle training is the use of weighted vaginal cones. This involves a set of cones of increasing weight that require pelvic muscle contraction to hold them within the vagina. Peattie and associates demonstrated an improvement in 70% of 30 premenopausal women with stress incontinence after only 1 month of exercise. A correlation was noted between decreased urine loss and the ability to retain cones of increased weight (Peattie, 1988).

Pelvic floor electrical stimulation has also been studied for improving pelvic floor muscle strength and decreasing symptoms of stress incontinence. A small, removable vaginal probe is placed in the vagina or anus and the electrical stimulation activates a pelvic muscle contraction. A randomized controlled trial by Goode and colleagues studied 200 women with stress incontinence and found that pelvic floor electrical stimulation did not increase effectiveness in a comprehensive behavioral training program (Goode, 2003).

Conservative Management: Pessaries

An incontinence pessary is a silicone ring device with a knob placed in the vagina, with the goal of stabilizing the urethra to eliminate hypermobility and increase urethral pressure during increases in intraabdominal pressure. This is a safe and effective conservative treatment (Richter, 2010b). The FemSoft urethral insert device (Rochester Medical, Stewartville, MN) is basically a urethral plug. Although women with stress incontinence may have greatly reduced leakage when wearing the insert, it is not popular because a new device needs to be placed after each void. Occasionally a woman who leaks only with vigorous exercise may choose to use this insert during her workout, but often a pessary can be used instead. Figure 21.15 shows each of these devices.

Conservative Management: Weight Loss

Weight loss in overweight and obese woman significantly reduces urinary leakage, as shown in a 2009 randomized controlled trial of 338 women (Subak, 2009). A 6-month behavioral intervention for weight loss included diet, exercise, and behavioral modification and was compared with a control group that received structured education not related to weight loss. The women in the intervention group lost 8% of their body weight (7.8 kg) compared with 1.6% (1.5 kg) in the control group. Incontinence episodes declined by 47% and 28%, respectively ($P = .01$), but this was only for stress incontinence, not urge incontinence.

Conservative Management: Others

In postmenopausal women, estrogen therapy was thought to increase the vasculature and mucosal seal of the urethra, thereby increasing urethral closing pressure and overcoming the effects that may have led to mild degrees of stress incontinence. However, randomized studies have called into question these effects and, in fact, the opposite effect

Box 21.3 Methods of Pelvic Muscle Strengthening

- Kegel exercises
- Biofeedback
- Isometric with vaginal cones (weights)
- Electrical stimulation of pelvic floor

has been shown. The Heart and Estrogen/Progestin Replacement Study (HERS) found the women taking combined hormone replacement actually reported worsened incontinence (Grady, 1998). Both the Women's Health Initiative (WHI) and Nurses' Health Study also found increased risk of incontinence; the WHI found that the risk was greatest for stress incontinence. Oral estrogen is no longer advised for stress incontinence. (See [Estrogen and the Lower Urinary Tract](#), presented later in the chapter.)

Other non-FDA-approved drugs and combinations of drugs have been studied to determine whether pharmacologic therapy can aid stress incontinent women. Imipramine, a tricyclic antidepressant, has α -adrenergic enhancement characteristics. Its action

on the α receptors in the bladder neck and urethra may cause muscle contraction and could theoretically lessen stress incontinence. However, imipramine has limited benefit for treating stress incontinence, and there is weak evidence to suggest that any adrenergic drugs are better than placebo treatment.

Duloxetine is not FDA approved for treating stress incontinence in the United States but has been approved in Europe. Duloxetine is a serotonin and norepinephrine reuptake inhibitor that stimulates pudendal motor neuron activity in Onuf's nucleus in the spinal cord and causes rhabdosphincter contraction in the urethra. Several large randomized trials have compared duloxetine to placebo, but reduction in incontinence is modest, and cure rates are no different than placebo. Nausea is a frequent side effect. For a woman considering treatment for depression, who also has bothersome stress incontinence, duloxetine is a reasonable medication to consider. [Table 21.5](#) summarizes classes of other agents that may affect urinary function.

Surgical Management

Hundreds of surgical procedures have been developed to treat stress incontinence. Today, the most commonly performed surgeries for stress incontinence are midurethral slings with synthetic mesh. These are more or as effective as other surgeries and have decreased morbidity. Before describing midurethral slings in detail, a historical review of surgeries developed to treat stress incontinence. Familiarity with these procedures is necessary because these women often present with recurrent stress incontinence. Scarring in the vagina and retropubic space can increase the risk of complications, particularly bladder injuries, from subsequent surgeries for stress incontinence.

Before the 1950s, the operative approach to treat stress incontinence primarily involved the plication of the bladder neck (Kelly plication procedure) with anterior colporrhaphy to reduce a cystocele via a vaginal approach. Published studies have demonstrated that retropubic urethropexy operations have a higher

Figure 21.15 Incontinence ring pessary and FemSoft urethral insert.

Table 21.5 Drugs with Possible Effects on the Lower Urinary Tract

Class	Possible Side Effects	Drug and Usual Indication	Action
Antihypertensives	Incontinence	Reserpine, hypertension Methyldopa, hypertension Angiotensin-converting enzyme inhibitors Alpha 1-blockers	Pharmacologic sympathectomy by depleting catecholamines Side effect of cough—may worsen stress incontinence Decreased urethral sphincter tone
Dopaminergic agonists	Bladder neck obstruction	Bromocriptine, galactorrhea Levodopa, Parkinson disease	Increased urethral resistance, decreased detrusor contractions
Cholinergic agonists	Decreased bladder capacity and increased intravesical pressure	Digitalis, cardiotropic	Increased bladder wall tension
Neuroleptics	Incontinence	Major tranquilizers: prochlorperazine, promethazine, clozapine, trifluoperazine, chlorpromazine, haloperidol	Dopamine receptor blockade, with internal sphincter relaxation or decreased contractility from anticholinergic effects or mixed effects
β -Adrenergic agents	Urinary retention	Isoxsuprine, vasodilator Terbutaline, bronchodilator	Inhibited bladder muscle contractility
Estrogen orally	Incontinence		Worsens stress and mixed urinary incontinence
Xanthines	Incontinence	Caffeine	Increased contractility or rate of emptying Decreased urethral closure pressure
Alcohol	Frequency, urgency		Sedation and immobility may inhibit ability to recognize urgency

cure rate than anterior colporrhaphies for stress incontinence when the patients are followed long term (Bergman, 1995; Harris, 1995). Anterior colporrhaphy has been largely abandoned as a surgical procedure for treating stress incontinence.

Transvaginal needle suspensions (TVNSs) were introduced in the late 1950s as a less invasive alternative to retropubic operations. Special needles were developed by Pereyra in 1959 that could be used to guide sutures from the paravaginal tissue through the space of Retzius to be suspended from the rectus fascia, just above the bladder neck. This was carried out through small suprapubic and vaginal incisions. Stamey's 1973 modification of the Pereyra procedure used a small tube of Dacron material to buttress the suture and prevent it from pulling through the rectus fascia. Many other modifications of TVNS have been described.

Several national and international organizations convened and reviewed the long-term success rates of incontinence operations when it became apparent that TVNS held up poorly after 2 to 3 years. Consensus statements suggested slings and retropubic suspensions have more durable results than TVNS or anterior repair for stress incontinence. Like anterior repairs, TVNS have rapidly declined as a primary treatment option for stress incontinence.

Before midurethral synthetic slings for woman with stress incontinence were popularized, the two most common surgeries were suprapubic urethropexies and pubovaginal bladder neck slings. The Marshall-Marchetti-Krantz suprapubic urethrovesical suspension operation was first reported in 1949 and for years was the mainstay of many surgeons attempting to alleviate stress incontinence in these patients. The space of Retzius is entered, the bladder neck is identified, generally with a 30-mL bulb Foley catheter in the bladder, and the paravaginal tissue adjacent to the bladder neck is identified and sutured to the pubic symphysis using two or three interrupted sutures on each side of the bladder neck. The surgeon must be careful not to place undue stress on the bladder neck (Fig. 21.16). A rare (1% to 2%) but painful complication of the Marshall-Marchetti-Krantz procedure is osteitis pubis. This condition is an inflammatory reaction in the

periosteum of the pubic bone that is more often associated with permanent suture material.

In 1961, Burch advocated a modification of the suprapubic bladder neck suspension by suspending the vaginal wall to Cooper's ligament, now referred to as a *Burch colpo suspension* or *Burch procedure* (Fig. 21.17). Polyglycol or nonabsorbable sutures are appropriate. At times, patients have difficulty voiding for prolonged periods, and the occasional woman may report that she needs to rise off the commode to a semistanding position to void.

Colombo and coworkers performed a prospective randomized clinical trial using the Burch and Marshall-Marchetti-Krantz procedures (Colombo, 1994). The follow-up was 2 to 7 years. They reported subjective and objective cure rates of 92% and 80%, respectively, for the Burch procedure and 85% and 65%, respectively, for the Marshall-Marchetti-Krantz procedure. These differences were not statistically significant. A 2005 Cochrane Database review of 39 trials of the Burch procedure noted that the success rate reported ranged from 85% to 90% at 1 year, and 70% were dry at 5 years (Lapitan, 2005). Follow-up urodynamic studies performed 10 years later in one study reported a surgical cure rate of 90.3%, but five of the seven patients who were considered failures thought that their symptoms had improved.

Pubovaginal slings are most commonly created with the patient's rectus fascia or fascia lata. Strips of fascia are then placed under the proximal urethra and attached to the abdominal wall to compress the urethra and decrease incontinence.

A 2007 multicenter randomized controlled trial compared 655 women assigned to have an autologous fascial sling or Burch procedure (Albo, 2007). At 24 months, the success rates were higher for women who had the fascial sling than the Burch procedure, 44% versus 38% ($P = .01$), using the strictest outcome criteria and 66% versus 49% ($P < .001$), respectively, if specifically considering stress incontinence outcomes. However, the fascial sling group had more complications with UTIs, voiding

Figure 21.16 Demonstration of the relative position of a pair of sutures adjacent to the urethra, securely placed into the pubic symphysis. (Modified from Buchsbaum HJ, Schmidt JD, eds. *Gynecologic and Obstetric Urology*. Philadelphia: WB Saunders; 1982.)

Figure 21.17 Burch Procedure. The lateral edges of the vagina have been sutured to Cooper's ligament. (Modified from Burch JC. Urethrovaginal fixation to Cooper's ligament for correction of stress incontinence, cystocele, and prolapse. *Am J Obstet Gynecol*. 1961;81:281-290.)

difficulty, and postoperative urge incontinence. The Burch procedure can also be performed laparoscopically. Saidi and colleagues reported comparable 12-month cure rates in 70 patients undergoing laparoscopic procedures (91.4%) and 87 patients undergoing open procedures (92%) (Saidi, 1998). The laparoscopic procedures had a somewhat shorter operative time and a much shorter hospital stay. Ross followed 48 consecutive patients who underwent laparoscopic Burch procedures and found a cure rate of 93% and 89% at 1 and 2 years, respectively, using multichannel urodynamic studies (Ross, 1998).

Surgical Management: Midurethral Slings

Tension-free midurethral slings using permanent mesh have become the most commonly used surgical procedures for stress incontinence. The first to be introduced was the retropubic tension-free vaginal tape sling (TVT). It was developed based on the theory that the tension on the pubourethral ligaments interacts with muscles of the pelvic floor and suburethral vaginal support structure. Ulmsten and coworkers published a 1996 article on 75 women treated with a midurethral sling made of permanent mesh (Fig. 21.18) (Ulmsten, 1996). The sling was placed under local anesthesia with sedation. A small vaginal incision was made under the midurethra. Small tunnels were made bilaterally to aid in passage of the trocar from the vaginal area through the retropubic space against the pubic bone, and exiting through abdominal skin punctures suprapubically. Cystoscopy was performed to evaluate for bladder perforation before the sling was brought into place. The sling was a monofilament polypropylene synthetic mesh, 1 cm wide and 40 cm long. An 84% cure rate was reported, an additional 8% were improved, and 8% failed. At 3 years after surgery, Ulmsten and colleagues reported an 86% cure rate.

Figure 21.18 Tension-free vaginal tape (TVT) sling with Prolene mesh placed midurethrally, without the need for fixation. (Courtesy of Gynecare, Ethicon, Somerville, NJ.)

Many other researchers worldwide have published similar success rates. Complications have included retropubic hematoma, bladder perforation, intraoperative bleeding, urinary retention, mesh exposure, and, rarely, bowel and urethral injuries. Ward, Hilton, and the UK and Ireland TVT trial group published a prospective randomized study comparing TVT with Burch colposuspension for primary urodynamic stress incontinence (Ward, 2004). With strict outcome data, the TVT procedure appears to be as effective as the Burch procedure at 2 years, with 63% and 51% cured by objective outcome data, respectively. The lower cure rates in this trial are likely because of the strict outcome criteria. Although the Burch procedure is often successful, the 2- to 3-day hospital stay, 4- to 6-week recovery, and additional risks are much less attractive than a short outpatient procedure (usually less than 30 minutes) with three small incisions and a 2-week recovery time. However, the placement of a permanent mesh has additional risks of mesh erosion and infection not seen with the Burch procedure.

Delorme introduced the transobturator tape (TOT) sling approach in 2001 with the hope of avoiding vascular, bladder, and bowel injuries (Delorme, 2001). TOT sling trocars traverse the obturator canal instead of the retropubic space and enter through small groin incisions at the level of the clitoris bilaterally. Delorme described an out-to-in passage through the obturator membrane along the inferior pubic ramus. Two years later, an in-to-out passage was described and touted to reduce urethral injury. Complications include bleeding, groin or leg pain, and urethral injuries. Objective and subjective cure rates were similar in a randomized trial comparing a TOT tape sling with a Burch colposuspension. In the largest multicenter randomized trial comparing retropubic TVT with TOT sling, 597 women were randomized, and 95% completed 12-month follow-up for treatment success analysis (Richter, 2010a). Objective treatment success required a negative cough stress test, negative pad test, and no retreatment. Objective success was 80.8% for the retropubic sling and 77.7% for a TOT sling; subjective success rates were 62.2% and 55.8%, respectively. Voiding dysfunction was significantly more common in the retropubic sling group (2.7% vs. 0%; $P = .004$). Neurologic symptoms of thigh and groin pain were higher in the TOT group (9.4% vs. 4%; $P = .01$). Because retropubic and transobturator midurethral slings have similar cure rates, the choice regarding which sling is appropriate for each patient is based on risks of complications and surgeon expertise. Either procedure can also lead to de novo development of urge incontinence, mesh erosion, mesh infection, or dyspareunia.

Single-incision mini-slings are the most recent permutation of the synthetic midurethral sling and were designed to avoid both the retropubic space and the groin by anchoring to the obturator membrane through a single vaginal incision. Meta-analyses comparing older versions of mini-slings suggested worse outcomes compared with full-length midurethral slings (Schimpf, 2014), but a more recent analysis that includes only newer mini-slings suggests comparable outcomes (Mostafa, 2014). Because they are newer to the market, there is less long-term data about them.

A 2012 review by the Society for Gynecologic Surgeons analyzed all 48 randomized controlled trials of slings with at least 12 months of follow-up (Schimpf, 2014). This group concluded that Burch and midurethral slings had similar cure rates, so the decision for one or the other should be based on minimizing risks. They recommended midurethral slings over pubovaginal

slings to optimize subjective cure rates, and, similar to studies referenced earlier, found similar success rates between full-length midurethral slings.

POSTOPERATIVE VOIDING TRIAL

It is usual postoperatively to check a woman for residual urine after she voids because she has a 24% chance of needing a catheter for temporary urinary retention after surgery (Richter, 2010a); after a retrograde fill of 300 mL, she should be able to void about 200 mL, and if not the catheter should be replaced for 1 to 3 days or the patient should be instructed on clean intermittent self-catheterization. The risk of continued catheterization is 6% 2 weeks after sling surgery and 2% after 6 weeks. In these circumstances, loosening or cutting the sling may be indicated. Voiding trials are discussed in more detail in Chapter 20.

URODYNAMICS

As discussed in the Evaluation section of this chapter, urodynamics are no longer routinely done before stress incontinence surgery in uncomplicated cases. Studies have questioned the role of urodynamics, particularly in women with straightforward stress incontinence, no urge incontinence, no voiding complaints, and no prior incontinence surgery. One study of a carefully selected group of women at low risk of voiding problems found that preoperative urodynamic studies did not predict postoperative voiding dysfunction or the risk of surgical revision in the pubo-vaginal sling group (Lemack, 2008). Another study reported that the level of Valsalva leak point pressure (VLPP) and presence of detrusor overactivity did not predict the success of a Burch colposuspension or an autologous fascial sling in women with pure stress incontinence. In women with straightforward, demonstrable stress urinary incontinence randomized to undergo preoperative urodynamics or not, outcomes at 1 year were not inferior in the group that did not undergo urodynamics (Nager, 2012).

RISKS OF MESH

Synthetic mesh is a permanent implant. In 2008, the U.S. Food and Drug Administration created a public health notification regarding complications from the transvaginal use of mesh for prolapse and incontinence (FDA, 2008). New data suggest that the risks from transvaginal mesh for prolapse is more of a concern than transvaginal mesh for incontinence, and so in 2011 the U.S. FDA advisory refers to prolapse only (FDA, 2011). Mesh complications from midurethral slings are uncommon but can include mesh erosions into the bladder or urethra, mesh exposures in the vagina, pain, dyspareunia, and rare complications such as severe infections. Despite the small risks associated with using a permanent implant, midurethral slings are the most studied anti-incontinence surgery in medical history and remain the most commonly performed surgeries for stress incontinence.

INTRINSIC SPHINCTER DEFICIENCY

In 1981, McGuire noted the loss of intrinsic urethral tone in a number of women, particularly those with a history of pelvic trauma, radiation, underlying neurologic conditions, or scarring of the urethral sphincter. This has been termed *intrinsic sphincter*

deficiency (ISD). Currently, the two types of stress incontinence, hypermobility and ISD, are thought to be interdependent and not separate entities. However, it is still useful to discuss severe stress incontinence in women with a fixed and poorly functioning urethra.

Sand and associates offered some insight into why at least some retropubic urethropexy procedures fail (Sand, 1987). In a study of 86 patients evaluated preoperatively and postoperatively with urodynamic studies, they noted that in women younger than 50 years, there was a significant risk of failure if the preoperative urethral closure pressure was less than 20 cm H₂O. Although low urethral closure pressure was found to be an independent risk factor in women younger than 50 years, it was not found to be the case in women older than 50. Horbach and Ostergard retrospectively evaluated 263 consecutive patients undergoing a complete urodynamic evaluation because of urinary leakage (Horbach, 1994). Intrinsic sphincter dysfunction was defined as maximum urethral closure of 20 cm H₂O or less in the sitting position at maximum cystometric capacity; 132 women (50.2%) were found to have intrinsic sphincter dysfunction. Women in this group tended to be older and more likely to have undergone a hysterectomy and at least one anti-incontinence procedure compared with women with continence problems who had normal urethral pressure. By multivariate analysis, it was noted that age older than 50 years was the only independent variable that could predict the presence of intrinsic sphincter dysfunction in women with stress urinary incontinence.

At present, treatment for urinary stress incontinence caused by ISD consists of one of the following: periurethral bulking substance injections, urethral bladder neck sling procedures in select woman, midurethral synthetic sling, or use of an artificial sphincter device. A number of substances have been used for periurethral bulking injections. These include the individual's blood or fat, polytetrafluoroethylene (Teflon), bovine collagen, silicone microspheres, and pyrolytic zirconium oxide. Injection of blood or fat has provided only transient relief, and the use of Teflon has resulted in several complications, primarily caused by wandering of the Teflon to distant sites. Glutaraldehyde cross-linked (GAX) collagen has been used as a urethral bulking agent. This is a bovine dermal collagen first used by Appell and colleagues, who reported a high success rate. It has a relatively high incidence of hypersensitivity reaction and therefore women should be skin-tested before its use. Without hypersensitivity, it appears to be a relatively safe and minimally invasive means of closing the urethra. It is currently not commercially available because no companies are producing it. It seems to have a positive effect for at least 2 years, and it is possible to reinject patients. Long-term follow-up has been disappointing, with a 26% success rate at 5 years. Part of the failure may be because collagen is biodegradable and not necessarily durable. Permanent materials of silicone microimplants and pyrolytic zirconium oxide beads have been studied. Short-term success rates have ranged widely from 33% to 60% for cure or improvement. No material has proved better than another. Nonetheless, for older unfit women and women who have failed other incontinence surgeries, an injectable material for stress incontinence may be an attractive option.

Midurethral synthetic slings have been studied for ISD. The differing definitions of ISD with urethral hypermobility versus a fixed nonmobile urethra have made comparisons difficult. In published trials of a retropubic midurethral sling with

hypermobility and a low maximum urethral closure pressure (MUCP), the low MUCP did not seem to affect the outcome. Reported cure rates range from 73% to 86%. One study with a 5-year follow-up found that 57% of the women were very satisfied, and another 17% had improved continence. In contrast, using a TOT approach in this circumstance resulted in more failures. In the setting of a fixed urethra, only 33% of women reported being cured of incontinence.

A variety of traditional sling procedures, including the use of fascia lata, anterior rectus fascia tissue, cadaveric fascia lata, and inert materials such as polyethylene terephthalate (Mersilene) mesh, can be used. These procedures mobilize the bladder neck, often by a vaginal or vaginal and abdominal approach, and allow the interposition of a strip of material under the proximal urethra surrounding the bladder neck, which is attached to the anterior rectus sheath. This creates support and compression to the urethra and prevents urethral movement during increased abdominal pressure. This procedure is generally effective in creating continence.

The surgeon must exercise care in determining the tension to be applied on the bladder neck when the sling is fixed. Making it too tight may interfere with voiding and may actually damage the bladder neck or lead to de novo development of urge incontinence; making it too loose will abrogate its effectiveness. Generally, with a “No.” 16 or 18 Foley catheter in the urethra, it should be possible for the surgeon to judge the tension so that the sling fits comfortably against the urethra without compressing it. Concomitant cystoscopy may also be used.

Many other reports using other sling materials have shown success rates (cure or improvement) of 86% to 92%, with complications of UTIs, urinary retention, and de novo development of urgency.

An anterior rectus sheath fascial sling procedure is now generally reserved for patients with intrinsic sphincter deficiency or women whose previous anti-incontinence procedure failed and have a fixed urethra, because midurethral slings do not work as well with a fixed urethra. Fascia lata slings have been used by many surgeons and can be performed mostly vaginally in a relatively short operative time. However, the woman then has a leg incision to harvest the fascia lata, which can be painful. Autologous fascia lata is more effective than irradiated and freeze-dried donor fascia lata, with the use of the latter type leading to a concern about graft degeneration and, thus procedure failure.

The use of the artificial urinary sphincter may be a viable option for some women and will generally produce continence. Artificial urinary sphincters are generally placed by abdominal and vaginal surgical approaches. The artificial sphincter consists of a cuff surrounding the urethra. The device is controlled by a pressure balloon placed in the space of Retzius. The woman controls the device by releasing pressure via a pump in the labia when she wishes to void and reestablishing pressure when she wishes to be continent. Diokno and coworkers reported a 91% success rate in 32 patients in whom they implanted the device in 1988. Their use has been limited by side effects including erosion and mechanical problems.

OVERACTIVE BLADDER

Overactive bladder (OAB) is defined as the symptom of urgency, with or without urge incontinence, usually with frequency and

nocturia in the absence of UTI or other pathology. Urgency is the complaint of a sudden compelling desire to pass urine, which is difficult to defer. Urge incontinence is the complaint of involuntary leakage of urine accompanied by or immediately preceded by urgency. This condition is generally chronic and may wax and wane, but it is slowly progressive and associated with an urgency-frequency problem that is often accompanied by painless, involuntary urine loss. Generally, a large volume of urine is lost; leakage may occur in any position and often with a change in position. Rarely, an event usually associated with stress incontinence, such as coughing, will trigger this urge incontinence, but it is generally delayed until seconds after the stress has occurred. Large-volume urine loss is more characteristic of urge incontinence compared with stress incontinence. Stress incontinence frequently disappears when recumbent, but urge incontinence continues, often with nocturia. Table 21.6 summarizes the differences in symptoms. OAB occurs in approximately 17% of the population and the incidence increases with age. OAB patients have a lower quality of life than women with stress incontinence. Differential diagnoses include urinary tract pathology, PBS-IC, polydipsia, polyuria, nocturnal polyuria, and medical conditions that are associated with nocturia (vascular or sleep disorders).

Detrusor overactivity is a urodynamic observation; it is the result of sudden, spontaneous detrusor contraction. It has previously been termed *detrusor dyssynergia*, *unstable bladder*, or *detrusor instability*. The term *idiopathic detrusor overactivity* is used as a urodynamic definition when there is no defined cause of the condition. If a neurologic disorder, such as stroke, Parkinson disease, multiple sclerosis, spinal cord injury, or other CNS pathology is present, the term *neurogenic detrusor overactivity* is appropriate. In older women, urgency and incomplete bladder emptying can coexist. Dribbling often results. This condition is termed *detrusor hyperactivity with impaired contractile function* (DHIC), and these two conditions may have different causative factors.

The loss of urine in OAB is probably triggered by sudden uninhibited stimulation of receptors in the bladder wall. The problem may be caused by the breakdown of normal neurologic and inhibitory reflexes. A postal survey of 6000 women in a Washington State health maintenance organization estimated the prevalence of urinary incontinence to be 42% and major depression 3.7% (Melville, 2005). However, the depression

Table 21.6 Typical Symptom Differences in Stress and Urge Incontinence

Symptom	Stress Incontinence	Urge Incontinence
Leakage with exertion, cough, sneeze, activity	Yes	No
Leakage with sensation or urgency	No	Yes
Frequency, nocturia	No	Yes
Large volume urine loss	No	Yes
Leakage with running water, key in the door	No	Yes
Leakage with position change from sitting to standing	Possible	Yes
Leakage while recumbent	No	Possible
History of childhood bedwetting	No	Yes

rate was significantly higher in women with incontinence and, in particular, women with moderate and severe incontinence (5.7% and 8.3%, respectively). It also differed by incontinence type (4.7% stress, 6.6% in urge or mixed). The study did not indicate that one condition caused the other; however, there is an increased risk of major depression in women with urinary incontinence, so it is worth screening for depression in this population. It is possible that altered neurotransmitter function, such as serotonin or norepinephrine, could alter bladder function, contributing to uninhibited detrusor contractions and urge incontinence.

Women with both stress incontinence and OAB experienced a lower cure rate after surgery than women with stress incontinence only. No relationship could be found among preoperative symptoms, age, history of previous procedures, and cystometric parameters between those who were cured and those who were not. In addition, none of these criteria could predict which woman who was detrusor-stable before surgery would develop overactivity after surgery. In some women, overactive bladder symptoms improve after stress incontinence surgery. Risks of developing OAB symptoms or having persistent OAB after surgery must be recognized and incorporated into the preoperative counseling because it may require further medical therapy.

DIAGNOSIS

A bladder diary such as that shown in [Figure 21.7](#) can be useful in diagnosing OAB because it can document frequency (more than eight daytime voids), nocturia (more than one nighttime void), and episodes of incontinence preceded by urgency. Additional information can be obtained about incontinence related to activity (stress incontinence), fluid intake, pad usage, and voided volumes (a measure of bladder capacity). The ideal diary duration has yet to be established, but 1 to 3 days is generally recommended. Filling cystometry, which evaluates the pressure-volume relationship of the bladder, allows the detection of spontaneous involuntary detrusor contractions in the bladder, which are noted as the bladder fills. However, even in women who clearly describe urgency urinary incontinence symptoms, the single snapshot of one urodynamic study frequently fails to detect involuntary detrusor contractions. Sensitivity is increased with standing and provocative maneuvers such as running water, but because sensitivity remains low, treatment for urgency incontinence is reasonable even if not demonstrated during urodynamic studies.

TREATMENT: BEHAVIORAL

Behavioral therapy is first-line treatment. In women with stress and urgency urinary incontinence, it is unclear which to address first, but if the predominant symptom is urgency, this should probably be treated first. Urgency incontinence can improve, worsen (or develop de novo), or be unchanged after sling surgery, so patients who have undergone an operation for stress urinary incontinence and continue to be incontinent should be evaluated for detrusor overactivity.

Behavioral management includes fluid management, avoidance of bladder irritants, and bladder training. Because most patients with detrusor overactivity have abnormal voiding habits, bladder retraining or bladder drills are useful. This involves

a programmed progressive lengthening of the period between voiding, with or without the addition of biofeedback techniques. Women need to be taught urge suppression using distraction, relaxation techniques, or pelvic floor muscle contractions. The goal is to increase the voiding interval to 2 to 3 hours with normal fluid intake. In their study, Millard and Oldenburg demonstrated improvement in 74% of women with detrusor overactivity using these techniques ([Millard, 1983](#)). Cystometric studies performed on these patients revealed a reversion to stable bladder function. However, compliance with bladder retraining by patients is often a problem. Visco and associates studied 123 women who were offered bladder retraining and found that 55% never started treatment or were noncompliant ([Visco, 1999](#)). They noted that women who were given concurrent pharmacologic therapy had a higher (87%) compliance rate. Other behavioral treatments such as scheduled voiding, fluid management, and a bedside commode may be particularly helpful for older women with OAB.

In a 2006 Cochrane Database review, it was concluded that women with incontinence who performed pelvic floor muscle training were more likely to report cure or improvement, although they averaged only approximately one less incontinence episode daily ([Hay-Smith, 2006](#)). Although women with urge incontinence may experience less benefit than women with stress incontinence, there did appear to be improvement and few adverse effects. Women also need a strategy for urge suppression to prevent leakage, and a few quick Kegel exercises followed by deep breathing and relaxation may help reduce urge. Given the noninvasive nature of muscle training, it makes sense as initial therapy for all urinary incontinence problems over a 3-month period.

TREATMENT: MEDICAL

Anticholinergic (antimuscarinic) or beta-3 adrenergic receptor agonist drugs may be useful; [Table 21.7](#) shows currently available drugs. These medications, in conjunction with bladder retraining, have greater efficacy than either alone. In one trial, combination therapy yielded better outcomes over time on the Urogenital Distress Inventory and Overactive Bladder Questionnaire ($P < .001$) at both time points studied for patient satisfaction and perceived improvement but not health-related quality of life ([Burgio, 2000](#)).

Table 21.7 Medications for Overactive Bladder

Drug	Dosage*
Oxybutynin (Ditropan IR) †	5 mg bid, tid, qid
Oxybutynin (Ditropan XL) ‡	5 to 30 mg daily
Tolterodine (Detrol IR) †	1 or 2 mg bid
Tolterodine (Detrol LA) §	4 mg daily
Oxybutynin transdermal (Oxytrol)	3.9-mg patch (twice weekly)
Darifenacin (Enblex)	7.5 or 15 mg daily
Solifenacin (VESIcare)	5 or 10 mg daily
Trospium (Sanctura)	20 mg bid or 60 mg daily (ER) ‡
Fesoterodine (Toviaz)	4 mg to 8 mg daily
Mirabegron (Myrbetriq)	25 to 50mg daily

*bid, Twice per day; tid, three times per day; qid, four times per day.

†Intermediate-release (IR).

‡Extended release (XL, ER).

§Long acting (LA).

Overall, in clinical studies, antimuscarinic drugs reduce incontinence episodes by 60% to 75%, but only 20% to 40% of patients have no incontinent episodes. Although efficacy has been proven in many randomized trials, poor patient compliance is often found with these medications because of continued incontinence, expense without cure, and anticholinergic side effects. The most common side effect is dry mouth. Flexible-dosing schedules of several drugs, changing to a different drug, or using a drug patch delivery system are options for finding a tolerable drug for this chronic condition. Salvatore found that two thirds of women discontinued therapy within 4 months, likely because they do not provide long-lasting symptom relief (Salvatore, 2005). A randomized trial of adding behavioral training to medication therapy reduced incontinence frequency but did not allow the woman to stop the drug and maintain improvement. Caution must be advised in elderly patients as antimuscarinics can have more adverse effects (dizziness) and cognitive effects. One study linked higher cumulative anticholinergic use with an increased risk of dementia (Gray, 2015). Intravesical instillation of anticholinergic medication can provide an alternative delivery mechanism for women who fail or cannot tolerate oral therapy. The newer beta-3 adrenergic agonist drug Mirabegron has similar efficacy to the anticholinergics, but it works through a different mechanism to promote detrusor relaxation and facilitate urine storage. It appears to have fewer side effects than anticholinergic medications but is contraindicated in women with uncontrolled hypertension.

TREATMENT: PROCEDURES

Women with intractable detrusor overactivity who have failed conservative and medical treatment have procedural and surgical options. Figure 21.19 shows a therapeutic pathway for OAB that demonstrates first-line through third-line options.

Pelvic floor electrical stimulation has been studied for improving a woman's ability to inhibit involuntary detrusor contractions and decreasing symptoms of urge incontinence but has mixed results. A small removable vaginal probe is placed in the vagina or anus; electrical stimulation activates a pelvic muscle contraction. This transvaginal neuromodulation appears to be of benefit compared with placebo although data is limited.

Neuromodulation is increasingly recognized as beneficial for women with refractory symptoms (failed behavioral treatments and medications over roughly 3 months). It includes direct sacral neuromodulation of S3 and peripheral neuromodulation through peripheral tibial nerve stimulation (PTNS) to the sacral nerve plexus. In practice, PTNS is done weekly for 30 minutes for 12 weeks and then every 3 to 4 weeks for maintenance therapy. There are few reported side effects except for pain during the stimulation. Many women prefer this to long-term medication use. There are many trials and a randomized trial with a sham treatment group that support efficacy (Peters, 2010). One randomized, crossover trial compared PTNS with solifenacin (Vecchioli-Scaldazza, 2013). There were fewer daily voids, nocturia episodes, and urge incontinence events in both groups, but PTNS showed greater effectiveness than solifenacin. The PTNS group also reported better quality of life and perceived effectiveness of urgency control. Much remains to be learned about patient selection criteria and long-term effects.

Another route of neuromodulation involves an implantable device, which chronically stimulates the sacral nerves and reduces symptoms. The FDA approved InterStim (Medtronic, Minneapolis, MN) for sacral neuromodulation (SNS) in 1997 for urgency, urge incontinence, and later for urinary retention (Fig. 21.20). Patients have a stimulation test with either a tined lead wire placed in the office or a potentially permanent lead wire placed in the operating room under fluoroscopy. If the results showed a $\geq 50\%$ improvement in urge incontinence symptoms, the permanent stimulator is implanted. The device complication rate has decreased with improvement in the wire lead that is placed (Fig. 21.21) and other improvements in standardizing the implantation procedure, but infection, failure to improve symptoms long term, and the need for explanation problems remain. One randomized trial of SNS versus standard antimuscarinic medication in 147 subjects found that at 6 months, the success rate was 61% in the SNS group versus 42% in the medication group ($P = .02$) (Siegel, 2015). There were significant improvements in the quality of life scores in the SNS group. Furthermore, the improved or greatly improved urinary symptom scores were 86% for SNS versus 44% in the medication group. The complication rate for the SNS device was 30.5% compared with 27.3% medication adverse event rate. Multiple long-term outcome studies have been published confirming that this is a feasible option for many women with refractory urge incontinence. Women must have good cognitive function to consider this

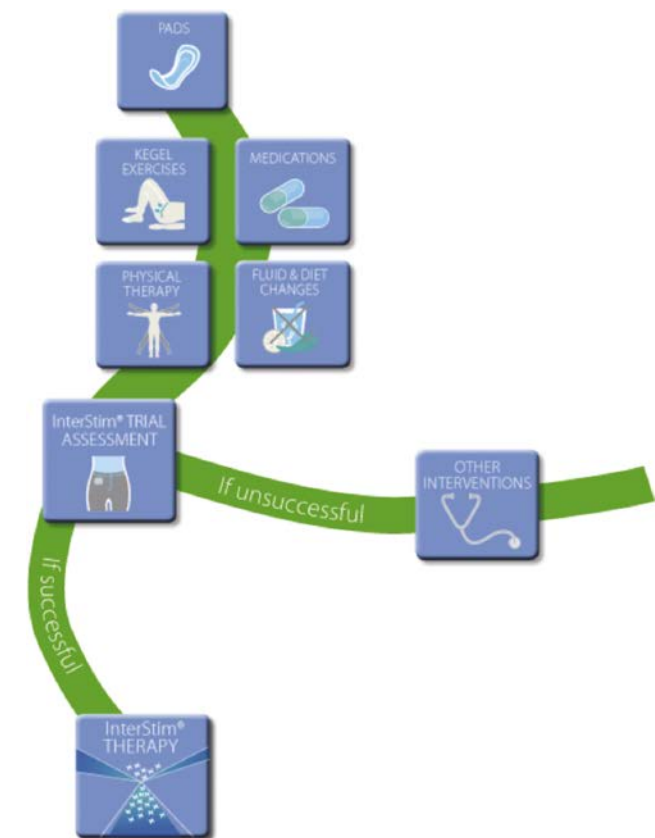

Figure 21.19 Treatment algorithm for urge incontinence. (Courtesy of Medtronic, Minneapolis, MN.)

Figure 21.20 InterStim test generator and permanent implantable generator, along with spinal cord model. (Courtesy of Medtronic, Minneapolis, MN.)

option. Reoperation is not uncommon with infection, lead movement, and battery replacement. Women cannot undergo MRI below the head, so this must be discussed and considered before placement.

Intradetrusor onabotulinumtoxin A blocks presynaptic acetylcholine from parasympathetic nerves, causing paralysis of the detrusor smooth muscle, although it may also affect bladder afferent or urothelial cell neurotransmitters. Onabotulinumtoxin A is injected into the bladder wall via cystoscopy either in the office or in an outpatient surgery setting. It is FDA approved,

Table 21.8 Effective Treatment Options for Women with Urinary Incontinence by Type of Incontinence

Treatment Option	Stress Incontinence	Urge Incontinence
Nonpharmacologic	Pelvic floor muscle training Bladder training Prompted voiding Incontinence pessary	Pelvic floor muscle training Bladder training Prompted voiding Posterior tibial nerve stimulation
Pharmacologic		Anticholinergic drugs (antimuscarinic) Beta agonist
Surgical	Midurethral synthetic sling Retropubic colposuspension Suburethral fascial sling	Botulinum toxin A injection Sacral neuromodulation

Modified from Holroyd-Leduc JM, Straus SE. Management of urinary incontinence in women: clinical applications. *JAMA*. 2004;291(8):996-999.

and published studies show 60% to 70% cure or improvement rates. Temporary urinary retention was reported as high as 40% with early studies using higher doses but is 5% to 10% in newer studies. Women should return for postvoid residual urine testing and be prepared to learn clean intermittent self-catheterization if needed until the drug wears off. Dose finding studies compared with placebo have found that 100 units and 150 units are superior to placebo. UTIs are more common after infection. Long-term efficacy data show that reinjection is usually necessary, but repeat injections remain as effective as initial injections. Benefit is maintained for 3 to 12 months. A randomized controlled trial directly compared onabotulinumtoxin A injection (100 units) with oral solifenacin and at 6 months; they had similar efficacy (Visco, 2012).

Table 21.8 summarizes the treatment options for the two most common types of urinary incontinence. Figure 21.22 shows an evaluation and treatment algorithm for stress, urge, and mixed incontinence.

MIXED URINARY INCONTINENCE

As the term implies, *mixed urinary incontinence* means that a woman complains of both stress and urge incontinence. The pathophysiology and treatment of mixed incontinence have not been well studied despite the fact that it accounts for one third of incontinence complaints. Sometimes the woman can articulate which problem is worse, and treatment can begin for the more bothersome condition. Pelvic floor muscle exercises and behavioral training are appropriate first-line therapies for both types of incontinence (see the stress and urge incontinence sections presented earlier). The literature supports trying antimuscarinic drugs, which in one trial significantly reduced incontinence episodes. Of five published studies of surgical trials for mixed incontinence using slings, varied cure rates have been reported. Although the stress incontinence component of the leakage may decrease, the woman is often disappointed to still be leaking because the urge component has not improved. The risk of having

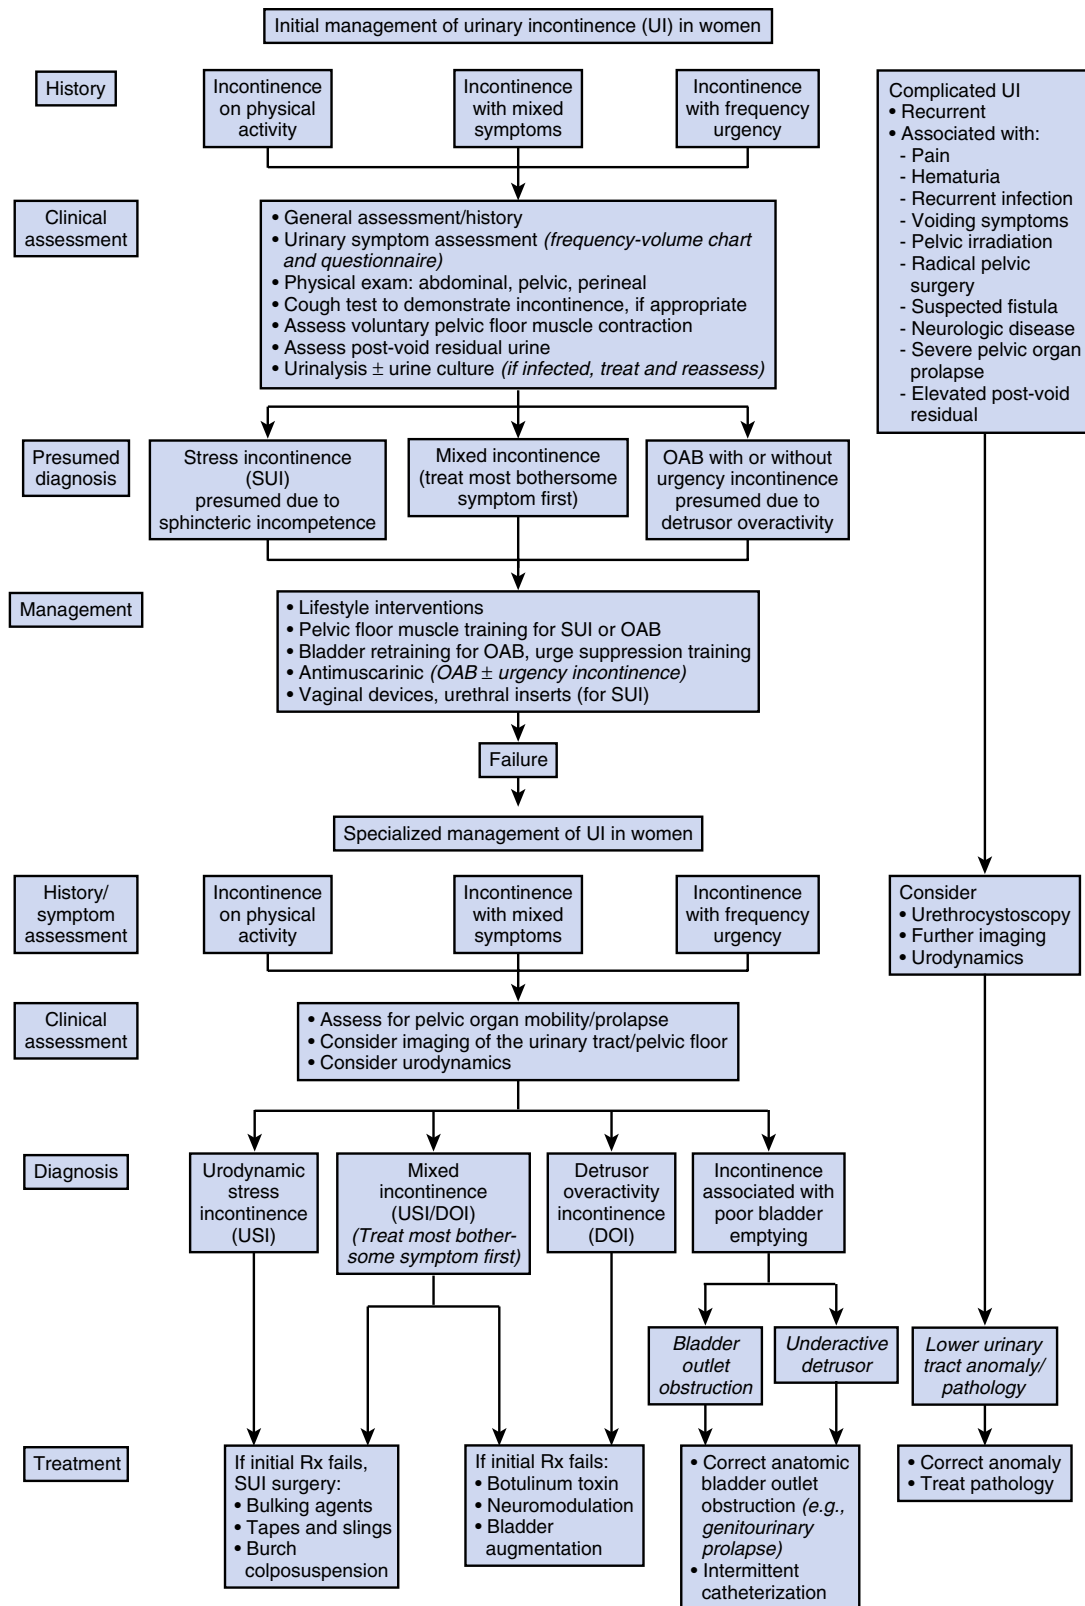

Figure 21.22 Summary treatment algorithm for stress, urge, and mixed incontinence.

persistent detrusor overactivity after surgery must be recognized and incorporated into the preoperative counseling.

OTHER TYPES OF INCONTINENCE

Nocturnal enuresis is the complaint of loss of urine during sleep. The term *continuous urinary incontinence* has been defined by the International Continence Society as the continuous leakage of urine where the woman does not describe urgency or activity associated with the leakage (Haylen, 2010). Extraurethral incontinence is defined as the observation of urine leakage through channels other than the urethra, including urinary fistulas, and an ectopic ureter.

Chronic Retention of Urine

Overflow incontinence is the old term used to describe chronic retention of urine. It occurs when a bladder does not empty. The problem may be caused by a neurologic disorder that interferes with normal bladder reflexes, neuropathy, myogenic failure, or obstruction of the urethra. Typically, the woman complains of voiding small amounts and still feeling that there is urine in the bladder, or she may only complain of incontinence and lose small amounts of urine without any control. Typically, the bladder is not painful and may be palpable after the woman has voided. The diagnosis is made when there is persistence of a significant amount of urine left in the bladder after voiding, as confirmed with ultrasound bladder scanning or catheterization. Typically in this setting, the postvoid residual urine volume is more than 300 mL.

This condition is mostly seen in patients after incontinence surgery and in patients with multiple sclerosis, diabetic neuropathy, and trauma or tumors of the central nervous system. A complete general medical and urologic workup is necessary to clarify the patient's condition. Therapy directed at the primary cause may be beneficial, such as releasing a suburethral sling that is obstructive. Often, the woman must be trained in techniques of intermittent self-catheterization. Sacral neuromodulation is FDA approved for women with urinary retention. Alpha-blockers used for men with prostatic hypertrophy are not FDA approved for women and rarely work.

Estrogen and the Lower Urinary Tract

Estrogen has long been known to play a role in lower urinary tract function because estrogen and progesterone receptors are found throughout the vagina, bladder, and urethra. Estrogens had been prescribed for years for the treatment of stress incontinence, until controlled trials (HERS, WHI, Nurses' Health Study) and the Hormones and Urogenital Therapy (HUT) Committee reported that estrogen was not an efficacious treatment for stress incontinence and actually increased the risk of incontinence. In postmenopausal women with vaginal atrophy, there may also be urethral mucosal epithelium atrophy because there are estrogen receptors in the urethra, which may lead to irritative symptoms. Vaginal estrogen does appear to be superior to placebo for recurrent cystitis and vaginal and urethral atrophy in the postmenopausal woman. Urethral atrophy and inflammation might contribute to irritate the bladder and lead to symptoms of urgency and frequency. A systematic review of the effects of vaginally administered estrogen has reported significant

improvement in frequency, nocturia, urgency, incontinence episodes, and bladder capacity in postmenopausal women. In doses used for the treatment of genital atrophy (0.5 g of unconjugated estrogen cream three times weekly), serum levels were low and endometrial thickness unchanged. An intravaginal estrogen ring that releases very low levels of estrogen over a 3-month period is a convenient method of administration for many women. The estrogen benefit may be caused by the treatment of vaginal atrophy rather than a specific bladder and urethral effect. Possible confounding effects of progestogens and the multitudes of different estrogen preparations, oral and vaginal, hamper most studies. Progestogens have been associated with increased bladder irritability.

KEY POINTS

- As many as 30% of all women may suffer from some degree of urinary incontinence during their lifetime.
- Continence is determined by the balance between forces that maintain urethral closure and those that affect detrusor function. Parasympathetic nervous system activity via the neurotransmitter acetylcholine stimulates receptors in the bladder wall to activate detrusor contraction. Sympathetic nervous system activation leads to bladder relaxation.
- The highest pressure zone in the urethra is approximately the midpoint in the functional urethra, which is roughly 0.5 cm proximal to the urogenital diaphragm.
- Approximately 50% of all women will develop urinary infections at some point in their lifetime and, by age 70 years, as many as 10% of women will have recurrent UTIs.
- Painful bladder syndrome–interstitial cystitis is a painful, chronic bladder condition that is not related to infection and is associated with symptoms of bladder and pelvic pain, urinary frequency, urgency, or nocturia, and often dyspareunia.
- The midurethral synthetic tape slings (retropubic and transobturator midurethral) appear to have similar efficacy for the surgical treatment of stress incontinence, with a shorter surgery and recovery time than a Burch colposuspension.
- Retropubic and transobturator midurethral slings have similar success rates for stress incontinence, although with different risk profiles. The retropubic approach has a significantly higher risk of bladder perforation, bleeding, and voiding dysfunction, and the obturator approach has a higher risk of groin and leg pain.
- Approximately 20% of women with urinary incontinence suffer from detrusor overactivity. Behavioral changes and oral medications are first-line treatments, although often they have disappointing cure rates. Neuromodulation and surgical procedures are available and effective for refractory symptoms.
- Being obese or overweight increases the risk of urinary incontinence, and weight loss can reduce stress incontinence significantly.

Anal Incontinence Diagnosis and Management

Gretchen M. Lentz, Mukta Krane

Anorectal disorders are common in women and anal incontinence is particularly distressing. Despite the negative impact on quality of life, women may be reluctant to discuss this with their physician because of embarrassment. As one of the most common contributing factors to anal incontinence is pregnancy and delivery, the obstetrician-gynecologist will often be the first to assess the problem. The prevalence of anal incontinence increases with age, so it is imperative that physicians are equipped to address these problems in postmenopausal women and be aware of the significant effects that these disorders can have on a woman's self-sufficiency and ability to carry out activities of daily living. Anal incontinence is a general term that refers to loss of gas or fecal material via the anus. Fecal incontinence is the inability to prevent loss of stool from the anus until desired. This chapter addresses the causes, diagnosis, and treatment of anal incontinence. *Accidental bowel leakage* is also a newer term being used.

ANAL INCONTINENCE

Fecal incontinence (FI) is one of the most devastating of all physical disabilities but, because of the social embarrassment and psychological effects, most patients fail to report their symptoms and many physicians do not ask. Therefore the exact prevalence of this condition is unknown. Estimates range from 9% to 16% of community-dwelling women with average age of onset between 47 and 55 years. Part of this variability relates to study definition differences for fecal incontinence. Occasional fecal soiling will not be as devastating as gross fecal incontinence, but both may be reported as part of the same study definition. Approximately 10% of women will report some change in bowel habits after one vaginal delivery. Prevalence increases with age. Little is known about racial differences in fecal incontinence, but a 2010 study found a prevalence of 6.1% in noninstitutionalized African Americans aged 52 to 68 years. Over 30% of women reporting urinary incontinence also report fecal incontinence, known as *dual incontinence*. Fecal incontinence is the second leading cause of nursing home placement. [Box 22.1](#) lists common risk factors for this condition. Late-onset fecal incontinence may have a different set of risk factors and, in one nested case-control study, bowel disturbances rather than obstetric events were more important.

Anal incontinence is the inability to defer the elimination of stool or gas until there is a socially acceptable time and place to do so. Fecal incontinence is the inability to defer the elimination of stool and can be subdivided into three groups: fecal urge incontinence, passive incontinence, and fecal seepage. Fecal urge incontinence is the loss of fecal contents despite attempts to avoid defecation. Passive incontinence refers to the involuntary discharge of feces without awareness or sensation. Fecal seepage is most often defined as the involuntary leakage of small amounts of stool. Because maintaining continence is a complex physiologic process that requires a person's ability to perceive the type of fecal bolus, store or retain when necessary, and excrete when desirable, the loss of that ability is equally complex.

In the evaluation of anal incontinence, it is important for the physician to understand the woman's symptoms, type of loss (i.e., flatus or liquid/solid stool), frequency of incontinence, effect on the quality of her life, and concurrent pelvic floor derangements. Fecal incontinence affects each woman's life in a different manner. What may be acceptable for one woman may be intolerable to another. Evaluation and treatment should be directed by the severity of the woman's symptoms and the expected goals of therapy.

PHYSIOLOGY OF FECAL CONTINENCE

Fecal continence is significantly affected by stool consistency and volume, colonic transit time, rectal compliance, innervation of the pelvic floor and anal sphincter, and interplay among the puborectalis muscle, rectum, and anal sphincters. Loss of one or more of these functions can lead to fecal incontinence.

As a bolus of stool or gas passes from the sigmoid colon to the rectal canal, receptors in the wall of the puborectalis sense the distention of the rectum. As long as the pressure in the anal canal is maintained at a higher level than the rectal pressure, continence is maintained. Anal canal pressure depends on a competent internal anal sphincter (IAS) and external anal sphincter (EAS). The IAS is a thickened continuation of the circular muscle of the colon and provides 75% to 85% of the resting tone of the anal canal, but there is a lower rectal sphincter pressure when the anal canal is distended with stool. The IAS, under autonomic control, maintains the high-pressure zone or continence zone and, along with the EAS, keeps the anal canal closed. Disruption or dysfunction of the IAS may result in passive incontinence. The shape of the combined IAS and

EAS is almost cylindrical as it encircles the anal canal. Magnetic resonance imaging (MRI) scans from nulliparous women have shown that the EAS does not appear as a cylinder but rather has lateral winged projections. The function of this component is not known. The sphincter complex averages 18.3 mm in thickness and 2.8 cm in length in the midline anteriorly; 54% of the anterior thickness is attributable to the IAS and the remainder to the EAS. The EAS provides the voluntary squeeze pressure that prevents incontinence with increasing rectal or abdominal pressure and is related to urge incontinence. The EAS is innervated by the hemorrhoidal branch of the pudendal nerve from the S2-S4 nerve roots. Contraction of the

EAS, voluntarily or through a spinal reflex, increases the anal canal pressure by 25%, but this tone cannot be maintained indefinitely because these are fatigable, fast-twitch muscles.

The third muscular component of the sphincter complex is the puborectalis muscle (Fig. 22.1). The puborectalis, part of the levator ani muscle complex, originates from the pubic bone on either side of the midline, passes beside the vagina and rectum, and fuses posteriorly behind the anorectal junction to form the U-shaped sling that cradles the rectum while sending some fibers onto the walls of the anal canal. Unlike most other striated muscles, the puborectalis, like the IAS, maintains a constant muscle tone that is directly proportional to the volume of the rectal content and pressure, and it relaxes at the time of defecation. Both the puborectalis and EAS contain a majority of type I, or slow-twitch, muscle fibers, which are ideally suited to maintaining a constant contraction or tone. Each muscle group also contains a small proportion of type II, or fast-twitch, fibers that allow for quick responses to rapid increases in intraabdominal pressure. The puborectalis is innervated by direct branches from S3 and S4 and, to a lesser degree, from the pudendal nerve. The constant contraction of the puborectalis creates a 90-degree angle between the rectum and anal canal. This angle, known as the *anorectal angle*, has been the source of much discussion and evaluation in determining its role in the maintenance of continence. Parks has postulated that this angle creates a flap valve effect that presses the anterior rectal wall down onto the upper anal canal and thereby prevents the rectal contents from entering the anal canal when intraabdominal pressure is applied. The anterior rectal wall therefore acts as a plug. However, Bartolo has found that when the anal sphincter is maximally stressed and the

Box 22.1 Risk Factors for Fecal Incontinence

General

- Aging
- Obstetric anal sphincter laceration
- Operative vaginal delivery with forceps
- Neuropathy
- Bowel motility disorders
- Hemorrhoids and previous anal surgery

Late-Onset (After Age 40)

- Current smoking
- High body mass index
- Diarrhea
- Irritable bowel syndrome
- Cholecystectomy
- Rectocele
- Urinary incontinence
- Bariatric surgery

Figure 22.1 Coronal section of the anal canal and lower rectum. ARR, Level of anorectal ring; CLM, conjoined longitudinal muscle; IRN, inferior rectal nerve; LA, levator ani muscles; PRD, puborectalis/deep external sphincter complex; SC, subcutaneous external sphincter. Table 22.1 Anal Incontinence: Components of the Continence Mechanism

Component	Function	Symptoms of Deficit
External anal sphincter	Provides emergency control for liquid stool and flatus	Fecal urgency; urge-related incontinence of liquid stool and flatus
Puborectalis	Maintains continence of solid stool	Incontinence of solid stool
Internal anal sphincter	Keeps anal canal closed at rest; allows sampling of stool content and enhances continence of liquid stool and flatus	Fecal soiling Incontinence of liquid stool and flatus
Anal sensation	Allows discrimination of gas, liquid, and solid stool; provides warning of impending incontinence	Fecal soiling; fecal leakage that is promptly halted by voluntary contraction on conscious detection
Colonic motility	Controls stool volume, consistency, and delivery rate to the rectum	Incontinence of liquid or loose stools during prolonged or severe diarrheal states
Rectal reservoir	Maintains adequate reservoir under low pressure	Incontinence of solid stool associated with sudden rectal distention; fecal urgency and urge-related incontinence

From Toglia M. Anal incontinence: an underrecognized, undertreated problem. *Female Patient*. 1996;21:27.

rectum is visualized radiographically, there is no contact between the rectal wall and anal canal (Bartolo, 1986). In addition, surgical procedures that try to recreate this angle in an attempt to restore continence have not proved effective.

When a bolus of stool or gas is sensed in the rectum, the IAS has a reflex relaxation that allows for colonic contents to be sampled by the anal canal to distinguish solid, liquid, and gas forms of fecal material. After the sampling, the IAS contracts and the fecal material is pushed back into the rectum. This reflex, known as the *rectoanal inhibitory reflex (RAIR)*, is absent in patients with Hirschsprung disease. This reflex can also be inhibited by chronic dilation of the anus with fecal impaction and can lead to incontinence. If the impaction is cured, the reflex and anal tone can return to normal.

If the rectum has normal compliance and the person chooses to defer defecation, the IAS and EAS sphincters and puborectalis remain contracted until the appropriate time to eliminate. As seen in Table 22.1, loss of any of these important components can lead to incontinence of flatus, liquid, or solid stool.

CAUSES AND PATHOPHYSIOLOGY

There are many causes of fecal incontinence (Box 22.2). One way to categorize the reasons for fecal incontinence is to separate the initial cause into those that start outside the pelvis with a normal pelvic floor from those that start with an abnormal pelvic floor. Causes that start outside the pelvis include all the pathologies that cause diarrhea or increased intestinal motility, overflow incontinence from fecal impaction, and rectal neoplasms. Known or diagnosable neurologic conditions such as multiple sclerosis, diabetic neuropathy, trauma, or neoplasms in the spinal cord or cauda equina initially begin as pathologies outside the pelvis, and the pelvic floor is presumed to be normal. As these neuropathies progress, there is damage to the pelvic floor musculature or rectal sensation, resulting in fecal incontinence.

Fecal incontinence secondary to an abnormal pelvic floor is caused by congenital anorectal malformations, surgery, obstetric injury, aging, or pelvic floor denervation without a known neurologic disease. Historically, incontinence secondary to denervation has been designated as idiopathic and represents 80% of patients with fecal incontinence. Pelvic floor denervation has been studied extensively in women with urinary and fecal incontinence, as well as pelvic organ prolapse. Denervation may be secondary to vaginal

Box 22.2 Common Causes of Fecal Incontinence

- Obstetric injury
 - Disruption of internal anal sphincter
 - Disruption of external anal sphincter
 - Pelvic floor denervation
- Trauma
 - Pelvic fracture
 - Accidental injury
 - Anal intercourse
 - Anorectal surgery
 - Rectovaginal fistula
- Diarrheal states
 - Irritable bowel syndrome
 - Infectious diarrhea
 - Inflammatory bowel disease
 - Short gut syndrome
 - Laxative abuse
 - Radiation
- Malabsorption
- Rectal neoplasia
- Rectal prolapse
- Rectocele
- Hemorrhoids
- Overflow
 - Impaction
 - Encopresis
- Neurologic disease
 - Congenital anomalies (e.g., myelomeningocele)
 - Multiple sclerosis
 - Diabetic neuropathy
 - Neoplasms or injury of brain, spinal cord, cauda equina
 - Pudendal neuropathy (e.g., from childbirth, chronic straining, perineal descent)
 - Congenital anomalies of the anorectum or pelvis

delivery, chronic straining with constipation, rectal prolapse, or descending perineal syndrome. Histologic studies of the EAS and puborectalis show fibrosis, scarring, and fiber-type grouping consistent with nerve damage and reinnervation in women with idiopathic fecal incontinence. Electromyography (EMG) studies have demonstrated reinnervation of the pelvic floor with increased fiber density and prolongation of nerve conduction on pudendal nerve terminal motor latency (PNTML) studies.

In healthy women, the most common cause of fecal incontinence is damage to the anal sphincters at the time of vaginal delivery, with or without neuronal injury. This type of incontinence is often referred to as anal incontinence. Damage can occur by mechanical disruption or separation of the IAS, EAS, or both, or by damage to the muscle innervation by stretching or crushing the pudendal and pelvic nerves. Sultan and coworkers' 1993 landmark study showed that 13% of primiparas and 23% of multiparas developed fecal incontinence or fecal urgency by 6 weeks postpartum (Sultan, 1993). By endoanal ultrasound, all but one of the women had evidence of anal sphincter disruption. The incidence of occult external anal sphincter disruption after vaginal delivery determined by endoanal ultrasound ranged from 11% to 35%. Most of the women showed pudendal nerve conduction prolongation but recovered by 6 months postpartum. Because anal sphincter injury correlated with the development of symptoms, reducing anal sphincter injury and understanding risk factors are critical to prevention. The chance of anatomic sphincter injury is increased with midline episiotomy, instrumented delivery, vaginal delivery of larger infants, and persistent occiput posterior presenting head position. Other risk factors include increasing maternal age, prolonged second stage (longer than 2 hours), epidural anesthesia, and clinically diagnosed sphincter laceration at the time of delivery. The first vaginal delivery appears to have the greatest effect on pelvic floor function and risk of EAS disruption, but subsequent deliveries can increase the risk of permanent damage, especially in women with transient symptoms of fecal incontinence after their first delivery. Not all risk factors are known, and not all women are susceptible to pelvic floor and sphincter damage with vaginal delivery.

Diabetes mellitus deserves mention because of its rising prevalence. Diabetics can develop autonomic neuropathy and can have decreased IAS resting pressure. Either of these might contribute to fecal incontinence.

DIAGNOSIS AND ASSESSMENT

For fecal incontinence, even more than urinary incontinence, if the physician does not ask, the woman will not volunteer the information. Ideally, a question such as "How often do you leak gas, liquid, or solid stool?" should be placed on the standard office intake questionnaire. Several reports have shown that twice as many patients complain of fecal or flatal incontinence when given a written questionnaire rather than answering verbal questioning.

Because approximately 1 in 10 women will develop some fecal incontinence or fecal urgency after one vaginal delivery, it is especially important to incorporate open-ended questions concerning flatal or fecal incontinence as part of the 6-week postpartum visit. In addition, as women age, the chance of developing fecal incontinence increases, so it is also important to target older women for questioning.

Evaluation

Assessment of the woman with fecal incontinence must include a thorough history because the origin of the problem may be the single most important criterion of therapy. Box 22.3 lists some questions to be asked when taking a history regarding fecal incontinence.

Box 22.3 History in a Patient with Suspected Fecal Incontinence

- Onset and precipitating event(s)
- Duration, severity, and timing
- Stool consistency and urgency
- Coexisting problems, surgery, urinary incontinence, back injury
- Obstetric history—forceps, tears, presentation, repair
- Drugs, caffeine, diet
- Clinical subtypes—passive or urge incontinence or fecal seepage
- Clinical grading of severity
- History of fecal impaction

Table 22.2 Continence Grading Scale*

Type of Incontinence	FREQUENCY				
	Never	Rarely	Sometimes	Usually	Always
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Wears pad	0	1	2	3	4
Lifestyle alteration	0	1	2	3	4

*The continence score is determined by adding points from this table, which takes into account the type and frequency of incontinence and the extent to which it alters the patient's life.
From Jorge JM, Wexner SD. Etiology and management of fecal incontinence. *Dis Colon Rectum*. 1993;36:77-97.
0 = perfect, 20 = complete incontinence; never = 0 (never); rarely = < 1/month; sometimes = < 1/week, ≥ 1/month; usually = < 1/day, ≥ 1/week; always = ≥ 1/day.

The history should include onset, duration, severity of the condition, effect on the woman's daily activities, pad use, frequency and consistency of bowel movements, use of laxatives, fiber intake, and dietary habits. Specific questions concerning diarrhea, amount of flatus, average number of stools per day, passage of mucus, and bloating should be asked. Physicians and patients define normal bowel function differently. Diarrhea may mean frequent bowel movements to one person but loose and watery bowel movements to another. It is best to have the woman quantitate the number of bowel movements and incontinent episodes and describe the stool consistency. A diary of bowel habits and incontinent episodes can be useful, and several standardized classification systems are available. Table 22.2 gives a frequently used scoring system developed by Jorge and Wexner (1993). The woman circles the appropriate number on each line of the scale. The numbers are then added. A perfect score, or 0, indicates no incontinence and a score of 20 indicates complete incontinence. The value of this continence grading scale is that it can be used before and after treatment to determine the efficacy of the intervention. A standardized questionnaire should be used whenever possible to direct diagnosis and treatment and assess treatment success.

The history should also identify specific complaints such as feelings of incomplete emptying, straining with bowel movements, fecal urgency, pain with defecation, and insensible loss of stool. It is important to determine whether the woman senses the need to have a bowel movement or if she is unaware

Stool Diary								
PLEASE RECORD YOUR STOOL HABITS FOR ONE WEEK:								Name: Hosp #:
Date	Time of bowel movement	Incontinence Yes / No	Stool seepage or straining Yes / No	Stool consistency (Type 1–7) See below	Urgency – unable to postpone BM for more than 15 minutes Yes / No	Use of pads Yes / No	Medications	Comments

Use the following descriptors for describing stool consistency:

Type 1: **Separate hard lumps.** Type 2: **Sausage-shaped but lumpy.** Type 3: **Like a sausage but with cracks on its surface.** Type 4: **Like a sausage or snake, smooth and soft.** Type 5: **Soft blobs with clear-cut edges (passed easily).** Type 6: **Fluffy pieces with ragged edges, a mushy stool.** Type 7: **Watery.**

Figure 22.2 Stool diary. This is a sample stool diary for assessing patients with fecal incontinence. (From Rao SS. American College of Gastroenterology Practice Parameters Committee: diagnosis and management of fecal incontinence. American College of Gastroenterology Practice Parameters Committee. *Am J Gastroenterol.* 2004;99:1585.)

that she needs to defecate but finds stool in her undergarments. A sensory impairment or hygiene problem is implied when stool leakage occurs without warning. If the woman is aware of impending incontinence but cannot prevent the passage of stool, a motor impairment is suggested. Patients may have pseudo-incontinence secondary to soiling from prolapsing hemorrhoids or rectovaginal or anovaginal fistulas. Patients should also be questioned about other pelvic floor pathologies, particularly rectal prolapse, rectovaginal fistulas, and urinary incontinence.

The review of systems should include abdominal pain or cramping, lower back or pelvic pain, any changes in pelvic or lower extremity sensation, and changes in sexual response. Changes in the neurologic function of the pelvis or lower extremities or a history of an acute onset of fecal incontinence should direct the physician to rule out a neurologic disease, such as multiple sclerosis or a neoplasm of the brain or lumbosacral spinal cord.

The past medical history should include detailed history of vaginal deliveries, including birth weights, length of second stage, episiotomies or lacerations, and use of forceps. Any breakdown or complications of episiotomy healing should be noted. The past history of abdominal and pelvic surgeries or trauma to the back or pelvis should be reviewed. Details and operative reports of any anal dilations, anal sphincterotomy, hemorrhoidectomy, rectovaginal fistula repairs, or posterior colporrhaphy should be obtained. Patients should also be questioned about previous evaluations and results of flexible sigmoidoscopy, colonoscopy,

and barium enemas. Any family history of colon cancer, inflammatory bowel disease, or familial polyposis should be elicited.

Many medications also affect bowel function. The woman should not only be asked about laxatives and bowel stimulants, but a complete list of all prescription and over-the-counter medications, as well as any dietary or herbal supplements, should be reviewed. Many drugs, including anticholinergics, antidepressants, iron, narcotics, nonsteroidal anti-inflammatory drugs (NSAIDs), and pseudoephedrine, can cause chronic constipation that may contribute to overflow incontinence or pelvic floor neuropathy secondary to straining.

Women can be instructed on how to keep a daily stool diary (Fig. 22.2). This is a good baseline evaluation tool and can later be used to assess conservative treatment with dietary changes and fiber intake.

Physical Examination

Undergarments or pads should be inspected for stool, mucus, blood, or pus. If material is found, the woman should be asked if this is her normal leakage. Physical examination begins with inspection of the perineum and anal region. Pruritus ani, or discoloration and irritation of the perianal skin, is commonly seen with fecal incontinence of liquid stool and chronic diarrhea. Perianal skin creases or folds should completely encircle the anus. Note the presence of protruding tissue around or from the anus and determine whether there are external hemorrhoids or mucosal or full-thickness rectal prolapse (Fig. 22.3). The dovetail sign, or loss of anterior perineal folds, indicates a defect

Figure 22.3 Combined severe rectal prolapse and vaginal pelvic organ prolapse. Note the protrusion of the rectal mucosa from the anus.

in the EAS or chronic third-degree laceration (Fig. 22.4). Previous episiotomy, laceration, or surgical scars should be noted. The size of the genital hiatus and presence of genital prolapse should be assessed as an indicator of pelvic floor neuromuscular function. The innervation of the EAS can be grossly tested by eliciting the clitoral-anal or bulbocavernosus reflex. Using a cotton swab, a gentle, quick touch beside the clitoris or over the bulbocavernosus muscle should elicit a contraction of the EAS. If intact, the reflex implies that the pudendal nerve afferents and rectal or external hemorrhoidal branch of the pudendal efferent nerves are functional. Unlike men, who should always exhibit this reflex, approximately 10% of women lack this reflex naturally. However, if absent, and in the presence of fecal incontinence, further neurologic testing is indicated. Sensation in the S2-S4 dermatomes should be screened by dull and pinprick discrimination when touching the perineum. The same wooden cotton swab used to elicit bulbocavernosus reflexes can be broken and then used for pinprick (broken end) and dull (cotton end) sensation testing. Loss of sensation should direct the clinician to further neurologic or radiologic assessment of the nervous system.

Next, the woman should be asked to squeeze as if trying not to pass gas. Inspection of the perianal folds should be evaluated for a concentric contraction and some upward movement of the perineal body as she contracts the EAS and levator ani. Substitution with contraction of the buttocks, upper thighs, or abdomen should be noted. The woman should then be asked to bear down as if trying to have a bowel movement. She should be reassured that it is expected that she might pass flatus during this part of the examination. The degree of perineal descent and any prolapse of the vagina, pelvic viscera, or rectum should be noted. If

Figure 22.4 Perineum with chronic laceration of external anal sphincter (EAS). Inspection of the perineum shows the classic dovetail sign with loss of the anal skin creases anteriorly because of a chronic third-degree laceration of the EAS. Normally, with an intact sphincter, the skin creases are arranged radially around the anus. (From Stenchever MA, Benson JT, eds. *Atlas of Clinical Gynecology*. New York: McGraw-Hill; 2000.)

there appears to be any pelvic organ prolapse, the examination should be performed with the woman in the standing position or after straining on a commode to maximize the prolapse.

Rectal examination is used to assess resting and squeeze tones of the anal canal. The resting tone of the anal canal is an indicator of IAS function. When asked to squeeze, the woman should feel a circumferential contraction and tightening. An upward movement of the rectum and posterior compartment of the pelvis should be seen as the levator ani muscles contract. Because these muscles also play an important role in anal continence, palpation of the levators for strength and symmetry should be performed by palpating the muscles on each side of the vagina at the introitus.

In addition to assessing rectal tone, the anal canal and rectum should be palpated for masses and a dilated rectum or the presence of stool in the rectal vault. A chronically distended rectum, with stool, a tumor, or an intussuscepting bowel will disrupt the normal rectoanal inhibitory reflex that allows the highly sensitive anal canal to sample the stool contents by relaxing the IAS while time-contracting the EAS to prevent incontinence. If this reflex is suppressed, the anal canal remains dilated, the EAS fatigues, and incontinence will occur.

While doing the rectal examination, the doctor asks the woman to strain to diagnose the presence of a rectocele, enterocele, rectal prolapse, or bowel intussusception. With the examiner's finger in the rectum, the integrity of the rectovaginal septum,

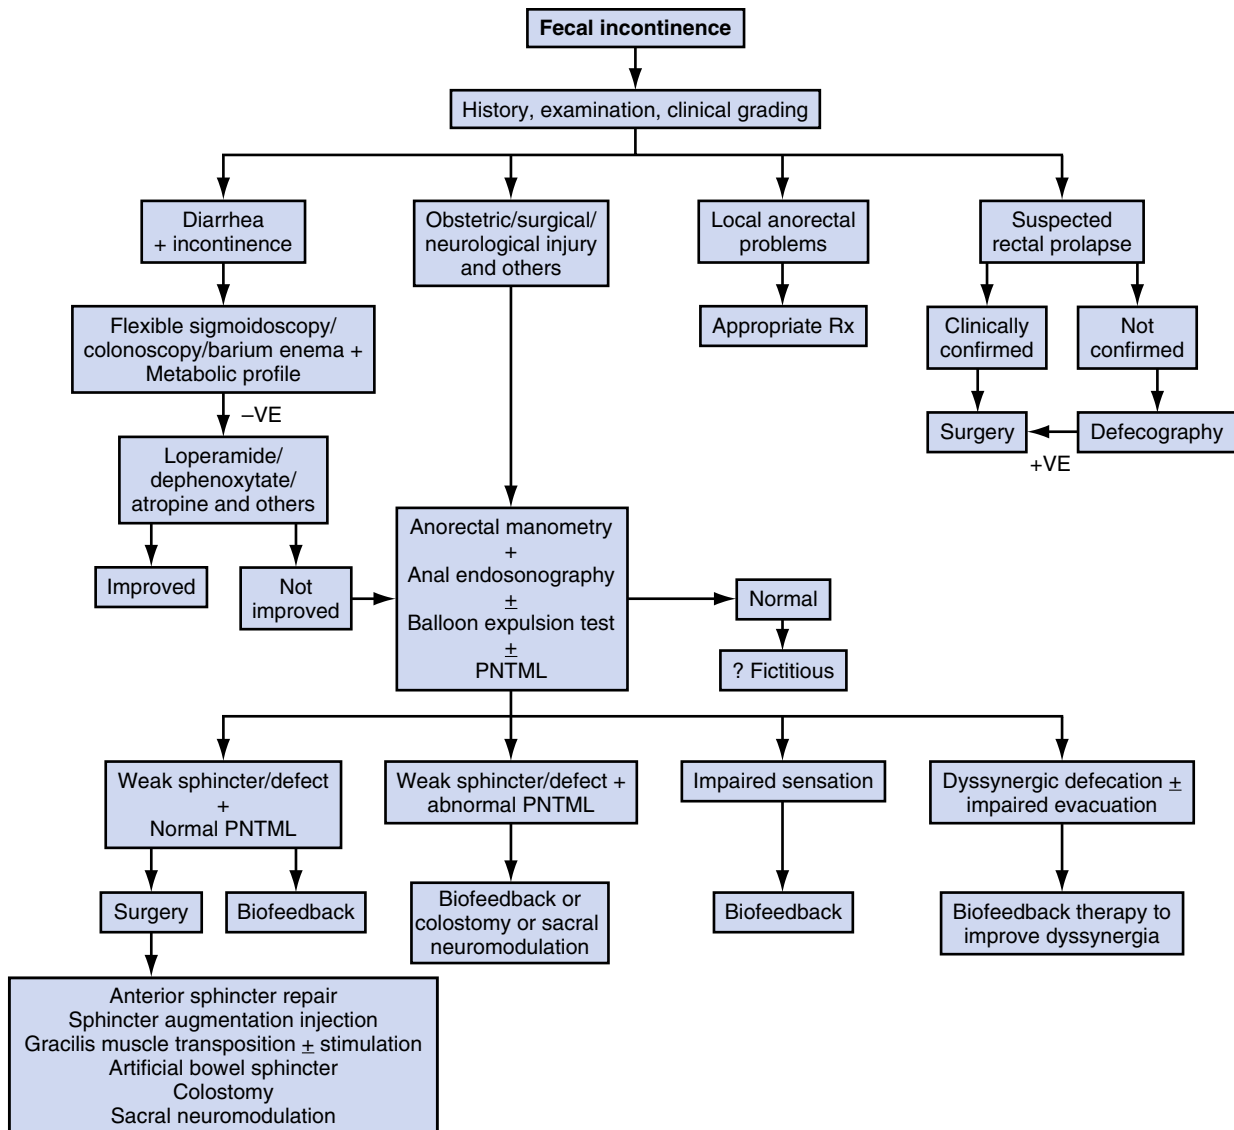

Figure 22.5 Algorithmic approach to the evaluation and management of fecal incontinence. A detailed history differentiates incontinence of gas, liquid, or solid stool, along with frequency, onset, and effect on the patient's quality of life. The history should assess the possibility of Crohn disease, ulcerative colitis, irritable bowel syndrome, radiation to the pelvis, neurologic diseases such as multiple sclerosis, and prior anorectal surgeries. A detailed obstetric history should include type of delivery, weight of largest infant, length of second stage, episiotomy or lacerations, and use of forceps or vacuum extraction. Rectal examination should assess resting and squeeze tone, presence of a rectocele or rectal mass, and fecal impaction. Inspection of the rectum and vagina should evaluate for a rectovaginal fistula, prolapsing hemorrhoids, or rectal prolapse. Further evaluation, including radiologic and physiologic tests, have been shown in a prospective study at a tertiary colorectal referral clinic to alter the final diagnosis of the cause of fecal incontinence in 19% of cases. (From Rao SS. American College of Gastroenterology Practice Parameters Committee: diagnosis and management of fecal incontinence. American College of Gastroenterology Practice Parameters Committee. *Am J Gastroenterol*. 2004;99:1585.)

posterior vaginal wall, and perineal body can be assessed by palpating through the vagina via bimanual examination.

Testing

Clinical diagnosis based on physical examination and history alone will be accurate in most patients. However, further evaluation, including radiologic and physiologic tests, have been

shown in a prospective study at a tertiary colorectal referral clinic to alter the final diagnosis of the cause of fecal incontinence in 19% of cases. Which tests to consider should be based on history and physical examination, prior treatment, and proposed therapy. The algorithm outlined in [Figure 22.5](#) recommends further evaluation based on history and the rectal tone. Normal rectal tone directs the clinician away from anal

incontinence and toward a metabolic or colonic origin. Metabolic tests, including determination of thyroid-stimulating hormone and glucose levels, should be carried out. If chronic diarrhea is present with normal rectal sphincter tone, stool cultures, colonoscopy, and diarrhea evaluation are indicated. Differential diagnosis for a diarrhea workup will include lactose intolerance, celiac sprue, inflammatory bowel disease, irritable bowel syndrome, and bacterial overgrowth from diabetic gastroparesis. In cases of fecal incontinence with normal rectal sphincter tone without diarrhea, anal manometry to evaluate rectal sensation is useful and can help in the consideration of peripheral neuropathy causes.

Poor resting tone on rectal examination directs the clinician to a neuromuscular cause. A normal resting tone, but with poor squeeze, suggests an anterior sphincter defect and chronic third-degree laceration of the EAS. If poor rectal squeeze is detected, endoanal ultrasonography is the best first-line test.

Evaluation or further testing is performed not only for diagnostic purposes but also to determine which nonsurgical and surgical therapies are most likely to benefit the woman. In addition, certain tests, such as anal manometry or an anal sphincter ultrasound, can be used for baseline assessment to which post-treatment assessment or function can be compared. Whenever the woman's history does not match her physical examination findings, further testing should be considered. In addition, if the woman has had prior surgery or has other pelvic floor dysfunction, testing before treatment, especially surgical, may help direct care. It is important to remember that the woman may have more than one cause or pathology contributing to her fecal incontinence, such as pudendal neuropathy and an anal sphincter defect or irritable bowel in combination with a weakened pelvic floor (Table 22.3).

Diagnostic Procedures

Colonoscopy

A colonoscopy is indicated for any woman with chronic diarrhea to evaluate for inflammatory bowel disease and infectious diarrhea. Endoscopic evaluation detects mucosal disease or neoplasia effectively. This is also acceptable bowel screening for any woman older than 50 years, particularly if an acute change in bowel habits is reported. In addition, any patient presenting with fecal incontinence in the setting of rectal prolapse should undergo a colonoscopy to ensure that a rectal mass is not the cause of the prolapse.

Endoanal Ultrasound

Endoanal ultrasound (EAUS) has significantly enhanced the ability to delineate defects of the IAS and EAS. EAUS is one of the simplest and least expensive tests for imaging sphincter defects, and a study evaluating the role of anorectal physiology testing found it to be the test that most often informed management decisions. However, EAUS is user dependent and requires significant training. It is generally performed with a 10-MHz rigid probe that creates a 360-degree circular image of the anal sphincter complex, allowing assessment of the integrity, thickness, and length of the IAS and EAS. The IAS is visible as a hypoechoic circle, and the EAS is seen as a hyperechoic or mixed echogenic circle (Fig. 22.6). The distal anal canal is characterized by the presence of the EAS but a thin or absent IAS. The IAS and EAS are both robust in the mid anal canal and the proximal anal canal is identified by visualization of the puborectalis, which forms a posterior sling. Endoanal ultrasound is most useful in the evaluation of patients for chronic third-degree lacerations or occult sphincter tears. Breaks in the EAS can be readily noted. A gloved finger should always be inserted into the vagina to oppose the rectovaginal septum to the probe to determine the size of the perineal body. Knowing the boundaries of the sphincter defect and whether both the EAS and IAS are disrupted can direct the surgeon at the time of anal sphincteroplasty. Similar information can be obtained from EMG of the EAS when used to map the sphincter defect. In general, transanal ultrasound is less painful and better tolerated by the woman.

Anal Manometry

Anal manometry is a commonly used test that objectively assesses rectal sensation, anal canal pressures, and the RAIR. Anal manometry is helpful for patients who have had prior surgery to the anorectal canal or radiation therapy that could have altered the rectal storage function.

Anal manometry uses a rectal balloon to assess rectal sensation, rectal compliance, the RAIR, and maximal tolerable rectal volume (Fig. 22.7). Normal values include an initial sensation of 20 mL, urge to defecate at 80 to 120 mL, and maximum tolerable capacity at 200 to 250 mL. The RAIR is a reflex response to increased pressure in the rectum from gas or stool. Normally, the IAS relaxes to allow a sampling of the rectal contents by the anal canal to determine whether the contents are gas or stool and whether it is an appropriate time to defecate or pass flatus. At the same time, the EAS squeezes to prevent incontinence.

Table 22.3 Tests of Anorectal Function for Patients with Fecal Incontinence

Test	Measures	Indication
Anal manometry	Resting anal pressures	Low resting and squeeze pressure on rectal examination
	Maximum squeeze pressure	Prior radiation treatment
	Rectoanal inhibitory reflex	Fecal urgency
	Rectal sensation	Fecal impaction
Single-fiber EMG	Fiber density	Denervation
	Muscle activity	Reinnervation injury
		Map EAS defect
Pudendal nerve motor latency	Speed of signal along pudendal nerve	Pudendal nerve damage from childbirth or straining
Endoscopic ultrasound	IAS and EAS defect	Obstetric or traumatic sphincter injuries
Defecating proctography or MRI	Movement of pelvic floor	Perineal descent
defecography	Pelvic floor defects	Posterior compartment deficits

EAS, External anal sphincter; EMG, electromyography; IAS, internal anal sphincter.

In addition to rectal function, resting and squeeze pressures in the anal canal are obtained by pulling a perfusion catheter with radial ports (four or eight) through the anal canal. The IAS contributes 80% of the resting pressure. Although there are slight variations depending on the equipment and technique

used, normal resting pressure is in the range of 60 to 80 mm Hg. Voluntary contraction of the EAS or squeeze pressure is assessed by the force of the squeeze, which is known as the maximum pressure, and the duration of the squeeze. Normal squeeze pressure is in the 120 to 180 mm Hg range and is sustained for 20

Figure 22.6 Anal ultrasound. **A**, Anal ultrasound has significantly enhanced the ability to delineate defects of the internal and external anal sphincters. The internal anal sphincter (IAS, labeled as INT SPHINCTER) is visible as a hypoechoic circle, and the external anal sphincter (EAS, labeled as EXT SPHINCTER) is seen as a hyperechoic circle. Scarred areas have a homogeneous gray appearance. **B**, With the patient supine, a defect in the IAS from 3 to 9 o'clock and a defect at 12 o'clock in the EAS are shown. **C**, Again, with the vagina at the 12 o'clock position, there is an intact IAS and defect in the EAS. (From Stenchever MA, Benson JT, eds. *Atlas of Clinical Gynecology*. New York: McGraw-Hill; 2000.)

seconds (Fig. 22.8). Both resting and anal squeeze pressures are reduced in women with anorectal incontinence.

The utility of anal manometry is debated as most treatment decisions are based on symptoms rather than a manometric value. In addition, some studies have demonstrated that manometry poorly predicts response to surgical intervention and may not correlate well with incontinence scores after intervention.

Electromyography

EMG is used for mapping the EAS defect and for determining the presence and degree of neuropathy, denervation, and reinnervation. EMG evaluates the bioelectrical action potentials generated by the depolarization of skeletal striated muscle. This

Figure 22.7 Anal manometer, a four-channel perfusion catheter with balloon tip. There are many different types and methods for performing anal manometry. A balloon or probe is inserted into the rectum, and a pressure transducer relays information to a recorder or computer. Important manometric parameters include sphincter length, resting and squeeze pressures, rectal sensation, and presence of the anorectal inhibitory reflex (RAIR). The balloon is placed in the rectum and inflated by 10-cm³ increments to determine rectal sensation and compliance. The presence of the RAIR is determined with balloon inflation and observing the IAS relax and the EAS contract to allow for the sampling of rectal contents. The four radial ports are perfused with sterile water, and resting and squeeze pressures around the anal canal are measured at 1-cm intervals along the anal canal. The catheter can be pulled at a constant rate to determine the length of the sphincter and high-pressure or continence zone.

evaluation consists of systematic examination of spontaneous activity, recruitment patterns, and the waveform of the motor unit action potentials (MUAPs).

Performance and interpretation of EMG of the EAS requires special training and experience. A needle electrode is inserted into the skeletal muscle of the EAS. First, spontaneous activity is heard and seen. Next, the woman voluntarily squeezes her pelvic floor and recruitment activity is recorded. Straining should decrease activity and coughing should increase recruitment. The final step in analysis is evaluation of the MUAP waveform. Following nerve damage, as seen with a vaginal delivery, reinnervation of the muscle fibers leads to a single motor unit innervating multiple muscle fibers. On single-fiber EMG, the MUAPs have larger amplitudes, longer duration, and more phases or crossings of the baseline. Because discomfort and pain can occur with needle electrodes, endoanal ultrasound has replaced EMG for assessing the anatomy of the anal sphincter.

Pudendal Nerve Terminal Motor Latency

Nerve conduction studies measure the time from stimulation of a nerve to a response in the muscle it innervates. The PNTML is determined by using a glove-mounted electrode known as a *St. Mark's pudendal electrode*, connected to a pulsed stimulus generator; with the examiner's index finger in the vagina or anus, the pudendal nerve is stimulated at the ischial spine.

The latent period between the pudendal nerve stimulation and the electromechanical response of the muscle is measured. Normal PNTML is 2.0 ± 0.2 milliseconds. A normal PNTML is the measurement of the fastest response of the pudendal nerve and does not necessarily mean that the entire nerve is normal (Fig. 22.9). Prolonged PNTMLs have been found in patients with idiopathic fecal incontinence and in patients with rectal prolapse and may be predictive of continence following surgical repair. Gilliland's 1998 study suggested that PNTML was the most sensitive predictor of functional outcome of overlapping EAS repairs (Gilliland, 1998). However, these tests are rarely performed now because newer research shows poor correlation of prolonged pudendal terminal latencies with clinical symptoms, and PNTML does not seem to directly reflect nerve function in the way that quantitative EMG can.

Figure 22.8 A single-channel recording of the resting pressure of the anal canal (R) and the squeeze pressure (S). The IAS contributes 80% of the resting pressure. Voluntary contraction or squeezing of the EAS should double the resting pressure.

Defecography

Dynamic cystoproctography, or defecography, is an imaging technique that has been widely used in the evaluation of anorectal function and anatomy, dating back to the mid-1960s. Defecography may be used as an adjunct to physical examination in patients with chronic constipation and pelvic floor defects or hernias that may be contributing to their fecal incontinence. Rectal intussusceptions, rectal prolapse, and sigmoidocele can be seen on defecography, along with rectoceles that do not empty at the time of defecation. Stool retained in the rectocele can cause chronic distention of the rectum and loss of rectal sensation. The loss of rectal sensation leads to chronic constipation or impaction, causing further neuromuscular damage to the pelvic floor and ultimately fecal incontinence. Perineal descent and the anorectal angle can be objectively measured using defecography.

Fluoroscopic defecography usually involves the insertion of radio-opaque contrast transanally. The patient is then often placed into a seated position and asked to defecate, and real-time fluoroscopic images are obtained. Defecography is user dependent, and there may be significant interobserver differences in the interpretation of these images.

Magnetic Resonance Imaging of the Anal Sphincters

MRI of the anal sphincters can evaluate muscular and connective tissue supports of the pelvis. Advances in MRI technologies

using the endoanal coil, rapid sequencing, and cinematic display have replaced defecography for the evaluation of the pelvic floor and defecation disorders in some centers. Muscular defects, along with pelvic organ prolapse and perineal descent, can be assessed. Specialized dynamic MRI has the advantage of evaluating other pelvic anatomy, which may assist in the interpretation of the images. A common criticism of MRI defecography is that it is often performed in the supine position, which is not physiologic. Although open MRI technology addresses this issue, it is not readily available at most centers.

Transit Study

A colonic transit study is used to evaluate colonic motility and is most often used for the evaluation of chronic constipation. For patients for whom fecal impaction or overflow incontinence is high on the differential, a transit study may be indicated. There are numerous variations of the study. The woman ingests a Sitzmark capsule containing 20 or 25 radiopaque rings. She does not take any laxatives or bowel stimulants. On days 1, 3, and 5 after taking the capsule, an abdominal flat radiographic plate is obtained. Normally, 80% of the capsules should have been passed. Diffuse or global colon dysfunction is indicated if the rings are dispersed throughout the colon or segmental abnormalities can be seen if the rings are clustered in one area or trapped in a rectocele.

Figure 22.9 Pudendal nerve terminal motor latencies (PNTML). Normal bilateral PNTML have been shown to be 2.0 ± 0.2 milliseconds. The latency response is measured from the onset of the stimulus to the onset of the response in the EAS. A normal PNTML is the measurement of the fastest response of the pudendal nerve and does not necessarily mean that the entire nerve is normal, and neither does an abnormal latency indicate abnormal muscle function. A damaged nerve can heal and reinnervate the muscle and, although the PNTML may be slightly prolonged, the muscle functions normally. (From Stenchever MA, Benson JT, eds. *Atlas of Clinical Gynecology*. New York: McGraw-Hill; 2000.)

Table 22.4 Treatment of Fecal Incontinence

Management	Option
Education and lifestyle interventions	Regular bowel evacuation, optimization of stool consistency, unclear role for caffeine restriction, weight reduction, smoking cessation, gastrointestinal medication review and change, treatment of reversible causes of diarrhea
Diet	Dietary manipulation with soluble fiber for avoiding loose stools and for mild FI
Anal sphincter exercises or biofeedback training	Weak evidence suggesting efficacy for exercises, but safe, noninvasive treatment; biofeedback has insufficient evidence to recommend because of inadequate trials, but is noninvasive
Electrical stimulation	Insufficient evidence to recommend but small trials show some benefit
Medications	Loperamide, diphenoxylate plus atropine (concern of central nervous system side effects) for diarrhea; enemas, laxatives, suppositories for complete bowel emptying
Sacral nerve stimulation	Approved by the U.S. Food and Drug Administration in 2011, and multiple studies show benefit up to 5 years
Surgery	Anal sphincteroplasty indicated for postobstetric laceration or highly symptomatic women who have failed conservative measures with defined sphincter defect

TREATMENT

Treatment of fecal incontinence includes lifestyle changes, dietary management, biofeedback, electrical stimulation, medications, devices, sacral nerve stimulation, and surgery (Table 22.4). Obstructive devices, including transanal plugs, have been marketed but are not widely used. A vaginal pessary-like bowel control device that inflates posteriorly to obstruct the bowel is recently approved and shows some promise. Obviously, fecal incontinence should be treated based on the diagnosis as in medications or surgery for inflammatory bowel disease or surgery for a neoplasm of the cauda equina. Treatment of any underlying conditions that may be causing fecal incontinence is the first step in management. For all women with fecal incontinence, maintaining normal stool consistency and frequency is essential first-line treatment. For women with associated liquid or watery stools, dietary modifications and medications are first-line therapy.

Education, Diet, and Lifestyle Interventions

Education regarding good bowel function makes sense, but little research exists to support this strategy. Having a predictable, regular bowel evacuation program and optimizing stool consistency to avoid the loose stool or frank diarrhea that taxes the system seems to improve fecal incontinence. Having a larger and formed stool, rather than liquid stool, allows for rectal distention and sensation that may provide earlier warning and better emptying.

Increasing dietary fiber with diet changes, bulking agents, or fiber supplements such as methylcellulose or psyllium helps increase stool size. Eating high-fiber cereals and drinking hot coffee or tea at breakfast are encouraged to stimulate the gastrocolic reflex and elimination before leaving home. There is

reasonable evidence that adding soluble dietary fiber compared with placebo in women with loose stools reduces the rate of FI. However, women must be warned that fiber supplements can worsen diarrhea and cause bloating in some people. Increases in fiber also had benefit for women with mild FI, without loose stools. By keeping a food diary, women may identify offending foods (e.g., lactose, fructose) that aggravate their FI and learn to avoid those foods. Nicotine can hasten rectosigmoid transit time and stimulate distal colonic motility, so it may exacerbate fecal urgency. In a nursing home study, a daily exercise program with education around toileting opportunities improved FI. Brisk exercise, particularly after meals, may precipitate FI because of increased colonic activity.

Biofeedback

For fecal incontinence, like urinary incontinence, biofeedback requires a motivated woman, feedback device, and planned exercise program. Although the woman may not perceive normal sensation or be able to contract her pelvic floor voluntarily, she must be neurologically intact to benefit from biofeedback. No correlation has been seen with premanometry testing as long as some neuromuscular function is present.

One trial has reported 60% to 70% of patients with fecal incontinence secondary to an abnormal pelvic floor will have a 90% reduction in incontinence with biofeedback. Further studies have shown varying success rates of 38% to 100%. A National Institutes of Health (NIH) consensus statement has concluded that biofeedback is effective in the first year postpartum for reversing some pregnancy-related fecal incontinence. The largest prospective study, by Norton and others, compared standard care with biofeedback (Norton, 2003). The improvement was 54% in the biofeedback group and 53% in the standard care group. Although this questions the effectiveness of biofeedback, it is important to consider that the standard group received nine 40- to 60-minute sessions with a nurse specialist on diet, fluid management, bowel evacuation techniques, bowel training, and use of antidiarrheal medications. Also, biofeedback helped over 50% of patients with this difficult problem. The other lesson from this trial is that more than 50% of patients improved with conservative measures.

Biofeedback of any type is based on the woman hearing, seeing, or sensing a response from a planned exercise. A measuring device, electrode or pressure transducer, is used transvaginally or transanally to record and provide feedback to the woman on how she is squeezing the pelvic floor. She then uses this feedback to increase or lengthen the pelvic floor contraction. If the woman has incontinence secondary to a sensory deficit in the rectum, rectal balloons can be used to “retrain” the woman to perceive rectal distention while squeezing her external sphincter in response to rectal distention. The woman can be taught by a physical therapist, who not only provides encouragement but also instructs on proper technique. Although initially labor-intensive, biofeedback has no side effects or morbidity and can be used in conjunction with other treatment modalities, including surgery. The American College of Gastroenterology recommends biofeedback therapy despite imperfect evidence to support its use. In addition, for patients with urinary and fecal incontinence, a single therapy may improve both conditions.

Biofeedback is often used in conjunction with pelvic floor physical therapy and in a single-center randomized control trial

the addition of biofeedback to a regimen of pelvic floor exercises resulted in 44% of patients reporting complete continence at 3 months compared with 21% in patients undergoing pelvic floor exercises alone ($P = .008$).

Electrical Stimulation Therapy

Functional electrical stimulation therapy has been shown to improve fecal incontinence in patients with a weakened pelvic floor who are unable to contract their EAS or puborectalis on command. Because of the expense, electrical stimulation is generally reserved for patients who are unable to respond to traditional biofeedback protocols. Both transvaginal and transrectal probes are available. Most protocols recommend high-frequency stimulation at a maximum tolerable stimulation of 50 Hz for 15 to 20 minutes twice daily. Response to therapy is usually seen in 6 weeks, with maximum improvement by 12 weeks, but reported benefits are slight. New stimulation protocols with both biofeedback and electrical stimulation in a 2010 randomized trial of 158 patients were promising at 3 months, with a 50% continence rate.

Devices

A vaginal bowel-control system that looks like a pessary with an inflatable posterior balloon has been tested. One multicenter study found 61 of 110 women (56%) were successfully fit with the device. The success rate at 3 months was 86%, which meant the women considered their bowel symptoms to be “much better” or “very much better” with improvement in quality of life (Richter, 2015). Pelvic cramping or discomfort occurred in 23%. This is a promising nonsurgical option and is just becoming clinically available.

Percutaneous Tibial Nerve Stimulation

Tibial nerve stimulation is thought to lead to changes in anorectal neuromuscular function because of shared sacral segmental innervation. Some initial trials were promising. Unfortunately, the most recent randomized controlled trial of 227 patients given percutaneous tibial nerve stimulation (PTNS) like that used for urinary urge incontinence showed no significant benefit over sham stimulation (Knowles, 2015). In the PTNS group, 38% had a greater than 50% reduction in episodes of fecal incontinence per week compared with 31% in the sham stimulation group. Although this was not statistically significant, it may have been a clinically relevant improvement to individual patients. The study was not large enough to look at subgroups, but patients with marked fecal urgency and inability to delay defecation would be a further group to study.

Medications

No specific medication is approved for fecal incontinence except for antidiarrheal medications. A Cochrane review concluded that there is little evidence to guide clinicians in the selection of pharmacologic agents to treat fecal incontinence. To slow intestinal transit and allow for increased water absorption, several medications (Table 22.5) are available. Loperamide is an antidiarrheal agent that slows small and large bowel peristalsis, thereby increasing transit time through the gastrointestinal tract. Loperamide appears more effective than diphenoxylate for fecal urgency-related incontinence and also increases IAS tone and decreases sensitivity of the RAIR. In addition, loperamide is almost completely

Table 22.5 Medications for Treatment of Diarrhea

Drug	Dosage*	Mechanism of Action
Loperamide	2 mg tid or 4 mg followed by 2 mg after loose bowel movement Maximum, 8 mg/day	Inhibits circular and longitudinal muscle contraction
Diphenoxylate with atropine	5 mg qid initial dose	Direct action of circular smooth muscle to decrease peristalsis
Hyoscyamine sulfate	0.375 mg bid timecaps	Anticholinergic
Cholestyramine	4-mg pack qid or bid	Binds bile acids after cholecystectomy

*bid, Twice a day; tid, three times per day; qid, four times per day.

metabolized in the liver, resulting in minimal levels entering the systemic circulation. Also, unlike diphenoxylate, it does not cross the blood-brain barrier and therefore has fewer central nervous system (CNS) side effects. Amitriptyline, a tricyclic antidepressant, has also been shown in a small study of 42 patients to significantly improve symptoms of fecal incontinence, likely by increasing colonic transit time. In addition, in some patients who fail to respond to loperamide, cholestyramine has proved to be effective. Hyoscyamine is recommended for women with fecal incontinence after meals. Taking this before meals is recommended. For some patients, a daily cleansing of the rectum with an enema allows for several hours of freedom from their incontinence.

Surgery

Surgical management of fecal incontinence includes sacral neuromodulation, repair of rectal prolapse, anal sphincteroplasty, radiofrequency treatment of the anal canal, injectable perianal bulking materials, anal sphincter neomuscular flaps, and implantation of artificial sphincters. Unfortunately, postanal repair or posterior levatoroplasty has not been shown to be effective for the treatment of fecal incontinence in most patients and will not be discussed here. Patients with anatomic defects that may be causing or contributing to their fecal incontinence including full thickness or hemorrhoidal prolapse, fistula in ano, and rectovaginal fistula should have these repaired first as this often improves or resolves the incontinence.

Injectables

Perianal injection of bulking agents for fecal incontinence has been done with several materials, including silicone, collagen, and carbon-coated microbeads. The goal is for the bulking agent to augment the IAS closing the anal canal or raising pressure inside the anal canal. A double-blinded trial randomized patients who had failed conservative measures to either nonanimal stabilized hyaluronic acid (NASHA Dx) ($n = 136$) or sham treatment ($n = 70$) (Graf, 2011). Patients with persistent complaints of fecal incontinence at 1 month were offered retreatment. At 6 months, 71 patients (52%) in the treatment group compared with 22 patients (31%) in the sham group reported $\geq 50\%$ improvement from baseline in the number of fecal incontinent episodes ($P = .0089$). However, whereas patients in the treatment group had a higher number of incontinence-free days, incontinence scores were not significantly different between the

two groups. Danielson evaluated quality of life 2 years after injection of bulking agents for the treatment of fecal incontinence and found that patients who received two injections were more likely to achieve 50% improvement compared with those receiving one injection (Danielson, 2013). However, only patients who achieved at least a 75% improvement in symptoms reported a benefit in terms of quality of life (Danielson, 2013). A Cochrane review from 2013 concluded that although several studies demonstrated short-term benefits, the overall quality of the data is poor and long-term follow-up is still needed (Maeda, 2013). Injection of bulking agents is contraindicated in patients with full-thickness rectal prolapse, rectocele, anorectal malformations, active inflammatory bowel disease, and a history of anorectal radiation.

SECCA Procedure

The SECCA procedure, or radiofrequency anal sphincter remodeling, involves delivering temperature-controlled radiofrequency waves to the anal canal resulting in denatured collagen and changes to tissue compliance potentially narrowing the anal canal. A review of the literature reveals that most studies are small, single institution series with short follow-up. Data from randomized control trials are lacking, but one small trial with a 12-month follow-up showed modest improvement (Frascio, 2014). Complications, including pain, bleeding, and ulceration, are rare. The procedure is contraindication in patients previously treated with injection of a bulking agent.

Anterior Sphincteroplasty

Sphincteroplasty is a common surgical treatment for persistent anal incontinence after obstetric anal sphincter lacerations, but long-term results remain disappointing. The literature is conflicting regarding overlapping versus end-to-end sphincteroplasty techniques. Anterior overlapping sphincteroplasty is performed through a curvilinear incision in the perineum over the outer edge of the EAS defect. The entire sphincter complex is dissected widely to the anorectal ring. The incision should not extend beyond 180 degrees of the circumference to avoid injury to the pudendal nerves posterior laterally. Since it is important to dissect out to healthy sphincter muscle, this technique should not be used for sphincter injuries that extend greater than 180 degrees of the circumference. The scar is divided anteriorly and overlapped to create a narrowed anal opening being careful to avoid stenosis. Using 2-0 or 3-0 prolonged absorbable sutures, mattress sutures are placed through the sphincters (Fig. 22.10). The perineal body is reapproximated and the anoderm closed loosely with interrupted 3-0 chromic sutures, allowing space for drainage. Alternatively a drain may be placed in the perineal closure. It is important to avoid separating the internal and external sphincters or excising the scar. The advantage of the overlapping sphincteroplasty over the traditional end-to-end repair is decreased tension to prevent separation of the suture line once anesthesia no longer prevents sphincter contraction.

Overlapping anterior anal sphincteroplasty provides symptomatic control of incontinence in 60% to 80% of patients with anatomic EAS defects in the short term. Repair of an anal sphincter laceration includes not only repair of the EAS but also identification and repair of any IAS defects. Because the IAS maintains the resting tone of the anus, it is important to restore sphincter integrity, especially for control of flatus. Unfortunately,

symptomatic relief is often not durable, and overlapping sphincteroplasty cure rates 5 to 10 years after surgery may be as low as 1% to 28% (Table 22.6). This has called into question the use of overlapping sphincteroplasty as the primary surgical treatment for fecal incontinence particularly in women who develop symptoms years after their initial sphincter injury.

A number of studies have attempted to identify factors associated with sphincteroplasty outcomes, but no single variable has proved predictive. Unilateral or bilateral pudendal nerve injury has been associated with worse outcomes in some reports, and therefore patients who have an anal sphincter defect and prolonged PNTML should be counseled that their chance of continence following surgery may be decreased (Gilliland, 1998).

When anal sphincter injury occurs during vaginal delivery, the type of repair needed has been debated. To date, according to only a few studies, there is no significant difference between end-to-end and overlapping anal sphincteroplasties. The outcome of anal sphincteroplasties after delivery is unacceptably poor, with 47% to 67% of women complaining of defecatory symptoms such as flatus incontinence, fecal urgency, and fecal incontinence. Although frank fecal incontinence is reported at a much lower rate, 2% to 9%, the other defecatory symptoms are nonetheless bothersome to women. Furthermore, endoanal ultrasound examinations after sphincteroplasty show persistent anatomic defects in 40% to 85% of repairs.

Because the outcome after anal sphincteroplasty is suboptimal, prevention emerges as an even more important consideration. Vaginal childbirth injury to the anal sphincter is such a common cause of fecal incontinence that prevention should start here. Midline episiotomy has been shown repeatedly in various studies to be strongly associated with anal sphincter damage. Avoidance of routine episiotomy and consideration of a mediolateral episiotomy when absolutely necessary could be beneficial in prevention efforts.

Sacral Nerve Stimulation

In 2011, a sacral nerve stimulation device was FDA approved for treating chronic fecal incontinence. In one randomized controlled trial, 54 of 120 patients with severe fecal incontinence improved with the test stimulation and had the permanent generator placed, and 22 (47%) were continent. Observational studies have reported similar improvements. A 2010 study reported on long-term outcomes in a cohort analysis of consecutive patients. Treatment success was defined as a more than 50% reduction in episodes of fecal incontinence compared with baseline. Temporary sacral nerve stimulation was performed in 118 patients and 91 (77%) were considered suitable for permanent implantation. The median follow-up period was 22 months (range, 1 to 138 months); 70 patients were followed for 1 year, with success in 63 (90%). Of 18 patients followed for 5 years, 15 (83%) reported continued success—11 (61%) maintained full efficacy, 4 (22%) reported some loss, and 3 (17%) reported complete loss. Three patients with a 10-year follow up had no loss in efficacy. A systematic review reported that 79% of patients experienced at least 50% improvement in weekly fecal incontinence episodes in the short term and 84% in the long term (>36 months) based on a pooled analysis of all current studies in the literature (Thin, 2013). When these pooled data were analyzed on an intention-to-treat basis, 63% of patients achieved improvement of at least 50% in the short term and 35% reported 100% continence in

Figure 22.10 Sphincter drawing. **A**, Dovetail sign with loss of anal skin creases anteriorly. **B**, Trans-perineal incision. **C**, EAS identified. **D**, Overlapping sphincteroplasty and IAS repaired.

the long term. A large, prospective, multi-institutional, non-randomized study found that 89% of patients achieved greater than 50% improvement in fecal incontinence episodes and at 5 years 36% of patients had complete continence (Hull, 2013). The infection rate was reported at 10.8% and at 5 years 24.4% of patients had undergone at least one revision or replacement.

Sacral neuromodulation was initially viewed as a treatment for patients who had failed an anterior sphincteroplasty or did not have a sphincter defect, but it is increasing being seen as an alternative to other surgical options and according to the

latest practice parameters of the American Society of Colon and Rectal Surgeons it may be considered a first-line surgical treatment of fecal incontinence (Paquette, 2015). A study that included 91 patients with no sphincter defect and 54 patients with a complete external sphincter defect confirmed with ultrasound showed that the presence of a sphincter defect did not affect the outcome of sacral neuromodulation (Johnson, 2015). Significant improvements in fecal incontinence scores have been seen in patients with up to a 120-degree sphincter defect (Tjandra, 2008). In fact, symptomatic relief may be

achieved with neuromodulation in patients with a history of sphincter defect, previous sphincter repair, and pudendal neuropathy (Brouwer, 2010). However, there have been no randomized control trials comparing sacral neuromodulation to overlapping sphincteroplasty.

Sacral neuromodulation is a less invasive treatment than other surgical alternatives and has few complications, so it is a promising option that is gaining popularity. Long-term follow-up is required, though, to ensure continued success.

Neosphincters

There are basically two types of neosphincters, one using the woman's own skeletal muscle, usually the gracilis, and the other using an artificial Silastic cuff connected to a fluid reservoir to occlude the anal canal. The gracilis muscle wrap has been shown to have inconsistent results. Initially described by Pickrell and colleagues in 1952, the entire muscle is mobilized and its distal portion wrapped snugly around the anus, anchored to the contralateral ischial tuberosity (Pickrell, 1952). The addition of chronic, low-frequency electrical stimulation of the nerve or muscle has been used to convert fatigue-prone type II to fatigue-resistant type I muscle fibers. Once converted, the muscle may be continuously stimulated, resulting in prolonged closure of the anal canal. A report by Baeten and colleagues for the Dynamic Graciloplasty Therapy Study Group reported on 123 adults treated at 20 institutions with dynamic graciloplasty and found that 63% of patients reported a 50% or greater improvement in incontinent events 1 year after surgery (Baeten, 2000). Another 11% noted some improvement, and 26% reported no improvement or worsened incontinence. There was one surgery-related death; 74% of patients experienced an adverse event related to the treatment, with 40% of patients requiring

additional surgery. Despite these frequent complications, most patients showed a significant improvement in quality of life postsurgery.

Artificial sphincters are indicated for patients with anal incontinence caused by neuromuscular disease, congenital malformations, sphincter defects greater than 180 degrees, or patients who have failed all other treatments. A Silastic cuff is connected to a fluid reservoir that encircles the anal canal to cause closure. The cuff is deflated before defecation. Although most studies are small and retrospective, there have been a few prospective studies that have shown improvement in symptoms if the device is retained without complication (Ruiz Carmona, 2009; Wong, 2011). However, complications including infection, anorectal ulceration, device migration, pain, device erosion, and mechanical breakdown are common.

Stoma Creation

A stoma may be offered if all other acceptable treatments have failed or the patient does not want to pursue other surgical options. Although this sounds extreme, it can greatly improve the quality of life for women with severe fecal incontinence.

RECTOVAGINAL FISTULAS

Although not a true source of fecal incontinence by definition, rectovaginal fistulas (RVFs) are common enough complications of vaginal birth and gynecologic surgeries to be addressed under this heading. An RVF is an abnormal connection between the vagina and rectum. Whenever a woman presents with complaints of fecal or flatal incontinence, an RVF should be included in the differential diagnosis.

Table 22.7 Origin of Rectovaginal Fistula

Category	Condition	Mechanism
Traumatic Obstetric	Prolonged second stage of labor	Pressure necrosis of rectovaginal septum
	Midline episiotomy	Extension directed into rectum
	Perineal lacerations	
Foreign body	Vaginal pessaries	Pressure necrosis
	Violent coitus	Mechanical perforation
	Sexual abuse	Mechanical perforation
Iatrogenic	Hysterectomy	Injury to anterior rectal wall
	Stapled colorectal anastomosis	Staple line includes vagina
	Transanal excision of anterior rectal tumor	Deep margin of resection into vagina
	Enemas	Mechanical perforation
	Anorectal (e.g., incision and drainage of intramural abscesses)	Mechanical perforation
Inflammatory	Crohn disease	Transmural inflammation-perforation
	Pelvic radiation	Early tumor necrosis
	Pelvic abscess	Late transmural inflammation
	Perirectal abscess	Late transmural inflammation
Neoplastic	Rectal	Local tumor growth into neighboring structure
	Cervical	
	Uterine	
	Vaginal	
	Primary or recurrent tumors	

From Stenchever MA, Benson JT, eds. *Atlas of Clinical Gynecology*. New York: McGraw-Hill; 2000.

The causes of RVF, as seen in Table 22.7, include traumatic, inflammatory, and neoplastic origins, but obstetric injuries are the most common cause. It is estimated that 0.1% of vaginal births will result in an RVF.

A fistula occurring caudad or adjacent to the EAS is termed an *anovaginal fistula* and is managed differently from an RVF. Fistulas that occur more than 3 cm above the anal verge are true RVFs. Most RVFs secondary to obstetric injury occur in the lower third of the vagina and may be associated with a sphincter defect in the EAS. It is important to evaluate the EAS (discussed earlier) with transanal ultrasound or EMG to map any defects prior to surgical treatment.

Fistulas secondary to surgical trauma, malignancy, or an inflammatory process may occur at any point along the vaginal wall, including the apex. If a fistula develops after a difficult surgery, such as after pelvic inflammatory disease, or radiotherapy, it is important to check for more than one fistula prior to repair. If the woman has a history of malignancy, examination with biopsy specimens should be performed to rule out cancer as the cause of the fistula.

Depending on the size and location of the fistula, the woman may be almost asymptomatic or complain of a small amount of flatus passing into her vagina with a low small fistula. With a large fistula, she may have formed stool coming

through the vagina with every bowel movement, causing significant distress and hygiene problems. Rectal bleeding is more likely to be reported with a neoplastic process or post-pelvic radiation.

Evaluation of a woman includes a history and physical examination to determine cause. If there is suspicion of inflammatory bowel disease, a colonoscopy is warranted. Perineal skin and rectal examinations are important to visualize the fistula tract and determine the integrity of the anal sphincters and quality of the tissues surrounding the fistula, and to palpate for abscesses and other masses. Most obstetric-related RVFs show the fistula along the scar line. Methylene blue mixed in lubricant and placed in the rectum can help identify the fistula. If still not identified, a dilute methylene blue enema with a tampon in the vagina may help in isolating the fistula. If the vaginal orifice is found, but not the rectal opening, insertion of an angiocatheter with a squirting of hydrogen peroxide can show bubbling on the rectal side. A small lacrimal duct probe may allow passage through the vaginal tract to identify the rectal exit site.

An office anoscopy or proctoscopy may also help evaluate the surrounding tissues. In general, a mature epithelialized fistula that is not infected is not painful on digital examination. If the examination in the office is not successful in locating the fistula or is too painful for the woman, she should be taken to the operating room for examination under anesthesia. If the fistula has still not been identified, filling the vagina with water and insufflating the rectum should produce bubbling in the vagina that can be traced to the opening. A barium enema may also be helpful for identifying high fistulas. Vaginography using dilute barium solution may also help to identify a fistula.

Surgical management of an anovaginal or anoperineal fistula is accomplished by opening the fistula tract, curetting the tract, and leaving the tract open to heal secondarily. Excision of the tract and primary closure will result in recurrent fistula formation in most cases.

Many surgical procedures have been described for the treatment of RVF. Regardless of the procedure chosen, basic surgical principles must be followed. The tissue must be healthy, well vascularized, and free of infection and induration. This may require waiting for up to 3 months following the original trauma or surgery for complete healing. If there is significant fecal contamination, prior radiation, or persistent abscess, a diverting colostomy should be considered. After a colostomy, a delay of 8 to 12 weeks is generally required for the inflammation and cellulites around the fistula to heal. At the time of repair, a Martius fat pad graft can be used to increase the vascular supply to the area. Preoperatively, the woman should have a complete mechanical bowel preparation starting several days before the surgery to prevent liquid stool from contaminating the field. Some surgeons may place the woman on a liquid diet several days before surgery with no mechanical bowel preparation except enemas until clear the night before surgery. The goal is to have no liquid stool in the rectum and to have the woman's first postoperative bowel movement, several days after surgery, be soft but formed. Antibiotic bowel prophylaxis is warranted.

Other surgical principles include excision of the entire fistulous tract, wide mobilization of the rectal tissue, and broad

tissue-to-tissue closure without tension. The rectal side is the high-pressure side and requires attention to repair. The vaginal side may be closed or left open to drain, if indicated, and should close spontaneously. A delayed absorbable suture, such as 3-0 Polysorb (glycolide-lactide copolymer), is used on all layers. Alternatively, a monofilament delayed absorbable suture such as Maxon (monofilament polyglyconate) or PDS (polydioxanone) may lower the risk of infection over a braided suture. Permanent sutures are not used.

Transvaginal and transrectal repairs have been described, but gynecologists generally prefer the transvaginal approach. Depending on the location and need to repair the anal sphincters, an uncomplicated fistula can be repaired as for a fourth-degree laceration as a perineoproctotomy with layered closure. After cutting from the perineal body, through the sphincters and to the fistulous tract, care must be taken to excise the tract and any surrounding scar tissue. A two-layered closure of the rectum and anal canal is then performed, as in a fourth-degree closure. Care should be given to closing the EAS.

To preserve an intact sphincter, the RVF can be cored out by placing a pediatric Foley transvaginally, filling the balloon on the rectal side, and then using the Foley for traction by pulling upward. After excision, depending on the size, a small fistula can be closed with two-layer purse-string sutures or with an interrupted two-layer closure.

Transrectal repairs, preferred by many colorectal surgeons, generally involve the development of rectal mucosal flaps, mobilized and brought down or lateral to cover the excised fistula site. In 23 patients treated at the Cleveland Clinic with rectal advancement flaps, fistulas were successfully cured in 77% of patients with obstetric or surgical injury and 60% of patients with Crohn disease.

Postoperatively, the woman's diet and medications should be managed to keep her bowel movements soft, but formed. In most cases, a clear liquid diet is continued for the first 3 days after surgery, followed by a low-residue diet. Broad-spectrum antibiotics should be continued for 2 weeks. Sitz baths, two or three times daily, followed by the use of a blow dryer or heat lamp, keep the area clean and dry.

KEY POINTS

- Estimates of fecal incontinence range from 11% to 15% of community-dwelling women older than 64 years.
- Over 30% of women reporting urinary incontinence also report fecal incontinence, known as *dual incontinence*.
- The IAS, under autonomic control, maintains the high-pressure zone or continence zone and, along with the EAS, keeps the anal canal closed.
- The EAS provides the voluntary squeeze pressure that prevents incontinence with increasing rectal or abdominal pressure. The EAS is innervated by the hemorrhoidal branch of the pudendal nerve from the S2-S4 nerve roots.
- A common cause of fecal incontinence is damage to the anal sphincter at the time of vaginal delivery, with or without neuronal injury. Prevention of these injuries is critical.
- The incidence of occult external anal sphincter disruption after vaginal delivery determined by endoanal ultrasound ranges from 11% to 35%. The chance of muscular injury is increased with midline episiotomy, instrumented delivery, and vaginal delivery of larger infants.
- Approximately 1 in 10 women will develop some fecal incontinence or fecal urgency after one vaginal delivery.
- At a tertiary colorectal referral clinic, a prospective study showed that further evaluation, including radiologic and physiologic tests, altered the final diagnosis or the cause of fecal incontinence in 19% of cases.
- Biofeedback for patients with fecal incontinence shows a similar reduction in incontinence episodes after intense education with a nurse specialist on the subjects of bowel care, medications, and dietary and fluid management. This highlights the importance of conservative management techniques.
- Overlapping anterior anal sphincteroplasty provides symptomatic control of incontinence in 60% to 80% of patients initially, but long-term outcomes are not nearly as successful.

Genital Tract Infections

Vulva, Vagina, Cervix, Toxic Shock Syndrome, Endometritis, and Salpingitis

Carolyn Gardella, Linda O. Eckert, Gretchen M. Lentz

For clarity of presentation, discussion of infectious diseases of the female genital tract is divided into those of the lower genital tract, the vulva, vagina, and cervix; and those of the upper genital tract, the endometrium and fallopian tubes. However, the female genital tract has anatomic and physiologic continuity, so infectious agents that colonize and involve one organ often infect adjacent organs. To understand the pathophysiology and natural history of infectious diseases of the genital tract, one must keep this continuity in mind.

The symptoms caused by infections of the lower genital tract produce the most common conditions seen by gynecologists. Therefore the initial focus of this chapter is on clinical presentation and the differential diagnosis of vulvitis, vaginitis, and cervicitis.

Toxic shock syndrome (TSS) and syphilis are also discussed in this chapter. Although the most devastating pathologic processes from these diseases occur in sites other than the genital tract, they often obtain entry into the body through the vulvar, rectal, vaginal, or cervical epithelium.

Many of the infections discussed in this chapter may be acquired through sexual contact and are termed *sexually transmitted infections* (STIs). STIs often coexist—for example, *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. When one disease is suspected, appropriate diagnostic methods must be used to detect other infections.

The Centers for Disease Control and Prevention (CDC) regularly revises management protocols for STIs. Recommendations and medications in this edition are based on the 2015 CDC guidelines. Readers are urged to consult updates in the online CDC guidelines (<http://www.cdc.gov>) because bacterial sensitivities and epidemiologic concerns may lead to changes in treatment protocols.

INFECTIONS OF THE VULVA

The skin of the vulva is composed of a stratified squamous epithelium containing hair follicles and sebaceous, sweat, and apocrine glands. The subcutaneous tissue of the vulva also contains specialized structures such as the Bartholin glands. Similar to skin elsewhere on the body, the vulvar area is subject to primary and

secondary bacterial, viral, parasitic, or fungal infections and is sensitive to hormonal and allergic influences. Vulvar pruritus accounts for approximately 10% of outpatient gynecology visits. Vulvar itching or burning of acute onset and short duration suggests infection or contact dermatitis. Skin fissures and excoriation may be signs of infection, may be caused by the woman's scratching as a result of irritation from a vaginal discharge, or may be the manifestation of a primary dermatologic disease. [Box 23.1](#) presents the differential diagnosis of vulvar pruritus and irritation ([Prabhu, 2015](#)).

Box 23.1 Causes of Vulvar Pruritus and Irritation

Acute:

Contact Dermatitis

Allergic
Irritant

Infections

Candidiasis
Scabies
Human papilloma virus
Molluscum contagiosum
Trichomoniasis

Chronic:

Contact Dermatitis

Allergic
Irritant

Vulvar Dystrophies

Lichen planus
Lichen sclerosis
Lichen simplex chronicus
Psoriasis

Infections

Candidiasis
Human papillomavirus

Neoplasia

Paget disease
Vulvar cancer

Atrophy

INFECTIONS OF BARTHOLIN GLANDS

Bartholin glands are two rounded, pea-sized glands deep in the perineum that are not palpable unless enlarged. They drain via ducts approximately 2 cm long lined by transitional epithelium and located at the entrance of the vagina at 5 and 7 o'clock, in the groove between the hymen and the labia minora. Mucinous secretions from Bartholin glands provide moisture for the epithelium of the vestibule. Approximately 2% of adult women develop enlargements of one or both glands. The most common cause is cystic dilation of the Bartholin duct (Fig. 23.1), typically caused by distal obstruction secondary to non-specific inflammation or trauma. Following obstruction, there is continued secretion of glandular fluid, which results in the cystic dilation.

The differential diagnosis of vulvar cysts also includes mesonephric cysts of the vagina and epithelial inclusion cysts. Mesonephric cysts are generally more anterior and cephalad in the vagina, whereas epithelial inclusion cysts are more superficial. Rarely, a lipoma, fibroma, hernia, vulvar varicosity, or hydrocele may be confused with a Bartholin duct cyst.

Most women with Bartholin duct cysts are asymptomatic. The cysts may vary from 1 to 8 cm in diameter and are usually unilateral, tense, and nonpainful. Most cysts are unilocular. However, in chronic or recurrent cysts there occasionally are multiple compartments.

In contrast, an abscess of a Bartholin gland tends to develop rapidly over 2 to 4 days with significant symptoms, including difficulty in ambulation. Acute pain and tenderness can be severe and are secondary to rapid enlargement, hemorrhage, or secondary infection. The signs are those of a classic abscess: erythema, acute tenderness, edema and, occasionally, cellulitis of the surrounding subcutaneous tissue. Without therapy, most

Figure 23.1 Bartholin abscess. The mass is tender and fluctuant and is situated on the lower lateral aspect of labium minus at 5 o'clock. (From Kaufman RH. Cystic tumors. In: Kaufman RH, Faro S, eds. *Benign Diseases of the Vulva and Vagina*. 4th ed. St. Louis: Mosby-Year Book; 1994.)

abscesses tend to rupture spontaneously by the third or fourth day. Unilateral or bilateral Bartholin gland infection in most cases is not caused by a sexually transmitted infection. Positive cultures from Bartholin gland abscesses are often polymicrobial and contain a wide range of bacteria similar to the normal flora of the vagina.

The treatment of enlargement or infection of Bartholin glands depends on symptomatology. Asymptomatic cysts in women younger than 40 years do not need treatment. Simple incision and drainage of a Bartholin gland cyst or abscess is not recommended because recurrence after incision and drainage is frequent. Instead, the surgical treatment of choice is marsupialization to develop a fistulous tract from the dilated duct to the vestibule. An elliptical wedge of tissue is excised over the cyst just proximal to the hymenal ring. A cruciate incision is made into the cyst wall, and the edges of the duct or abscess are everted and sutured to the surrounding skin with interrupted absorbable sutures forming an epithelialized pouch that provides ongoing drainage for the gland. The recurrence rate following marsupialization is approximately 5% to 10%. An alternative surgical approach is to insert a Word catheter, a short catheter with an inflatable Foley balloon, through a stab incision into the abscess and leave it in place for 4 to 6 weeks (Fig. 23.2). During this period, a tract of epithelium will form. All the procedures mentioned may be performed with local anesthesia. Antibiotics are not necessary unless there is an associated cellulitis surrounding the Bartholin gland abscess.

Women older than 40 years with gland enlargement require a biopsy to exclude adenocarcinoma of the Bartholin gland. Excision of a Bartholin duct and gland is indicated for persistent deep infection, multiple recurrences of abscesses, or recurrent enlargement of the gland in women older than 40 years. Excision can be challenging because of the rich vascular supply to the region and may be accompanied by morbidity, including intraoperative hemorrhage, hematoma formation, fenestration of the labia, postoperative scarring, and associated dyspareunia. It is best to use regional block or general anesthesia for excision. Excision of a Bartholin gland for recurrent infection should be performed when the infection is quiescent (Heller, 2014; Kessous, 2013; Khanna, 2010; Li, 2011; Wechter, 2009).

Figure 23.2 Word catheters before and after inflation. They are used to develop a fistula from a Bartholin cyst or abscess to the vestibule. (From Friedrich EG. *Vulvar Disease*. 2nd ed. Philadelphia: WB Saunders; 1983.)

PEDICULOSIS PUBIS AND SCABIES

The skin of the vulva is a frequent site of infestation by animal parasites, the two most common being the crab louse and the itch mite. Ideally, early diagnosis and treatment are of the utmost importance in controlling parasitic infection.

Pediculosis pubis is an infestation by the crab louse, *Phthirus pubis*. The crab louse is also called the *pubic louse* and is a different species from the body or head louse. Lice in the pubic hair are the most contagious of all STIs, with over 90% of sexual partners becoming infected following a single exposure. The louse is usually transmitted by close contact, although nonsexual transmission of pubic lice has been documented from towels or bedding. *P. pubis* is generally confined to the hairy areas of the vulva. It may occasionally be found in other areas, such as the eyelids. The major nourishment of the louse is human blood.

The louse's life cycle has three stages, egg (nit), nymph, and adult. The entire life cycle is spent on the host. Eggs are deposited at the base of hair follicles. The adult parasite is approximately 1 mm long and dark gray when its alimentary tract is not filled with blood (Fig. 23.3). Of clinical importance for diagnosis is the fact that the louse moves slowly. The incubation period for pediculosis is approximately 30 days.

The predominant clinical symptom of louse infestation is constant pubic pruritus caused by allergic sensitization. Usually, initial sensitization takes several weeks to develop but may be as rapid as 5 days following initial infection. Following a reinfection, pruritus may occur within 24 hours. Examination of the vulvar area without magnification demonstrates eggs and adult lice and pepper grain feces adjacent to the hair shafts (Fig. 23.4). The tiny rough spots visualized with the naked eye are the alimentary tracts of lice filled with human blood. The vulvar skin may become secondarily irritated or infected by constant scratching. For definitive diagnosis, one can make a microscopic slide by scratching the skin papule with a needle and placing the crust under a drop of mineral oil. The louse's body looks like that of a miniature crab, with six legs that have claws on them.

Scabies is a parasitic infection of the itch mite, *Sarcoptes scabiei*. Similar to the crab louse, it is transmitted by close contact. Unlike louse infestation, scabies is an infection that is widespread over the body, without a predilection for hairy areas. The adult female itch mite digs a burrow just beneath the skin.

Figure 23.3 Pubic louse, *Phthirus pubis*, after blood meal. (From Billstein S. Human lice. In: Holmes KK, Mårdh PA, Sparling PF, et al, eds. *Sexually Transmitted Diseases*. New York: McGraw-Hill; 1984.)

She lays eggs in this home during her life span of approximately 1 month. The adult itch mite is usually less than 0.5 mm long, approximately the size of a grain of sand. Unlike the crab louse, an itch mite travels rapidly over skin and may move up to 2.5 cm in 1 minute. Mites are able to survive for only a few hours away from the warmth of skin.

The predominant clinical symptom of scabies is severe but intermittent itching. Generally, more intense pruritus occurs at night when the skin is warmer and the mites are more active. Initial symptoms usually present approximately 3 weeks after primary infestation. Scabies may present as papules, vesicles, or burrows. However, the pathognomonic sign of scabies infection is the burrow in the skin. The burrow usually has the appearance of a twisted line on the skin surface, with a small vesicle at one end. Any area of the skin may be infected, with the hands, wrists, breasts, vulva, and buttocks being most commonly involved. A handheld magnifying lens is helpful for examining suspicious areas. Microscopic slides may be made using mineral oil and a scratch technique (Fig. 23.5). Mites lack lateral claw legs but have two anterior triangular hairy buds. Scabies has been termed the *great dermatologic imitator*, and the differential diagnosis includes almost all dermatologic diseases that cause pruritus. The treatment of pediculosis pubis or scabies involves an agent that kills both the adult parasite and the eggs.

The therapy currently recommended by the CDC's 2015 guidelines for pediculosis pubis involves the use of permethrin, 1% cream rinse, applied to affected areas and washed off after 10 minutes, or pyrethrins, with piperonyl butoxide applied to the affected area and washed off after 10 minutes. Alternative regimens include malathion, 0.5% lotion, applied for 8 to

Figure 23.4 Crab lice and nits of pediculosis pubis (arrows). (From Kaufman RH. Miscellaneous vulvar disorders. In: Kaufman RH, Faro S, eds. *Benign Diseases of the Vulva and Vagina*. 4th ed. St. Louis: Mosby-Year Book; 1994.)

12 hours and washed off, or ivermectin, 250 µg/kg, repeated in 2 weeks. None of these should be applied to the eyelids. Retreatment may be necessary if lice are found or if eggs are observed at the hair-skin junction. Patients with pediculosis pubis should be evaluated for other STIs and evaluated after 1 week if symptoms persist. Those who do not respond to one of the recommended regimens should be retreated with an alternative regimen.

To treat scabies, CDC recommends permethrin cream applied to all areas of the body from the neck down and washed off after 8 to 14 hours or ivermectin, 200 µg/kg orally, repeated in 2 weeks, if necessary. Alternative regimens include lindane, 1%, 1 oz of lotion or 30 g of cream applied thinly to all areas of the body from the neck down and thoroughly washed off after 8 hours. Resistance to lindane has been reported in some parts of the United States. Lindane is not recommended as first-line therapy because of toxicity. It should only be used as an alternative if the woman cannot tolerate other therapies or if they have failed. Lindane should not be used immediately after a bath or shower and should not be used by persons who have extensive dermatitis, women who are pregnant or lactating, or children younger than 2 years. Patients with scabies have intense pruritus that may persist for many days following effective therapy. An antihistamine will help alleviate this symptom. Similar to pediculosis pubis, women should be examined 1 week following initial therapy and retreated with an alternative regimen if live mites are observed (Hu, 2008).

To avoid reinfection by pediculosis pubis or scabies, treatment should be prescribed for sexual contacts within the previous 6 weeks and other close household contacts. Those with close physical contact should be treated at the same time as the infected woman, regardless of whether they have symptoms. Bedding and clothing should be decontaminated (i.e., machine washed, machine dried using the heat cycle, or dry cleaned) or removed from body contact for at least 72 hours. Fumigation of living areas is not necessary. Importantly, women and physicians should not confuse the 1% cream rinse of permethrin dosage

recommended for pubic lice with the 5% permethrin cream recommended for scabies (Leone, 2007; Scott, 2011).

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a poxvirus that replicates in the cytoplasm of cells and causes a chronic localized infection consisting of flesh-colored, dome-shaped papules with an umbilicated center. Like many viruses in the pox family, molluscum is spread by direct skin-to-skin contact. However, lesions can be spread by autoinoculation, during contact sports, or by fomites on bath sponges or towels. The incubation period is 2 to 7 weeks. In adults, it is primarily an asymptomatic disease of the vulvar skin, and, unlike most STIs, it is only mildly contagious. Widespread infection in adults is most closely related to underlying cellular immunodeficiency, such as during an HIV infection. It can also occur in the setting of chemotherapy or corticosteroid administration.

Diagnosis is made by the characteristic appearance of the lesions. The small nodules or domed papules of molluscum contagiosum are usually 1 to 5 mm in diameter (Fig. 23.6). Close inspection reveals that many of the more mature nodules have an umbilicated center. An infected woman will typically have 1 to 20 solitary lesions randomly distributed over the vulvar skin. A crop of new nodules will persist from several months to years. If the diagnosis cannot be made by simple inspection, the white waxy material from inside the nodule should be expressed on a microscopic slide. The finding of intracytoplasmic molluscum bodies with Wright or Giemsa stain confirms the diagnosis. The major complication of molluscum contagiosum is bacterial superinfection. The umbilicated papules may resemble furuncles when secondarily infected.

Molluscum contagiosum is usually a self-limiting infection and spontaneously resolves after a few months in immunocompetent individuals. However, treatment of individual papules will decrease sexual transmission and autoinoculation of the virus. After injection of local anesthesia, the caseous material is

Figure 23.5 Skin scrapings of unexcoriated papules fortuitously disclose adults, larvae, eggs, and fecal pellets, any of which would be diagnostic of scabies. (From Orkin M, Howard IM. Scabies. In: Holmes KK, Mårdh PA, Sparling PF, et al, eds. *Sexually Transmitted Diseases*. New York: McGraw-Hill; 1984.)

Figure 23.6 Papule of molluscum contagiosum with umbilicated center. (From Brown ST. Molluscum contagiosum. In Holmes KK, Mårdh PA, Sparling PF, et al, eds. *Sexually Transmitted Diseases*. New York: McGraw-Hill; 1984.)

evacuated and the nodule excised with a sharp dermal curette. The base of the papule is chemically treated with ferric subsulfate (Monsel solution) or 85% trichloroacetic acid. Alternative methods are cantharidin, a chemical blistering agent, imiquimod, or cryotherapy (Al-Mutairi, 2010; Chen, 2013; Gamble, 2012; Mathes, 2010).

In immunocompromised individuals, treatment is more difficult. In the HIV-infected woman, there have been multiple reports of recalcitrant molluscum lesions resolving only after initiating highly active antiretroviral therapy (HAART).

GENITAL ULCERS

Herpes, granuloma inguinale (donovanosis), lymphogranuloma venereum, chancroid, and syphilis may all present as ulcerations in the genital area. However, their causes, disease courses, and treatments are different. Table 23.1 lists some of their major characteristics. Physicians must always consider the possibility of more than one STI concurrently infecting an individual.

Genital Herpes

Genital herpes is a recurrent viral infection that is incurable and highly contagious, with 75% of sexual partners of infected individuals contracting the disease. It is among the most frequently encountered STIs; a study of 5452 asymptomatic adults in private community-based clinics in six geographic regions in the United States found the seroprevalence of herpes simplex virus type 2 (HSV-2) was 25.5%. Approximately 80% of infected individuals are unaware that they are infected. Frequently, herpes is transmitted during episodes of asymptomatic shedding, which may occur as frequently as once in 5 days (Bernstein, 2013). It is important that the woman understand the natural history of disease with emphasis on the probability of recurrent attacks, effect of antiviral agents, and risks of neonatal infection. Although recurrent genital herpes is not a debilitating physical disease, it may present a psychological burden. Excellent online patient education and support can be found www.ashastd.org.

There are two distinct types of HSV, type 1 (HSV-1) and type 2 (HSV-2). In the past, a broad generalization was that HSV-1 tends to infect epithelium above the waist, and HSV-2 tends to cause ulceration below the waist. However, HSV-1 is the most commonly acquired genital herpes in women younger than 25 years and, in some series, HSV-1 may cause lower genital tract infection in 13% to 40% of patients. Genital HSV-1 is transmitted from orolabial lesions to the vulva during oral-genital contact or from genital to genital to genital contact with a partner with genital HSV-1.

In primary herpes, the incubation period is between 3 and 7 days (average, 6 days). Although subclinical primary herpes infection is common, both local and systemic disease manifestations occur when the primary infection is symptomatic. The woman typically experiences paresthesia of the vulvar skin followed by the eruption of multiple painful vesicles, which progress to shallow, superficial ulcers over a large area of the vulva. Patients experience multiple crops of ulcers for 2 to 6 weeks. The ulcers usually heal spontaneously without scarring (Fig. 23.7). Viral shedding may occur for 2 to 3 weeks after vulvar lesions appear and, during primary infections, positive cultures for herpesvirus may be obtained from lesions in 80% of women. Most symptomatic women have severe vulvar pain, tenderness, and inguinal adenopathy and simultaneous involvement of the vagina and cervix is common (Fig. 23.8).

Systemic symptoms, including general malaise and fever, are experienced by 70% of women during the primary infection. Rarely, there is central nervous system (CNS) infection, with the reported mortality rate from herpes encephalitis being approximately 50%. Primary infections of the urethra and bladder may result in acute urinary retention, necessitating catheterization. The symptoms of vulvar pain, pruritus, and discharge peak between days 7 and 11 of the primary infection. The typical woman experiences severe symptoms for approximately 14 days.

Recurrent genital herpes is a local disease with less severe symptoms. On average, a woman will have four recurrences during the first year and, in 50% of women, the first recurrence occurs within 6 months of the initial infection. The probability

Table 23.1 Clinical Features of Genital Ulcers

Parameter	TYPE				
	Syphilis	Herpes	Chancroid	Lymphogranuloma Venereum	Donovanosis
Incubation period	2-4 wk (1-12 wk)	2-7 days	1-14 days	3 days-6 wk	1-4 wk (up to 6 mo)
Primary lesion	Papule	Vesicle	Papule or pustule	Papule, pustule, or vesicle	Papule
Number of lesions	Usually one	Multiple, may coalesce	Usually multiple, may coalesce	Usually one	Variable
Diameter (mm)	5-15	1-2	2-20	2-10	Variable
Edges	Sharply demarcated	Erythematous	Undermined, ragged, irregular	Elevated, round or oval	Elevated, irregular
Depth	Superficial or deep	Superficial	Excavated	Superficial or deep	Elevated
Base	Smooth, nonpurulent	Serous, erythematous	Purulent	Variable	Red and rough (beefy)
Induration	Firm	None	Soft	Occasionally firm	Firm
Pain	Unusual	Common	Usually very tender	Variable	Uncommon
Lymphadenopathy	Firm, nontender	Firm, tender, often bilateral	Tender, may suppurate, usually unilateral	Tender, may suppurate, loculated, usually unilateral	

From Holmes KK, Mårdh PA, Sparling PF, et al, eds. *Sexually Transmitted Diseases*, 2nd ed. New York: McGraw-Hill, 1990.

and frequency of recurrence of herpes are related to the HSV serotype. Approximately 80% of women with an initial genital HSV-2 infection will experience a recurrence within 12 months. If her primary HSV-2 infection was severe, she will have recurrences approximately twice as often, with a shorter time to recurrence intervals compared with women with milder initial episodes of the disease. In contrast, if the initial pelvic infection was HSV-1, there is a 55% chance of a recurrence within 1 year, with the average rate of recurrence slightly less than one episode per year (Phipps, 2011; Tronstein, 2011).

Figure 23.7 Recurrent herpes genitalis. Superficial ulcers are noted following rupture of vesicles. (From Kaufman RH, Faro S. Herpes genitalis: clinical features and treatment. *Clin Obstet Gynecol.* 1985;28:152-163.)

Figure 23.8 Primary herpes involving the cervix. A necrotic exophytic mass is seen on posterior lip. This was clinically thought to be invasive carcinoma. Herpes simplex virus culture was positive. The lesion spontaneously disappeared. (From Kaufman RH, Faro S. Herpes genitalis: clinical features and treatment. *Clin Obstet Gynecol.* 1985;28:152-163.)

For recurrences, vulvar involvement is usually unilateral, attacks last an average of 7 days, and viral shedding occurs for approximately 5 days. The ability to culture herpesvirus successfully from recurrent herpetic ulcers is 40%. A common feature of recurrence is a prodromal phase of sacro-neuralgia, vulvar burning, tenderness, and pruritus for a few hours to 5 days before vesicle formation. Extragenital sites of recurrent infection are common. The herpesvirus resides in a latent phase in the dorsal root ganglia of S2, S3, and S4.

The clinical diagnosis of genital herpes is often made by simple clinical inspection. Women come to their physician when they develop symptoms from vulvar ulcers. Herpetic ulcers are painful when touched with a cotton-tipped applicator, whereas the ulcers of syphilis are painless. Viral cultures are useful in confirming the diagnosis in primary episodes when culture sensitivity is 80%, but less useful in recurrent episodes. Most herpesvirus cultures will become positive within 2 to 4 days of inoculation. The most accurate and sensitive technique for identifying herpesvirus is the polymerase chain reaction (PCR) assay. Serologic tests are helpful in determining whether a woman has been infected in the past with herpesvirus. The Western blot assay for antibodies to herpes is the most specific method for diagnosing recurrent herpes, as well as unrecognized or subclinical infection. However, Western blot tests are not widely available and are difficult to perform. Type-specific HSV serologic assays might be useful in the following situations: (1) recurrent genital symptoms or atypical symptoms, with negative HSV cultures; (2) clinical diagnosis of genital herpes without laboratory confirmation; or (3) partner with genital herpes. HSV serologic testing should be considered for persons presenting for an STI evaluation, especially for those with multiple sex partners or HIV infection and at increased risk for HIV acquisition. Screening for HSV-1 or HSV-2 in the general population is not indicated.

Enzyme-linked immunoassay (ELISA) and immunoblot tests are available for HSV-1 and HSV-2. Rapid serologic point-of-care tests are available for HSV-2 antibodies. Appropriate screening tests for other STIs should be obtained, because they may coexist with herpes.

Treatment of HSV-1 or HSV-2 may be used for three different clinical scenarios:

1. Primary episode
2. Recurrent episode
3. Daily suppression

In primary episodes, the duration and severity of symptoms are lessened, and shedding is shortened with antiviral therapy. Antiviral therapy is recommended for in all patients with primary episodes.

Episodic therapy for recurrences can shorten the duration of the outbreak if started within 24 hours of prodromal symptoms or lesion appearance. Because of the necessity of starting antiviral therapy immediately after recognizing symptoms, it is important that the woman with HSV be given a prescription for antiviral therapy to have at home.

Patient-initiated therapy has been found to be superior to therapy ordered by a physician because patients initiate therapy earlier in the course of a recurrence. The antiviral medication should be started as early as possible during the prodrome, and definitely within 24 hours of the appearance of lesions. Daily suppressive therapy is recommended when the woman has six

Table 23.2 Antiviral Treatment for Herpes Simplex Virus in the Nonpregnant Patient

Indication	ANTIVIRAL AGENT		
	Valacyclovir	Acyclovir	Famciclovir
First clinical episode	1000 mg bid, 7-10 days	200 mg five times/day; or 400 mg tid, 7-10 days	250 mg tid, 7-10 days
Recurrent episodes	1000 mg daily, 5 days; or 500 mg bid, 3 days	400 mg tid, 5 days; 800 mg bid, 5 days; or 800 mg tid, 2 days	125 mg bid, 5 days 500 mg once then 250 mg bid, 2 days; 1000 mg bid, 1 day
Daily suppressive	1000 mg daily (≥10 recurrences/year) or 500 mg daily (≤9 recurrences/year)	400 mg bid	250 mg bid

Data from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015; 64(RR-03):1-137. *bid*, Twice per day; *tid*, three times per day.

or more episodes annually or for psychological distress. It is important for patients to be aware that asymptomatic viral shedding can occur even when on daily suppressive therapy (Bavaro, 2008; Gupta, 2004).

In serodiscordant couples a prospective placebo-controlled randomized trial has demonstrated that daily use of valacyclovir for suppression in the seropositive partner results in significantly fewer cases of HSV acquisition in the seronegative partner. Regular use of condoms in serodiscordant couples also decreases transmission but is not 100% protective. HSV-seronegative women are three times as likely to acquire HSV infection from seropositive male partners compared with seronegative males acquiring HSV from infected female partners. A summary of CDC-recommended treatment regimens is presented in Table 23.2.

Acyclovir is a drug with relatively minimal toxicity and reports have documented its safety in patients receiving daily therapy with acyclovir for as long as 6 years and with valacyclovir or famciclovir for 1 year. However, the CDC recommends that acyclovir or other suppressive drugs be discontinued after 12 months of suppressive therapy to determine the subsequent rate of recurrence for each individual woman (Workowski, 2015). Even if herpes is not treated over time, clinical recurrences tend to dramatically decrease in number.

A vaccine would be the logical approach for optimum prevention of herpes. Research is ongoing.

Granuloma Inguinale (Donovanosis)

Granuloma inguinale, also known as *donovanosis*, is a chronic, ulcerative, bacterial infection of the skin and subcutaneous tissue of the vulva. Rarely, the vagina and cervix are involved in advanced untreated cases. Granuloma inguinale is common in tropical climates such as New Guinea and the Caribbean Islands, but fewer than 20 cases are reported each year in the United States. This disease can be spread sexually and through close nonsexual contact. However, it is not highly contagious, and chronic exposure is usually necessary to contract the disease. The incubation period is extremely variable, from 1 to 12 weeks. It is caused by an intracellular, gram-negative, nonmotile, encapsulated rod, *Klebsiella granulomatis*, which is difficult to culture on standard media. There are no U.S. Food and Drug Administration (FDA)-approved molecular tests for the detection of *K. granulomatis* DNA. Serologic tests are nonspecific.

The initial growth of granuloma inguinale is a nodule that gradually progresses into a painless, slowly progressing ulcer surrounded by highly vascular granulation tissue. This gives the

Figure 23.9 Donovanosis. Biopsy specimen shows intracytoplasmic Donovan bodies (H&E stain). (From Hart G. Donovanosis. In: Holmes KK, Mårdh PA, Sparling PF, et al, eds. *Sexually Transmitted Diseases*. New York: McGraw-Hill; 1984.)

ulcer a beefy red appearance, and it bleeds easily when touched. Unless secondarily infected, the ulcers are painless and without regional adenopathy. Typically, multiple nodules are present, resulting in ulcers that grow and coalesce and, if untreated, will eventually destroy the normal vulvar architecture. If untreated, the chronic form of the disease is characterized by scarring and lymphatic obstruction, which produces marked enlargement of the vulva. In endemic areas, the disease is usually diagnosed by its clinical manifestations. The diagnosis may also be established by identifying Donovan bodies in smears and specimens taken from the ulcers (Fig. 23.9). Donovan bodies appear as clusters of dark-staining bacteria with a bipolar (safety pin) appearance found in the cytoplasm of large mononuclear cells. The differential diagnosis includes lymphogranuloma venereum, vulvar carcinoma, syphilis, chancroid, genital herpes, amebiasis, and other granulomatous diseases.

A wide range of oral broad-spectrum antibiotics may be used to manage granuloma inguinale. The CDC recommends azithromycin 1 g orally once a week or 500 mg daily for 3 weeks and until all lesions have healed. Alternative antibiotic regimens include the following: doxycycline, 100 mg orally, twice daily for a minimum of 3 weeks; ciprofloxacin, 750 mg orally twice daily; erythromycin base, 500 mg orally four times daily; or trimethoprim-sulfamethoxazole (TMP-SMZ), one

double-strength tablet orally twice daily. Therapy should be continued until the lesions have healed completely. Alternative antibiotic therapy such as an aminoglycoside has been used in refractory cases. Rarely, medical therapy fails and surgical excision is required. Co-infection with another sexually transmitted pathogen is a distinct possibility. Sex partners of women who have granuloma inguinale should be examined if they have had sexual contact during the 60 days preceding the onset of symptoms (Workowski, 2015).

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is a chronic infection of lymphatic tissue produced by *Chlamydia trachomatis*. It is found most commonly in the tropics. Cases occur infrequently in the United States, with fewer than 150 new cases being reported each year, most of which occur in men. In women, the vulva is the most frequent site of infection, but the urethra, rectum, and cervix may also be involved. This sexually transmitted infection is caused by serotypes L1, L2, and L3 of *C. trachomatis*. Serologic studies in high-risk populations have found that subclinical infection is common. The incubation period is between 3 and 30 days.

There are three distinct phases of vulvar and perirectal LGV. The primary infection is a shallow, painless ulcer that heals rapidly without therapy. It is typically located on the vestibule or labia but occasionally in the periurethral or perirectal region. One to 4 weeks after the primary infection, a secondary phase marked by painful adenopathy develops in the inguinal and perirectal areas. Two thirds of women have unilateral adenopathy and 50% have systemic symptoms, including general malaise and fever. When the disease is untreated, the infected nodes become increasingly tender, enlarged, matted together, and adherent to overlying skin, forming a bubo (tender lymph nodes). A classic clinical sign of LGV is the double genitocrural fold, or groove sign (Fig. 23.10), a depression between groups of inflamed nodes. Within 7 to 15 days, the bubo will rupture spontaneously and form multiple draining sinuses and fistulas. These are classic signs of the tertiary phase of the infection. Extensive tissue destruction of the external genitalia and anorectal region may occur during the tertiary phase. This tissue destruction and secondary extensive scarring and fibrosis may result in elephantiasis, multiple fistulas, and stricture formation of the anal canal and rectum.

Diagnosis is established by detecting *C. trachomatis* by culture, direct immunofluorescence, or nucleic acid detection from the pus or aspirate from a tender lymph node. *Chlamydia* serology (complement fixation titers >1:64) can support the diagnosis in the appropriate clinical context. However, the diagnostic usefulness of serologic methods other than complement fixation and some microimmunofluorescence procedures remains unclear. In the absence of specific LGV diagnostic testing, patients should be treated based on the clinical presentation, including proctocolitis or genital ulcer disease with lymphadenopathy. The differential diagnosis of LGV includes syphilis, chancroid, granuloma inguinale, bacterial lymphadenitis, vulvar carcinoma, genital herpes, and Hodgkin disease.

The CDC recommends doxycycline, 100 mg twice daily for at least 21 days, as the preferred treatment. An alternative therapy choice is erythromycin base, 500 mg four times daily orally for 21 days. Azithromycin, 1 g orally once weekly for 3 weeks, is probably effective, but clinical data are lacking.

Figure 23.10 Lymphogranuloma venereum bubo with groove sign. (From Friedrich EG. *Vulvar Disease*. 2nd ed. Philadelphia: WB Saunders; 1983.)

Fluoroquinolone-based treatments may also be effective, but extended treatment intervals are likely required (Workowski, 2015).

Antibiotic therapy cures the bacterial infection and prevents further tissue destruction. However, fluctuant nodes should be aspirated to prevent sinus formation. Rarely, incision and drainage of infected nodes are necessary to alleviate inguinal pain. The late sequelae of the destructive tertiary phase of LGV often require extensive surgical reconstruction. It is important to administer antibiotics during the perioperative period.

Chancroid

Chancroid is a sexually transmitted, acute, ulcerative disease of the vulva caused by *Haemophilus ducreyi*, a highly contagious, small, nonmotile, gram-negative rod. Chancroid is a common disease in developing countries but infrequent in the United States. Epidemiologic studies have suggested that chancroid tends to occur in clusters and may account for a substantial portion of genital ulcer cases when present. However, difficulty in making the diagnosis may cause underreporting. The clinical importance of chancroid has been enhanced by reports that the genital ulcers of chancroid facilitate the transmission of HIV infection.

The soft chancre of chancroid is always painful and tender. In comparison, the hard chancre of syphilis is usually asymptomatic. On Gram stain, this facultative anaerobic bacterium exhibits a classic appearance of streptobacillary chains, or what has been described as an extracellular school of fish. The incubation period is short, usually 3 to 6 days. Tissue trauma and excoriation of the skin must precede initial infection because *H. ducreyi* is unable to penetrate and invade normal skin.

The initial lesion is a small papule. Within 48 to 72 hours, the papule evolves into a pustule and subsequently ulcerates.

The extremely painful ulcers are shallow, with a characteristic ragged edge, and usually occur in the vulvar vestibule and rarely in the vagina or cervix. The ulcers have a dirty, gray, necrotic, foul-smelling exudate and lack induration at the base (the soft chancre). Multiple papules and ulcers may be in different phases of maturation secondary to autoinoculation. Within 2 weeks of an untreated infection, approximately 50% of women develop acutely tender inguinal adenopathy, a bubo, which is typically unilateral. Fluctuant nodes should be treated by needle aspiration to prevent rupture or by incision and drainage if larger than 5 cm.

A definitive diagnosis of chancroid requires the identification of *H. ducreyi* on special culture media that are not widely available from commercial sources; even when these media are used, sensitivity is less than 80%. No FDA-approved PCR test for *H. ducreyi* is available in the United States, but this testing can be performed by clinical laboratories that have developed their own PCR test and conducted a Clinical Laboratory Improvement Amendments (CLIA) verification study. Sometimes, the clinical diagnosis is made in a woman with painful vulvar ulcers after excluding other common STIs that produce vulvar ulcers, including genital herpes, syphilis, LGV, and donovanosis.

Due to antibiotic resistance to tetracyclines and sulfonamides, the CDC recommends the following: azithromycin, 1 g orally in a single dose or ceftriaxone, 250 mg intramuscular (IM) in a single dose or ciprofloxacin, 500 mg orally twice daily for 3 days; or erythromycin base, 500 mg orally three times daily for 7 days. Sexual partners should be treated in a similar fashion. Successful antibiotic therapy results in symptomatic and objective improvement within 5 to 7 days of initiating therapy. Large ulcers may require 2 to 3 weeks to heal, with clinical resolution of lymphadenopathy slower than that of ulcers. Buboos respond at a slower rate than skin ulcers (Workowski, 2015). Approximately 10% of women whose ulcers initially heal have a recurrence at the same site. Women with HIV infection have an increased rate of failure to the standard treatments for chancroid and therefore often require more prolonged therapy. Co-infection with another ulcer causing an STI should be considered, especially in women lacking an appropriate response to treatment.

Syphilis

Syphilis is a chronic, complex systemic disease produced by the spirochete *Treponema pallidum*. The infection initially involves mucous membranes. Syphilis remains one of the important STIs in the United States, and epidemiologists speculate that only one of four new cases of syphilis is reported. Early syphilis is a cofactor in the transmission and acquisition of HIV and, currently, 25% of new syphilis cases occur in persons co-infected with HIV. Even with mandatory screening, congenital syphilis continues to be a public health problem. Mothers who experience stillbirth or neonatal death from syphilis usually have not received prenatal care. Syphilis should be included in the differential diagnosis of all genital ulcers and cutaneous rashes of unknown origin, and all women diagnosed with syphilis should be screened for HIV.

T. pallidum is an anaerobic, elongated, tightly wound spirochete. Because of its extreme thinness, it is difficult to detect by light microscopy. Therefore the presence of spirochetes is diagnosed by use of specially adapted techniques, dark-field microscopy, or direct fluorescent antibody tests (Fig. 23.11). These organisms have the ability to penetrate skin or mucous

Figure 23.11 Dark-field microscopic appearance of *Treponema pallidum*. (From Larsen SA, McGrew BE, Hunter EF, et al. Syphilis serology and dark field microscopy. In: Holmes KK, Mårdh PA, Sparling PF, et al, eds. *Sexually Transmitted Diseases*. New York: McGraw-Hill; 1984.)

membranes. The incubation period is from 10 to 90 days, with an average of 3 weeks. They replicate every 30 to 36 hours, which accounts for the comparatively long incubation period.

Syphilis is a moderately contagious disease. Approximately 3% to 10% of patients contract the disease from a single sexual encounter with an infected partner. Similar studies have documented that 30% of individuals become infected during a 1-month exposure to a sexual partner with primary or secondary syphilis. Patients are contagious during primary, secondary, and probably the first year of latent syphilis. Syphilis can be spread by kissing or touching a person who has an active lesion on the lips, oral cavity, breast, or genitals. Case transmission can occur with oral-genital contact.

The diagnosis of syphilis is complicated by the fact that the organism cannot be cultivated in vitro. Definitive diagnosis is via darkfield microscopy to detect *T. palladium* in lesion exudate or tissue. *T. palladium* detection kits are not commercially available, but some labs provide locally developed PCR tests. Therefore presumptive diagnosis and screening rely on serologic tests. There are two types of serologic tests, the nonspecific nontreponemal and the specific antitreponemal antibody tests. The nontreponemal tests, such as the Venereal Disease Research Laboratory (VDRL) slide test and the rapid plasma reagin (RPR) card test are inexpensive and easy to perform. They are used as screening tests for the disease, typically become positive 4 to 6 weeks after exposure, and also are a useful index of treatment response. These tests evaluate the woman's serum for the presence of reagin IgG and IgM antibodies as they react with an antigen from beef heart. Quantitative nontreponemal antibody titers usually correlate with the activity of the disease. Serologic testing is an indirect method of diagnosis because it relies on a humoral immune response to infection. As such, it has some inherent limitations. Approximately 1% of patients have technical or biologic false-positive results with the nonspecific tests. Many conditions produce biologic false-positive results, including a recent febrile illness, pregnancy, immunization, chronic active hepatitis, malaria, sarcoidosis, intravenous (IV) drug use, HIV infection, advancing age, acute herpes simplex, and

Table 23.3 Potential Causes of Biologic False-Positive Results in Syphilis Serology

Cause	BIOLOGIC FALSE-POSITIVE REACTION	
	Acute	Chronic
Physiologic	Pregnancy	Advanced age, multiple blood transfusions
Infectious	Varicella, vaccinia, measles, mumps, infectious mononucleosis, herpes simplex, viral hepatitis, HIV seroconversion illness, cytomegalovirus, pneumococcal pneumonia, <i>Mycoplasma pneumoniae</i> , chancroid, lymphogranuloma venereum, psittacosis, bacterial endocarditis, scarlet fever, rickettsial infections, toxoplasmosis, Lyme disease, leptospirosis, relapsing fever, rat bite fever	HIV, tropical spastic paraparesis, leprosy,* tuberculosis, malaria,* lymphogranuloma venereum, trypanosomiasis,* kala-azar*
Vaccinations	Smallpox, typhoid, yellow fever	
Autoimmune disease		Systemic lupus erythematosus, discoid lupus, drug-induced lupus, autoimmune hemolytic anemia, polyarteritis nodosa, rheumatoid arthritis, Sjögren syndrome, Hashimoto thyroiditis, mixed connective tissue disease, primary biliary cirrhosis, chronic liver disease, idiopathic thrombocytopenic purpura
Other		IV drug use, advanced malignancy hypergammaglobulinemia, lymphoproliferative disease

Data from Nandwani R, Evans DTP. Are you sure it's syphilis? A review of false-positive serology. *Int J STD AIDS*. 1995;6:241; Hook EW III, Marra CM. Acquired syphilis in adults. *N Engl J Med*. 1992;326:1062.

*Biologic false-positive reaction resolves with resolution of infection.

HIV, Human immunodeficiency virus.

autoimmune diseases such as lupus erythematosus or rheumatoid arthritis. Biologic false-positive serum tests usually are associated with extremely low titers (<1:8). A false-negative result is a possibility, occurring in approximately 1% to 2% of tests. This negative reaction occurs in women in whom there is an excess of anticardiolipin antibody in the serum, termed the *prozone phenomenon*. Women with immunocompromise also may have false-negative tests because of their inability to produce the antibodies detected by these screening tests.

If a nonspecific test result is positive, the significance of this result must be confirmed by a specific antitreponemal test. Antitreponemal tests are more sensitive; however, occasionally, they may produce false-positive results. Most false-positive results occur in women with lupus erythematosus (Table 23.3). The standard for antitreponemal tests are the fluorescent-labeled *Treponema* antibody absorption (FTA-ABS) test and the microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP). The MHA-TP does not have as high a rate of false-positive results as the FTA-ABS. A woman with a positive reactive treponemal test usually will have this positive reaction for her lifetime, regardless of treatment or activity of the disease.

Clinically, syphilis is divided into primary, secondary, and tertiary stages. In primary syphilis, a papule, which is usually painless, appears at the site of inoculation 2 to 3 weeks after exposure. This soon ulcerates to produce the classic finding of primary syphilis, a chancre that is a painless ulcer, 1 to 2 cm, with a raised indurated margin and a nonexudative base (Fig. 23.12). Usually, the chancre is solitary, painless, and found on the vulva, vagina, or cervix, although extragenital primary lesions, including lesions of the mouth, anal canal, and breast nipple, have been reported in approximately 5% of patients. Nontender and firm regional adenopathy is present during the first week of clinical disease. Within 2 to 6 weeks, the painless ulcer heals spontaneously. Hence, many women do not seek treatment, a feature that enhances the likelihood of transmission. Confirmation that the

ulcer is primary or secondary syphilis depends on the identification of *T. pallidum* by dark-field microscopy from wet smears of the ulcer. Special preparations must be made to obtain suitable smears. It is important to clean and abrade the ulcer with gauze before obtaining the serum for the slides. At the time of dark-field identification of *T. pallidum* from a primary chancre, approximately 70% of women will have a positive serologic test. If the serologic test result remains negative for 3 months, it is unlikely that the ulcer was syphilis. Syphilis is not frequently diagnosed in the primary stage in women.

If primary syphilis is untreated, approximately 25% of individuals develop secondary syphilis, which is the result of hematogenous dissemination of the spirochetes. Secondary syphilis is a systemic disease that develops between 6 weeks and 6 months (average, 9 weeks) after the primary chancre. The stages are not exclusive. Approximately 25% of women still have a primary chancre when the secondary lesions appear. An untreated attack of secondary syphilis will last 2 to 6 weeks, and a multitude of systemic symptoms may occur, depending on the major organs involved, such as rash, fever, headache, malaise, lymphadenopathy, and anorexia. The classic rash of secondary syphilis is red macules and papules over the palms of the hands and the soles of the feet (Fig. 23.13). Vulvar lesions of condyloma latum are large, raised, flattened, grayish white areas (Fig. 23.14). On wet surfaces of the vulva, soft papules often coalesce to form ulcers. These ulcers are larger than herpetic ulcers and are not tender unless secondarily infected. A woman with syphilis is most infectious during the first 1 to 2 years of disease, with decreasing infectivity thereafter.

The latent stage of syphilis follows the secondary stage and varies in duration from 2 to 20 years; it is characterized as positive serology without symptoms or signs of disease. Women with syphilis in the primary or secondary stages and during the first year of latent syphilis are believed to be infectious. Most women diagnosed with syphilis are detected via positive blood tests during

the latent stage of the disease. Early latent syphilis is an infection of 1 year or less. All other cases are referred to as *late latent* or *latent syphilis of unknown duration*. Women who have been sexually active with latent syphilis should have a pelvic examination to discover potential lesions involving the vagina or cervix.

The tertiary phase of syphilis is devastating in its potentially destructive effects on the central nervous, cardiovascular, and musculoskeletal systems. Tertiary syphilis develops in approximately 33% of patients who are not appropriately treated during the primary, secondary, or latent phases of the disease (Fig. 23.15). The manifestations of late syphilis

include optic atrophy, tabes dorsalis, generalized paresis, aortic aneurysm, and gummas of the skin and bones. A gumma is similar to a cold abscess, with a necrotic center and the obliteration of small vessels by endarteritis.

Parenteral penicillin G is the drug of choice for syphilis. *T. pallidum* is exquisitely sensitive to penicillin. However, because of the slow replication time of the spirochete, blood levels must be maintained for 7 to 14 days. The CDC recommends 2.4 million units of benzathine penicillin G IM in one dose for early syphilis (primary and early latent secondary syphilis). Patients who are allergic to penicillin should receive oral tetracycline,

Box 23.2 Centers for Disease Control and Prevention Recommended Treatment of Syphilis (2014)

Early Syphilis (primary, secondary, and early latent syphilis of less than 1 year in duration)

Recommended regimen: Benzathine penicillin G, 2.4 million U IM, one dose

Alternative regimen (penicillin-allergic nonpregnant patients):

Doxycycline, 100 mg orally bid for 2 wk *or* tetracycline, 500 mg orally qid for 2 wk

Late Latent Syphilis (>1 year in duration, gummas, and cardiovascular syphilis)

Recommended regimen: Benzathine penicillin G, 7.2 million U total, administered as three doses of 2.4 million U IM at 1-wk intervals

Alternative regimen (penicillin-allergic nonpregnant patients):

Doxycycline 100 mg orally 2 times a day for 2 wk if <1 year, otherwise, for 4 wk; *or* tetracycline, 500 mg orally qid for 2 wk if <1 year; otherwise, for 4 wk

Neurosyphilis

Recommended regimen: Aqueous crystalline penicillin G, 18–24 million U daily, administered as 3–4 million U IV every 4 hr, for 10–14 days

Alternative regimen: Procaine penicillin, 2.4 million U IM daily, for 10–14 days plus probenecid, 500 mg PO qid for 10–14 days

Syphilis in Pregnancy

Recommended regimen: Penicillin regimen appropriate for stage of syphilis. Some experts recommend additional therapy (e.g., second dose of benzathine penicillin, 2.4 million U IM) 1 wk after the initial dose for those who have primary, secondary, or early latent syphilis

Alternative regimen (penicillin allergy): Pregnant women with a history of penicillin allergy should be skin-tested and desensitized

Syphilis in HIV-Infected Patients

Primary and secondary syphilis: Benzathine penicillin G, 2.4 million U IM. Some experts recommend additional treatments, such as three weekly doses of benzathine penicillin G. Penicillin-allergic patients should be desensitized and treated with penicillin

Latent syphilis (normal CSF examination): Benzathine penicillin G, 7.2 million U as three weekly doses of 2.4 million U each

Data from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015;64(RR-03):1–137.

bid, Twice per day; *CSF*, cerebrospinal fluid; *qid*, four times per day.

500 mg every 6 hours for 14 days, or doxycycline, 100 mg orally twice a day for 2 weeks. Standard treatment protocols for syphilis are detailed in [Box 23.2](#). Approximately 60% of women develop an acute febrile reaction associated with flulike symptoms such as headache and myalgia within the first 24 hours after parenteral penicillin therapy for early syphilis. This response is known as the *Jarisch-Herxheimer reaction* ([Workowski, 2015](#)).

All women with early syphilis should be reexamined clinically and serologically at 6 and 12 months following therapy. With successful therapy in early syphilis, the titer should decline fourfold in 6 months and become negative within 12 months. Women with latent syphilis should have quantitative nontreponemal serologic tests 6, 12, and 24 months following therapy. During the first 3 to 4 years of the latent phase, a woman may

experience relapses of secondary syphilis. Women who have a sustained fourfold increase in nontreponemal test titers have failed treatment or become reinfected. They should be retreated and evaluated for concurrent HIV infection. When women are retreated, the recommendation is three weekly injections of benzathine penicillin G, 2.4 million units IM. For long-term follow-up, the same serologic tests should be ordered. Optimally, the test should be obtained from the same laboratory. The VDRL and RPR tests are equally valid, but RPR titers tend to be slightly higher than VDRL titers. With successful treatment, the VDRL titer will become nonreactive or, at most, be reactive, with a lower titer within 1 year. There is a 1% to 2% chance that the woman will not exhibit a fourfold titer decline, and these cases are considered therapeutic failures. They should be retreated. Patients with syphilis lasting longer than 1 year should have quantitative VDRL titers for 2 years following therapy because their titers will decline more slowly. A specific test for syphilis, such as the FTA-ABS, remains reactive indefinitely. In summary, all women with a first attack of primary syphilis should have a negative nonspecific serology within 1 year, and women treated for secondary syphilis should have a negative serology within 2 years. If they are not, treatment failure, reinfection, and concurrent HIV infection should be investigated.

Syphilis often involves the CNS. There is no established diagnostic test that is a gold standard for neurosyphilis. The diagnosis of neurosyphilis is based on a combination of clinical findings, reactive serologic tests, and abnormalities of cerebrospinal fluid, serology, cell count, or protein. Infection of the CNS by spirochetes may occur during any stage of syphilis. Women should undergo a cerebrospinal fluid examination if they develop neurologic or ophthalmologic signs or symptoms, evidence of active tertiary syphilis, treatment failures, and HIV infection with late latent syphilis or syphilis of an unknown duration. To treat neurosyphilis, the CDC recommends aqueous crystalline penicillin G, 18 to 24 million units daily, administered as 3 to 4 million units IV every 4 hours for 10 to 14 days. An alternative regimen is procaine penicillin, 2.4 million units IM daily, plus probenecid, 500 mg orally four times daily for 10 to 14 days. The duration of both these regimens for neurosyphilis is shorter than that of the regimen used for late syphilis in the absence of neurosyphilis. Therefore some experts administer benzathine penicillin, 2.4 million units IM, after completion of either regimen to provide a comparable total duration of therapy ([Workowski, 2015](#)).

It is important for all women with syphilis to be tested for HIV infection. Simultaneous syphilis and HIV infections alter the natural history of syphilis, with earlier involvement of the CNS. Women with HIV infection may have a slightly increased rate of treatment failure with currently recommended regimens. Similarly, they may exhibit unusual serologic responses. Usually, serologic titers are higher than expected. However, false-negative serologic tests or delayed appearance of seroreactivity has been reported. Nevertheless, the CDC's recommendation for treating early syphilis in women is the same whether or not they are concurrently infected with HIV. Following penicillin treatment for syphilis, women with HIV should be followed with quantitative titers at more frequent intervals—for example, at 3, 6, 9, 12, and 24 months following therapy.

Sexual partners of women with syphilis in any stage should be evaluated clinically and serologically. The time intervals used to identify an at-risk sex partner are 3 months plus duration of

symptoms for primary syphilis, 3 months plus duration of symptoms for secondary syphilis, and 1 year for early latent syphilis. Those who are exposed within the 90 days preceding the diagnosis of primary, secondary, or early latent syphilis in their sexual partners should be treated presumptively because they may be infected, even if seronegative.

VAGINITIS

Vaginal discharge is the most common symptom in gynecology. Other symptoms associated with vaginal infection include superficial dyspareunia, dysuria, odor, and vulvar burning and pruritus. The three common causes of vaginitis are (1) a fungus (candidiasis), (2) a protozoon (*Trichomonas*), and (3) a disruption of the vaginal bacterial ecosystem leading to bacterial vaginosis. Relative prevalence differs depending on the population studied; in a group of middle-class women in the reproductive range, bacterial vaginosis represents approximately 50% of cases, whereas candidiasis and *Trichomonas* infection each constitute approximately 25% of cases.

The vaginal environment has been described as a dynamic ecosystem. The normal vaginal pH is approximately 4.0 in premenopausal women. The maintenance of an optimum pH balance involves a complex interplay of hormonal, microbiologic, and other unknown factors. In women of reproductive age, estrogen stimulates the glycogen content of vaginal epithelial cells. The glycogen is metabolized to lactic acid and other short-chain organic acids, principally by the lactobacilli but also by other vaginal bacteria and enzymes. *Lactobacillus*, an aerobic, gram-positive rod, is found in 62% to 88% of asymptomatic women and is the regulator of normal vaginal flora. Lactobacilli make lactic acid, which maintains the normal vaginal pH of 3.8 to 4.5 and inhibits the adherence of bacteria to vaginal epithelial cells. Approximately 60% of vaginal lactobacilli strains make hydrogen peroxide, which inhibits the growth of bacteria and destroys HIV in vitro. Estrogen improves lactobacilli concentration by enhancing the vaginal epithelial cell production of glycogen, which breaks down into glucose and acts as a substrate for the bacteria.

One of the most helpful diagnostic aids in the differential diagnosis of vaginitis is the measurement of vaginal acidity with pH indicator paper. A vaginal pH higher than 5.0 indicates bacterial vaginosis or *Trichomonas* infection, or possibly an atrophic vaginal discharge. A vaginal pH less than 4.5 represents a physiologic discharge or fungal infection, although fungal infection can occur concurrently with bacterial vaginosis or *Trichomonas*. Cervical mucus and semen have neutral or basic pH and may temporarily change the normal acidity. Semen has been found to buffer vaginal acidity for 6 to 8 hours following intercourse. The vaginal pH is slightly higher in postmenopausal than in premenopausal women.

Normal physiologic vaginal discharge consists of cervical and vaginal epithelial cells, normal bacterial flora, water, electrolytes, and other chemicals. The quantitative concentration of bacterial organisms is 10^8 to 10^9 colonies/mL of vaginal fluid. The concentrations of anaerobic and aerobic bacteria vary considerably during the menstrual cycle. Qualitatively, the number of

<i>Clostridium</i> spp.	5-20
<i>Eubacterium</i> spp.	5-35
<i>Veillonella</i> spp.	10-30

From Eschenbach DA. Vaginal infection. *Clin Obstet Gynecol.* 1983;26(1):186-202.

bacterial species may vary from 17 to 29. Anaerobic bacteria are quantitatively the most prevalent, five times more common than aerobic bacteria.

In addition to lactobacilli, other common aerobic bacteria found in the vagina are diphtheroids, streptococci, *Staphylococcus epidermidis*, and *Gardnerella vaginalis*. The most common gram-negative bacillus is *Escherichia coli*. Anaerobic bacteria have been detected in approximately 80% of women, with the most prevalent being *Peptococcus*, *Peptostreptococcus*, and *Bacteroides* spp. (Table 23.4). *Candida* spp. and mycoplasmas are also common inhabitants of asymptomatic women. Our knowledge of vaginal flora has traditionally relied on classic microbiology. Newer molecular techniques are demonstrating even greater complexity in vaginal flora.

The clinical diagnosis of vaginitis depends on the examination of the vaginal secretions under the microscope and measurement of the vaginal pH. Nevertheless, it is helpful to generalize about the characteristics of normal secretions and the three common vaginal infections (Table 23.5).

Normal vaginal secretions are white, floccular or curdy, and odorless. In a woman with a normal or physiologic discharge, it is important to note that the vaginal discharge is present only in the dependent portions of the vagina. Pathologic discharges usually involve the anterior and lateral walls of the vagina. It should be emphasized that vaginal discharge characteristics, especially the amount of discharge, are insensitive and nonspecific diagnostic criteria for vaginitis. However, thick, white, curdy, patchy discharge, when present, is highly associated with fungal infections. Gray-white discharges that are thin and usually profuse suggest a differential diagnosis of *Trichomonas* or bacterial vaginosis, as do vaginal discharges that have a foul odor.

Table 23.5 Typical Features of Vaginitis

Condition	Symptoms and Signs*	Findings on Examination*	pH	Wet Mount	Comment
Bacterial vaginosis†	Increased discharge (white, thin), Increased odor	Thin, whitish gray, homogeneous discharge, cocci, sometimes frothy	>4.5	Clue cells (>20%) shift in flora Amine odor after adding potassium hydroxide to wet mount	Greatly decreased lactobacilli Greatly increased cocci Small curved rods
Candidiasis	Increased discharge (white, thick)‡ Dysuria Pruritus Burning	Thick, curdy discharge Vaginal erythema	<4.5	Hyphae or spores	Can be mixed infection with bacterial vaginosis, <i>T. vaginalis</i> , or both, and have higher pH
Trichomoniasis§	Increased discharge (yellow, frothy) Increased odor Dysuria Pruritus	Yellow, frothy discharge, with or without vaginal or cervical erythema	>4.5	Motile trichomonads Increased white cells	More symptoms at higher vaginal pH

From Eckert LO. Clinical practice: acute vulvovaginitis. *N Engl J Med*. 2006;355(12):1244-1252.

*Although these features are typical, their sensitivity and specificity are generally inadequate for diagnosis.

†For a diagnosis of bacterial vaginosis, a report of increased discharge has a sensitivity of 50% and a specificity of 49%; odor, a sensitivity of 49% and a specificity of 20%; and pH >4.7, a sensitivity of 97%, and a specificity of 65%, compared with the use of a Gram stain.

‡Of patients presenting with symptoms of vaginitis, 40% report increased (white) discharge, but this discharge is not related to *Candida albicans* in many studies.

§A report of a yellow discharge has a sensitivity of 42% and a specificity of 80%; a frothy discharge on examination has a sensitivity of 8% and a specificity of 99%.

BACTERIAL VAGINOSIS

Bacterial vaginosis is the most prevalent cause of symptomatic vaginitis, with a prevalence of approximately 15% to 50% (Allsworth, 2007). Bacterial vaginosis reflects a shift in vaginal flora from lactobacilli-dominant to mixed flora, including genital mycoplasmas, *G. vaginalis*, and anaerobes, such as peptostreptococci, and *Prevotella* and *Mobiluncus* spp. Although *Gardnerella* and anaerobic organisms can be found in women with normal vaginal flora, their concentration increases several-fold in women with bacterial vaginosis concurrent with a marked decrease in lactobacilli.

The origin of bacterial vaginosis remains elusive. No causative agent has been identified. Because of the inability to find a transmissible agent, bacterial vaginosis has not been classified as an STI. Currently, bacterial vaginosis is described as a “sexually associated” infection rather than a true sexually transmitted infection. Risk factors for bacterial vaginosis include new or multiple sexual partners. It also is prevalent in women who have sex with women; genotyping has revealed identical bacterial strains between monogamous lesbian partners. Also, bacterial vaginosis is more common in lesbian couples who share sex toys with each other without cleaning the toys between use (Bailey, 2004; Marrazzo, 2010a, 2010b). Molecular techniques have identified a cluster of noncultivable bacteria related to *Clostridium* in women with bacterial vaginosis (Fredricks, 2005; Hillier, 2005). As newer techniques analyzing vaginal flora evolve, it may be possible to determine a causal agent.

Other risk factors include douching at least monthly or within the prior 7 days, and social stressors (e.g., homelessness, threats to personal safety, insufficient financial resources). A lack of hydrogen peroxide-producing lactobacilli is also a recognized risk factor for bacterial vaginosis and may explain, in part, the higher prevalence of bacterial vaginosis in black women independent of other risk factors.

Histologically, there is an absence of inflammation in biopsies of the vagina—thus the term *vaginosis* rather than *vaginitis*. Bacterial vaginosis has been associated with upper tract

infections, including endometritis, pelvic inflammatory disease, postoperative vaginal cuff cellulitis, and multiple complications of infection during pregnancy, such as preterm rupture of the membranes, endomyometritis, decreased success with in vitro fertilization, and increased pregnancy loss of less than 20 weeks’ gestation.

In women with bacterial vaginosis, the most frequent symptom is an unpleasant vaginal odor, which patients describe as musty or fishy (Table 23.6). The odor is often stronger following intercourse, when the alkaline semen results in a release of aromatic amines.

The vaginal discharge associated with bacterial vaginosis is thin and gray-white. Speculum examination reveals that the discharge is mildly adherent to the vaginal walls, in contrast to a physiologic discharge, which is in the most dependent areas of the vagina. The vaginal discharge is frothy in approximately 10% of women, and it is rare to have associated pruritus or vulvar irritation.

Bacterial vaginosis is clinically diagnosed. The classic findings on wet smear are clumps of bacteria and clue cells, which are vaginal epithelial cells with clusters of bacteria adherent to their external surfaces (Fig. 23.16). Leukocytes are not nearly as frequent as epithelial cells underneath the microscope.

The four criteria for the diagnosis of bacterial vaginosis are (1) a homogeneous vaginal discharge is present; (2) the vaginal discharge has a pH of 4.5 or higher; (3) the vaginal discharge has an amine-like odor when mixed with potassium hydroxide, the whiff test; and (4) a wet smear of the vaginal discharge demonstrates clue cells more than 20% of the number of the vaginal epithelial cells. For the clinician, three of these four criteria are sufficient for a presumptive diagnosis. Fifty percent of women who have three of the four clinical criteria for bacterial vaginosis are asymptomatic. If available, Gram staining of vaginal secretion is an excellent diagnostic method. A colorimetric test that detects proline iminopeptidase has been developed for office use. Enzyme levels in vaginal fluid are elevated in women with bacterial vaginosis. Vaginal bacterial culture has no role in the evaluation of bacterial vaginosis.

Table 23.6 Diagnostic Tests Available for Vaginitis

Test	Sensitivity (%)	Specificity (%)	Comments
Bacterial Vaginosis			
pH >4.5	97	64	Must meet three of four clinical criteria (pH >4.5, thin watery discharge, >20% clue cells, positive whiff test), but similar results achieved if two of four criteria meet Nugent criteria; Gram stain morphology score (1-10) based on lactobacilli and other morphotypes; score of 1-3 indicates normal flora, score of 7-10 bacterial vaginosis; high interobserver reproducibility
Amsel's criteria	92	77	
Pap smear	49	93	
Point-of-care tests			
QuickVue Advance, pH + amines	89	96	Positive if pH >4.7
QuickVue Advance, <i>G. vaginalis</i>	91	>95	Tests for proline iminopeptidase activity in vaginal fluid; if used when pH >4.5, sensitivity is 95% and specificity is 99%
OSOM BV blue	90	<95	Tests for vaginal sialidase activity
Candida			
Wet mount			
Overall	50	97	<i>C. albicans</i> a commensal agent in 15%-20% of women
Growth of 3-4 + on culture	85		
Growth of 1 + on culture	23		
pH ≤4.5	Usual		If symptoms present, pH may be elevated if mixed infection with bacterial vaginosis or <i>T. vaginalis</i> present
Pap smear	25	72	
<i>Trichomonas vaginalis</i>			
Wet mount	45-60	95	Increased visibility of microorganisms with a higher burden of infection
Culture	85-90	>95	
pH >4.5	56	50	
Pap smear	92	61	False-positive rate of 8% for standard Pap test and 4% for liquid-based cytologic test
Point-of-care test: OSOM	83	98.8	10 min required to perform tests for <i>T. vaginalis</i> antigens

Figure 23.16 Vaginal epithelial cells from woman with bacterial vaginosis. These are typical clue cells, heavily covered by coccobacilli, with loss of distinct cell margins ($\times 400$). (From Holmes KK. Lower genital tract infections in women: cystitis/urethritis, vulvovaginitis, and cervicitis. In: Holmes KK, Mårdh PA, Sparling PF, et al, eds. *Sexually Transmitted Diseases*. New York: McGraw-Hill; 1984.)

Because there are no effective means of replacing lactobacilli, the treatment for bacterial vaginosis is to decrease anaerobes with antibiotic therapy and hope the woman will then regenerate her own lactobacilli. Table 23.7 provides treatment options. Cure rates are comparable; the agent used should depend on the woman's preference and cost factors. Treatment results in an 80% symptomatic and 70% microbiologic cure at 1 month. Single-dose oral therapy of 2 g of metronidazole is no longer recommended because of high failure rates. alternative regimens include the following: tinidazole, 2 g orally for 3 days or 1 g orally for 5 days; clindamycin, 300 mg orally, twice daily for 7 days; and clindamycin ovules, 100 mg intravaginally, once at bedtime for 3 days.

Recurrent bacterial vaginosis (three or more episodes in the previous year) is a common clinical problem. One double-blind, randomized, placebo-controlled trial demonstrated that after 10 days of daily induction therapy with vaginal metronidazole, the twice-weekly use of 0.75% metronidazole gel for 16 weeks maintains a clinical cure in 75% of patients at 16 weeks and 50% by 28 weeks.

Concurrent treatment of the male partner is not recommended at this time. Alternative therapies such as the use of oral or vaginal *Lactobacillus* are not efficacious.

Table 23.7 Centers for Disease Control and Prevention Recommendations for Treatment of Acute Vaginitis (2015)

Disease	Drug	Dose	Cost†
Bacterial vaginosis*	Metronidazole (Flagyl)	500 mg PO, bid for 7 days†	\$
	Tinidazole	2-g dose PO daily for 2 days	\$\$\$
	Tinidazole	1-g dose PO daily for 5 days	\$\$\$
	0.75% metronidazole gel (Metrogel)	One 5-g application intravaginally daily for 5 days‡	\$\$\$
	2% clindamycin cream (Cleocin vaginal)	One 5-g application intravaginally every night for 7 days	\$\$\$
	Clindamycin	300 mg PO, bid for 7 days	\$
	Clindamycin ovules	100 mg intravaginally every night for 3 days	\$\$
Vulvovaginal Candidiasis, Uncomplicated			
Intravaginal therapy‡ §	Azoles		
	2% butoconazole cream (Mycelex-3)	5 g/day for 4 days§	\$\$
	2% sustained-release butoconazole cream (Gynazole)	One 5-g dose	\$\$\$
	1% clotrimazole cream (Mycelex-7)	5 g for 7-14 days§	\$
	Clotrimazole (Gyne-Lotrimin 3)	Two 100-mg vaginal tablets/day for 3 days; one 500-mg vaginal tablet	\$
	2% miconazole cream	5 g/day for 7 days§	\$\$
	Miconazole (Monistat-7)	One 100-mg vaginal suppository/day for 7 days§	\$\$
	Miconazole (Monistat-3)	One 200-mg vaginal suppository/day for 3 days	\$\$
	Miconazole (Monistat-1)	One 1200-mg vaginal suppository§	
	6.5% tioconazole ointment (Monistat 1-day)	One 5-g dose§	\$
	0.4% terconazole cream (Terazol 7)	5 g/day for 7 days	\$\$\$
	0.8% terconazole cream (Terazol 3)	5 g/day for 3 days	\$\$
	Terconazole vaginal	One 80-mg vaginal suppository/day for 3 days	\$\$\$
	Oral therapy	Fluconazole (Diflucan)	One 150-mg dose PO
Vulvovaginal Candidiasis, Complicated††			
Intravaginal therapy‡	Azole	7-14 days	\$\$
Oral therapy¶	Fluconazole (Diflucan)	Two 150-mg doses PO, 72 hr apart	\$\$\$
Trichomoniasis	Metronidazole (Flagyl)	One 2-g dose PO, 500 mg orally bid for 7 days	\$
	Tinidazole (Tindamax)	One 2-g dose PO**	\$\$

Modified from Eckert LO. Clinical practice: acute vulvovaginitis. *N Engl J Med*. 2006;355(12):1244-1252. *Bid*, Twice per day.

*†Oral therapy is recommended for pregnant women.

††Drug may cause gastrointestinal upset in 5% to 10% of patients; a disulfiram reaction is possible; alcohol should be avoided for 24 hr after ingestion.

‡§Vaginal treatments cause local vaginal irritation in 2% to 5% of patients.

§This agent is available over the counter.

¶Complicated vulvovaginitis refers to disease in women who are pregnant, women who have uncontrolled diabetes, women who are immunocompromised, or women who have severe symptoms, non-*Candida albicans* candidiasis, or recurrent episodes (four or more/year).

¶Oral therapy is not recommended for pregnant women.

**Drug may cause gastrointestinal upset in 2% to 5% of patients; disulfiram reaction is possible; alcohol should be avoided 72 hr after ingestion.

TRICHOMONAS VAGINAL INFECTION

Trichomoniasis is caused by the anaerobic flagellated protozoan, *T. vaginalis* (Fig. 23.17), a unicellular organism that is normally fusiform in shape. Three to five flagella extend from one end of the organism and provide active movement of the protozoan.

It is estimated that there are 5 million new cases of trichomoniasis annually in the United States. The prevalence of the disease remains high, despite the availability of effective treatments since the early 1960s. *Trichomonas* vaginal infection is the cause of acute vaginitis in 5% to 50% of cases, depending on the population studied, and is the most prevalent nonviral, nonchlamydial STI of women.

This infection is a highly contagious STI; following a single sexual contact, at least two thirds of male and female sexual partners become infected. The protozoa are isolated from 30% to 40% of male partners of women with a positive culture and approximately 85% of female partners of a male with a positive culture. The incubation period is 4 to 28 days. *Trichomonas* is a hardy organism and will survive for up to 24 hours on a wet towel and up to 6 hours on a moist surface. However, experimental

studies have established that successful vaginal infection depends on the deposition of an inoculum of several thousand organisms. Hence, it is unlikely that infection may be related to exposure from infected towels or swimming pools.

Trichomonas produces a wide variety of patterns of vaginal infection. The primary symptom of *Trichomonas* vaginal infection is profuse vaginal discharge. Patients often complain that the copious discharge makes them feel “wet.” Approximately 50% of symptomatic women also detect an abnormal vaginal odor and experience vulvar pruritus; dysuria is a symptom in approximately one of five women with symptomatic *Trichomonas* infection. Women with chronic infection may have a malodorous discharge as their only complaint.

Many women with *Trichomonas* are symptom free. In one study of women with positive cultures, only one out of two women had symptoms of abnormal vaginal discharge, and only one out of six women complained of vulvar pruritus. Positive wet smears or cultures for *Trichomonas* are reported in 3% to 10% of asymptomatic gynecology patients, with a much higher percentage being found in women attending an STI clinic.

Figure 23.17 **A** and **B**, Trichomonads in wet mount prepared with physiologic saline. (**A**, From Faro S. Trichomoniasis. In: Kaufman RH, Faro S, eds. *Benign Diseases of the Vulva and Vagina*. 4th ed. St. Louis: Mosby-Year Book; 1994. **B**, From Friedrich EG. *Vulvar Disease*. 2nd ed. Philadelphia: WB Saunders; 1983.)

On physical examination, a woman with *T. vaginalis* may have erythema and edema of the vulva and vagina. Vulvar skin involvement is limited to the vestibule and labia minora, which helps distinguish it from the more extensive vulvar involvement of *Candida* vulvovaginitis. The discharge color may be white, gray, yellow, or green, and the classic discharge of *Trichomonas* infection is termed *frothy* (with bubbles) and often has an unpleasant odor. The classic sign of a strawberry appearance of the upper vagina and cervix is rare and is noted in less than 10% of women.

The CDC encourages use of highly sensitive tests to detect *T. vaginalis* in both symptomatic and asymptomatic women. Nucleic acid amplification tests (NAATs) are three to five times more sensitive than wet prep. NAAT can be performed on vaginal secretions or urine. There are several FDA-approved point of care NAATs to detect *T. vaginalis* (Workowski, 2015).

Previously, culture was considered the gold standard to detect *T. vaginalis*, and wet prep was the most commonly performed diagnostic test (see Table 23.7). Under best conditions when samples are viewed within 10 minutes of collection and the swab does not dry out, wet prep is 80% sensitive to identify trichomonads.

Attempts to diagnose *T. vaginalis* infection by Papanicolaou (Pap) smear results in an error rate of at least 50%. There have been a large number of false-positive and false-negative reports.

Nitroimidazoles are the only class of drugs recommended for treatment of *Trichomonas* vaginitis. A single oral dose (2 g) of metronidazole or tinidazole is recommended. An alternate regimen is metronidazole, 500 mg orally, twice daily for 7 days. Tinidazole is a second-generation nitroimidazole and has a longer half-life of 24 hours. Metronidazole is safe in all trimesters of pregnancy. Tinidazole is categorized as a category C drug in pregnancy. Nausea is the most frequent complication and is experienced by 5% of women. Patients should be warned that nitroimidazoles inhibit ethanol metabolism. Women should avoid alcohol for 24 hours after metronidazole and 72 hours after tinidazole therapy to avoid a disulfiram-like reaction.

Topical therapy for *Trichomonas* vaginitis is not recommended because it does not eliminate disease reservoirs in Bartholin and Skene glands. Data have shown that metronidazole, 2-g single oral dose, was not as effective as 500 mg twice daily for 7 days for trichomoniasis in HIV-infected women. Therefore a multidose treatment regimen for *T. vaginalis* may be considered for HIV-infected women.

Patients should be rescreened with a NAAT in 3 months due to high reinfection rates. In most cases, women who have a recurrence have been re-infected or complied poorly with therapy. The prevalence of low-level metronidazole resistance in *T. vaginalis* is 2% to 5%; in case series, prolonged treatment with higher doses of metronidazole and tinidazole has been successful. Because *T. vaginalis* is sexually transmitted, treatment of the woman's partner is important and increases cure rates. If reexposure is not an issue, and the infection is not cleared after adequate therapy, one should consult the CDC treatment guidelines for further therapeutic options or for assistance in performing susceptibility testing (Workowski, 2015).

Asymptomatic women with *Trichomonas* identified in the lower genital urinary tract should be treated. Extended follow-up studies have shown that one of three asymptomatic women will become symptomatic within 3 months. Furthermore, HIV acquisition is increased in women with *Trichomonas* infection. Similar to bacterial vaginosis, *T. vaginalis* is associated with upper genital tract infections, including infections after delivery, surgery, abortion, pelvic inflammatory disease, preterm delivery, infertility, and cervical dysplasia treatment. Because all STIs have common epidemiologic backgrounds, finding one dictates carrying out appropriate studies to rule out colonization or infection with another STI.

CANDIDA VAGINITIS

Candida vaginalis is produced by a ubiquitous, airborne, gram-positive fungus. In most populations, more than 90% of cases are caused by *Candida albicans* (Fig. 23.18), with 5% to 10%

Figure 23.18 High power microscopic view of *Candida albicans*. (From Marsh P, Lewis M, Williams D, et al, eds. *Oral Microbiology*. 5th ed. Edinburgh: Churchill Livingstone; 2010.)

Figure 23.19 Scanning electron micrograph of intraluminal debris of specimen of vaginal wall taken from patient with vaginal candidiasis (× 3500). The hyphae of *C. albicans* penetrate the epithelial layers of vaginal surface. (From Merkus JM, Bisschop MP, Stolte LA. The proper nature of vaginal candidosis and the problem of recurrence. *Obstet Gynecol Surv*. 1985;40:493-504.)

of vaginal fungal infections produced by *Candida glabrata* or *Candida tropicalis*. *Candida* spp. are part of the normal flora of approximately 25% of women, being a commensal saprophytic organism on the mucosal surface of the vagina. Its prevalence in the rectum is three to four times greater and in the mouth two times greater than in the vagina. *Candida* organisms develop filamentous (hyphae and pseudohyphae) and ovoid forms, termed *conidia*, *buds*, or *spores*. The filamentous forms of *C. albicans* have the ability to penetrate the mucosal surface and become intertwined with the host cells (Fig. 23.19). This results in secondary hyperemia and limited lysis of tissue near the site of infection. In contrast, *C. glabrata* does not produce filamentous forms.

When the ecosystem of the vagina is disturbed, *C. albicans* can become an opportunistic pathogen. Hormonal factors, depressed cell-mediated immunity, and antibiotic use are the

three most important factors that alter the vaginal ecosystem. The hormonal changes associated with pregnancy and menstruation favor growth of the fungus. The prevalence of *Candida* vaginitis increases throughout pregnancy, probably as a result of the high estrogen levels. The literature was initially mixed with respect to the relationship between oral contraceptives and candidiasis. However, with the currently used low-dose estrogen oral contraceptives, there is no increase in the incidence of fungal vaginitis. Women tend to report recurrent episodes of vaginitis immediately preceding and immediately following their menstrual periods.

Lactobacilli inhibit the growth of fungi in the vagina. Therefore when the relative concentration of lactobacilli declines, rapid overgrowth of *Candida* spp. occurs. Broad-spectrum antibiotics, especially those that destroy lactobacilli (e.g., penicillin, tetracycline, cephalosporins), are notorious for precipitating acute episodes of *C. albicans* vaginitis. Obesity and debilitating disease are other predisposing factors.

Probably the most important host factor is depressed cell-mediated immunity. Women who take exogenous corticosteroids and women with AIDS often experience recurrent *Candida* vulvovaginitis. Altered local immune responses, such as hyper-IgE-mediated response to a small amount of *Candida* antigen, may occur in women with recurrent vulvovaginal candidiasis. Also, some women with recurrent vulvovaginal candidiasis have tissue infiltration with polymorphonuclear (PMN) leukocytes. This high density of PMNs correlates with symptomatology but does not result in clearance of *Candida*.

Vaginitis caused by fungal infection is primarily a disease of the childbearing years. It is estimated that three of four women will have at least one episode of vulvovaginal candidiasis during their lifetime. The greatest enigma of this condition is the recurrence rate after an apparent cure, varying from 20% to 80%. Approximately 3% to 5% of these women experience recurrent vulvovaginal candidiasis (RVVC), which is defined as four or more documented episodes in 1 year.

Fungal vaginitis usually presents as a vulvovaginitis. Pruritus is the predominant symptom. Depending on the degree of vulvar skin involvement, pruritus may be accompanied by vulvar burning, external dysuria, and dyspareunia. The vaginal discharge is white or whitish gray, highly viscous, and described as granular or floccular, with no odor. The amount of discharge is highly variable. The vulvar signs include erythema, edema, and excoriation. With extensive skin involvement, pustules may extend beyond the line of erythema. During speculum examination, a cottage cheese-type discharge is often visualized, with adherent clumps and plaques (thrush patches) attached to the vaginal walls. These clumps, or raised plaques, are usually white or yellow. The vaginal pH associated with this infection is below 4.5, in contrast to bacterial vaginosis and *Trichomonas* vaginitis, which are associated with an elevated pH.

The diagnosis is established by obtaining a wet smear of vaginal secretion and mixing this with 10% to 20% potassium hydroxide (Fig. 23.20). The alkali rapidly lyses red blood cells and inflammatory cells. Active disease is associated with filamentous forms, mycelia, or pseudohyphae, rather than spores. However, it may be necessary to search the slide and scan many different microscopic fields to identify hyphae or pseudohyphae. The average concentration of organisms is 10^3 to 10^4 /mL. Although symptoms can be present at a low colony count, the ability to

Figure 23.20 Microscopic appearance of vaginal smear in a case of vaginal candidiasis (potassium hydroxide preparation, yeast cells and pseudomycelia; $\times 320$). (From Merkus JM, Bisschop MP, Stolte LA. The proper nature of vaginal candidosis and the problem of recurrence. *Obstet Gynecol Surv.* 1985;40:493-504.)

detect *C. albicans* on a wet mount is 80% when semiquantitative culture growth is 3 to 4+, but only 20% when culture growth is 2+. Hence, a negative smear does not exclude *Candida* vulvovaginitis. The diagnosis can be established by culture with Nicker-son or Sabouraud medium. These cultures will become positive in 24 to 72 hours. Vaginal culture for *Candida* is particularly useful when a wet mount is negative for hyphae, but the patients have symptoms and discharge or other signs suggestive of vulvovaginal candidiasis on examination. Fungal culture may also be useful for women who have recently treated themselves with an antifungal agent; up to 90% have a negative culture within 1 week after treatment. It should be stressed that obtaining a vaginal culture for bacteria is not useful because anaerobes, coliforms, and *G. vaginalis* all are part of normal vaginal flora. The differential diagnosis includes other common causes of vaginitis, such as bacterial vaginosis, *Trichomonas* vaginitis, and atrophic vaginitis. Also, one should consider noninfectious conditions such as allergic reactions, contact dermatitis, chemical irritants, and rare diseases such as lichen planus.

The over-the-counter (OTC) availability of vaginal antifungal therapy makes self-treatment an option for many women. However, it must be recognized that symptoms suggestive of uncomplicated vulvovaginal candidiasis may reflect an alternative diagnosis. One study of women seen at a clinic for STIs found that self-treatment of the symptoms listed on the package insert of an OTC medication for candidiasis would correctly treat only 28% of patients; 53% had bacterial vaginosis, infection with *T. vaginalis*, gonorrhea, or chlamydia. In another study involving women purchasing OTC antifungal therapy, only 34% had vulvovaginal candidiasis and no other vaginal infection. If a woman chooses self-treatment, she should be advised to come in for examination if the symptoms are not eliminated with a single course of OTC therapy.

For treatment of vulvovaginal candidiasis, the CDC recommends placing the woman into an uncomplicated or complicated category to guide treatment (Box 23.3). A number of azole vaginal preparations and a single oral agent, fluconazole, are approved for treatment. In patients with uncomplicated

Box 23.3 Classification of Vulvovaginal Candidiasis (VVC)

Uncomplicated VVC

- Sporadic or infrequent vulvovaginal candidiasis
- and
- Mild to moderate vulvovaginal candidiasis
- and
- Likely to be *C. albicans*
- and
- Nonimmunocompromised women

Complicated VVC

- Recurrent vulvovaginal candidiasis
- or
- Severe vulvovaginal candidiasis
- or
- Non-*albicans* candidiasis
- or
- Women with uncontrolled diabetes, debilitation, or immunosuppression

Modified from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(RR-03):1-137.

vulvovaginal candidiasis, topical antifungal agents are typically used for 1 to 3 days, or a single oral dose of fluconazole. Patient preference, response to prior therapy, and cost should guide the choice of therapy (Workowski, 2015).

For patients with complicated vaginitis, topical azoles are recommended for 7 to 14 days. If using oral therapy, a second dose of fluconazole (150 mg) given 72 hours after the first dose is recommended.

In women with RVVC, the resolution of symptoms typically requires longer duration of therapy. Seven to 14 days of topical therapy or three doses of oral fluconazole 3 days apart (e.g., days 1, 4, and 7) are options. After this initial treatment, maintenance therapy will help prevent recurrence of symptoms. Oral fluconazole (e.g., 100-, 150-, or 200-mg dose) weekly for 6 months is typically first-line treatment. However, topical treatments used intermittently as a maintenance regimen may be considered. Women with recurrent vulvovaginitis should receive a vaginal fungal culture to determine species and sensitivities.

Infections with *Candida* spp. other than *C. albicans* are often azole resistant. However, one study of terconazole for non-*C. albicans* fungal vaginitis resulted in a mycologic cure in 56% of patients and a symptomatic cure in 44% of women. Vaginal boric acid capsules (600 mg in 0 gelatin capsules) are another option. In one study, treatment for a minimum of 14 days resulted in a symptomatic cure rate of 70% for women with non-*C. albicans* infection. Boric acid inhibits fungal cell wall growth. It may also be used for suppression in women with recurrent vulvovaginal candidiasis. Following 10 days of therapy, one 600-mg capsule intravaginally twice weekly for 4 to 6 months decreases symptomatic recurrences. Boric acid is toxic if ingested, so it should be stored in a safe manner (Sobel, 1995, 2001, 2003).

Studies of alternative therapies for vulvovaginal candidiasis (such as oral or vaginal *Lactobacillus*, garlic, or diet alterations such as yogurt ingestion) do not show efficacy. A summary of diagnostic tools for determining the cause of vaginitis and a list treatment options are provided in Tables 23.6 and 23.7.

TOXIC SHOCK SYNDROME

Toxic shock syndrome (TSS) is an acute febrile illness produced by a bacterial exotoxin, with a fulminating downhill course involving dysfunction of multiple organ systems. The cardinal

features of the disease are its abrupt onset and rapidity with which the clinical signs and symptoms may present and progress. It is not unusual for the syndrome to develop from a site of bacterial colonization rather than from an infection.

A woman with TSS may develop a rapid onset of hypotension associated with multiorgan system failure. TSS was first described in 1978 by Todd as a sometimes fatal sequela of *Staphylococcus aureus* infection in children. In the early 1980s, more than 95% of the reported cases of TSS were diagnosed in previously healthy, young (<30 years), menstruating females. *S. aureus* was isolated from the vagina in more than 90% of these cases.

Between 1979 and 1996, 5296 TSS cases were reported. Menstrual cases accounted for 74% of total cases, although the proportion has decreased over time (91% from 1979 to 1980, 71% from 1981 to 1986, and 59% from 1986 to 1996). The number of cases of menstrual TSS has declined from 9 of 100,000 women in 1980 to 1 of 100,000 women since 1986. The case-fatality rate has also declined; it was 1.8% from 1987 to 1996 after a high of 5.5% in 1979 to 1980. Most likely, the withdrawal of highly absorbent tampons and polyacrylate rayon-containing products from the market partially explains the decrease. However, tampon use remains a risk factor for TSS. Women who develop TSS are more likely to have used higher absorbency tampons, several cycle days of tampons, and kept a single tampon in for a longer period of time.

Approximately 50% of cases of TSS are not related to menses. Nonmenstrual TSS may be a sequelae of focal staphylococcal infection of the skin and subcutaneous tissue, often following a surgical procedure. It has been recognized that occasionally severe postoperative infections by *Streptococcus pyogenes* produce a similar streptococcal toxic shock–like syndrome. TSS related to a surgical wound occurs early in the postoperative course, usually within the first 48 hours. The proportion of cases following surgical procedures increased from 14% in 1979 to 1986 to 27% in 1987 to 1996.

There are three requirements for the development of classic TSS: (1) the woman must be colonized or infected with *S. aureus*, (2) the bacteria must produce TSS toxin 1 (TSST-1) or related toxins, and (3) the toxins must have a route of entry into the systemic circulation. Most strains of *S. aureus* are unable to produce TSS toxin 1. Interestingly, approximately 85% of women have antibodies against TSST-1.

If an individual woman continues to use tampons when the vagina is colonized with *S. aureus*, there is a significant chance of recurrence. It has been reported that one woman experienced five episodes of the disease. There appears to be no pattern to these recurrent episodes. Interestingly, women with menstrual-related TSS do not respond immunologically to TSST-1 as do women with non-menstrual-related TSS. It is rare for a woman with nonmenstrual TSS to have a recurrence.

The signs and symptoms of TSS are produced by the exotoxin named *toxin 1*. Toxin 1 is a simple protein with a molecular weight of 22,000 kDa and is accepted as the underlying cause of the disease. Thus toxins act as superantigens, molecules that activate up to 20% of T cells at once, resulting in massive cytokine production. Pathophysiologically, superantigens do not require processing by antigen-presenting cells. The primary effects of toxin 1 are to produce increased vascular permeability, thus resulting in profuse leaking of fluid (capillary leak) from

the intravascular compartment into the interstitial space and an associated profound loss of vasomotor tone, causing decreased peripheral resistance.

Studies of the bacteriology of the vagina of normal menstruating females have documented that 5% to 17% of women are colonized with *S. aureus*. Approximately 5% test positive when the culture is obtained at midcycle, and the percentage increases to 10% to 17% during menses. Rarely are blood cultures positive for *S. aureus* in a woman with TSS. Thus the exotoxin is believed to be absorbed directly from the vagina. It is possible that microulcerations produced by use of tampons facilitate the toxin's entry into the systemic circulation. The risk of nonmenstrual TSS is definitely increased in women who use barrier contraceptives such as a diaphragm, cervical cap, or a sponge containing nonoxynol 9.

Because of the severity of the disease, gynecologists should have a high index of suspicion for TSS in a woman who has an unexplained fever and a rash during or immediately following her menstrual period. The syndrome has a wide range of symptoms. The varying degree of severity of symptoms and signs depends on the magnitude of involvement of individual organs. Most women experience a prodromal flulike illness for the first 24 hours. Between days 2 and 4 of the menstrual period, the patient experiences an abrupt onset of a high temperature associated with headache, myalgia, sore throat, vomiting, diarrhea, generalized skin rash, and often hypotension. It is important to consider that not all women with TSS experience the full-blown manifestations of the disease. The rigid criteria developed by the CDC are used for epidemiologic studies. Clinically, many women present with a forme fruste of TSS, with low-grade fever and dizziness rather than hypotension.

The most characteristic manifestations of TSS are the skin changes. During the first 48 hours, the skin rash appears similar to intense sunburn. During the next few days, the erythema will become more macular and resemble a drug-related rash. From days 12 to 15 of the illness, there is a fine, flaky desquamation of skin over the face and trunk, with sloughing of the entire skin thickness of the palms and soles. The vaginal mucosa is hyperemic during the initial phase of the syndrome. During pelvic examination, patients complain of tenderness of the external genitalia and vagina. More than 90% of women with TSS experience myalgia, vomiting, and diarrhea (Box 23.4). Many abnormal laboratory findings are associated with the disease and, again, they reflect the severity of involvement of individual organ systems (Box 23.5). The differential diagnosis of toxic shock syndrome includes Rocky Mountain spotted fever, streptococcal scarlet fever, and leptospirosis.

The management of a classic case of severe TSS demands an intensive care unit and the skills of an expert in critical care medicine. The first priority is to eliminate the hypotension produced by the exotoxin. Copious amounts of IV fluids are given while pressure and volume dynamics are centrally monitored. Mechanical ventilation is required for women who develop adult respiratory distress syndrome.

When the woman is initially admitted to the hospital, it is important to obtain cervical, vaginal, and blood cultures for *S. aureus*. Although there have been no controlled series documenting its efficacy, it is prudent to wash out the vagina with saline or dilute iodine solution to diminish the amount of exotoxin that may be absorbed into the systemic circulation.

Box 23.4 Case Definition of Toxic Shock Syndrome

1. Fever (temperature 38.9° C [102° F])
2. Rash characterized by diffuse macular erythroderma
3. Desquamation occurring 1–2 wk after onset of illness (in survivors)
4. Hypotension (systolic blood pressure \leq 90 mm Hg in adults) or orthostatic syncope
5. Involvement of three or more of the following organ systems:
 - a. Gastrointestinal (vomiting or diarrhea at onset of illness)
 - b. Muscular (myalgia or creatine phosphokinase level twice normal)
 - c. Mucous membrane (vaginal, oropharyngeal, or conjunctival hyperemia)
 - d. Renal (BUN or creatinine level \geq twice normal or \geq 5 WBCs/HPF in absence of UTI)
 - e. Hepatic (total bilirubin, SGOT, or SGPT twice normal level)
 - f. Hematologic (platelets \leq 100,000/mm³)
 - g. Central nervous system (disorientation or alteration in consciousness without focal neurologic signs when fever and hypotension are absent)
 - h. Cardiopulmonary (adult respiratory distress syndrome, pulmonary edema, new onset of second- or third-degree heart block, myocarditis)
6. Negative throat and cerebrospinal fluid cultures (a positive blood culture for *Staphylococcus aureus* does not exclude a case)
7. Negative serologic test results for Rocky Mountain spotted fever, leptospirosis, rubeola

From Centers for Disease Control (CDC). Toxic-shock syndrome, United States, 1970–1982. *MMWR Morb Mortal Wkly Rep.* 1982;31:201.
 BUN, Blood urea nitrogen; HPF, high-powered field; SGOT, serum glutamic-oxaloacetic transaminase; SGPT, serum glutamic-pyruvic transaminase; UTI, urinary tract infection; WBC, white blood cell count.

Box 23.5 Laboratory Abnormalities in Early Toxic Shock Syndrome

Present in >85% of patients
 Coagulase-positive staphylococci in cervix or vagina
 Immature and mature polymorphonuclear cells >90% of WBCs
 Total lymphocyte count <650/mm³
 Total serum protein level <5.6 mg/dL
 Serum albumin level <3.1 g/dL
 Serum calcium level <7.8 mg/dL
 Serum creatinine clearance >1 mg/dL
 Serum bilirubin level >1.5 mg/dL
 Serum cholesterol level \leq 120 mg/dL
 Prothrombin time >12 seconds
 Present in >70% of patients
 Platelet count <150,000/mm³
 Pyuria >5 WBCs/HPF
 Proteinuria \geq 2+
 BUN >20 mg/dL
 Aspartate aminotransferase (formerly SGOT) >41 U/L

From Chesney PJ, Davis JP, Purdy WK, et al. Clinical manifestations of toxic shock syndrome. *JAMA.* 1981;246:746.
 BUN, Blood urea nitrogen; HPF, high-powered field; SGOT, serum glutamic-oxaloacetic transaminase; WBCs, white blood cells.
 Results were available for at least 18 patients per category with the following exceptions: cervicovaginal cultures (12 patients), cholesterol level (15 patients), and prothrombin time (14 patients).

Women with TSS caused by methicillin-susceptible *S. aureus* should be treated with clindamycin, 600 mg IV every 8 hours, plus nafcillin or oxacillin, 2 g IV every 4 hours. Most experts recommend a 1- to 2-week course of therapy with an antistaphylococcal agent such as clindamycin or dicloxacillin,

even in the absence of a positive *S. aureus* culture. In patients with TSS caused by methicillin-resistant *S. aureus* (MRSA), clindamycin plus vancomycin (30 mg/kg/day IV in two divided doses) or linezolid (600 mg oral or IV every 12 hours) is used. If the diagnosis is questionable, it is best to include an aminoglycoside to obtain coverage for possible gram-negative sepsis. Antibiotic therapy probably has little effect on the course of an individual episode of TSS. However, if the underlying cause of toxic shock syndrome is a skin infection, the infected site should be drained and debrided. Treatment with mupirocin to decrease colonization is recommended, applying half of the ointment from a single-use tube into one nostril and the other half into the other nostril twice daily for 5 days.

In summary, the treatment of TSS depends on the severity of involvement of individual organ systems. Not all patients develop a temperature higher than 38.9° C and hypotension. Thus clinicians should be aware of the forme fruste manifestations of the syndrome. The foundation of treatment of the disease is prompt and aggressive management because of the rapidity with which the disease may progress.

It is possible to decrease the incidence of TSS by a change in the use of catamenial products. Women should be encouraged to change tampons every 4 to 6 hours. The intermittent use of external pads is also good preventive medicine. Women will usually accept the recommendation to wear external pads during sleep. The incidence of TSS has decreased dramatically with the removal of super-absorbing tampons from the market. A study by Tierno and Hanna reported that all-cotton tampons are the safest choice to avoid menstrual TSS.

Finally, there are cases of streptococcal toxic shock–like syndromes that are secondary to life-threatening infections with group A streptococcus (*Streptococcus pyogenes*). Several different exotoxins have been identified, and M types 1 and 3 are the two most common serotypes. In gynecology, most of these cases involve massive subcutaneous postoperative infections. One of the most distinguishing characteristics of a necrotizing skin infection is the intense localized pain in the involved area. Older women and women who are diabetic or immunocompromised are at much greater risk to develop invasive streptococcal infection and streptococcal toxic shock–like syndrome. The mortality rate is approximately 30% when TSS is secondary to group A streptococcal infections (Al-ajmi, 2012; LeRiche, 2012).

CERVICITIS

Cervicitis, an inflammatory process in the cervical epithelium and stroma, can be associated with trauma, inflammatory systemic disease, neoplasia, and infection. Although it is clinically important to consider all causes of inflammation, this section focuses on infectious origins.

The cervix acts as a barrier between the abundant bacterial flora of the vagina and the bacteriologically sterile endometrial cavity and oviducts. Cervical mucus is much more than a simple physical barrier; it exerts a bacteriostatic effect. Mucus may also act as a competitive inhibitor with bacteria for receptors on the endocervical epithelial cells. Cervical mucus also contains antibodies and inflammatory cells that are active against various sexually transmitted organisms.

Often, the woman is asymptomatic, even though the cervix is colonized with organisms. The cervix is a potential reservoir for *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, HSV, human papillomavirus, and *Mycoplasma* spp. Cervical infection can be ectocervicitis or endocervicitis. Ectocervicitis can be viral (HSV) or from a severe vaginitis (e.g., strawberry cervix associated with *T. vaginalis* infection) or *C. albicans*. Endocervicitis may be secondary to infection with *C. trachomatis* or *N. gonorrhoeae*. Bacterial vaginosis and *Mycoplasma genitalium* have also been associated with endocervicitis. Infection of the endocervix becomes a major reservoir for sexual and perinatal transmission of pathogenic microorganisms. Primary endocervical infection may result in secondary ascending infections, including pelvic inflammatory disease and perinatal infections of the membranes, amniotic fluid, and parametria.

The histologic diagnosis of chronic cervicitis is so prevalent that it should be considered the norm for parous women of reproductive age. The histopathology of endocervicitis is characterized by a severe inflammatory reaction in the mucosa and submucosa. The tissues are infiltrated with a large number of PMNs and monocytes and, occasionally, there is associated epithelial necrosis. Physiologically, there is a resident population of a small number of leukocytes in the normal cervix. Thus the emphasis is on a severe inflammatory reaction by a large number of PMNs. This section focuses on mucopurulent cervicitis and techniques to diagnose common cervical infections.

MUCOPURULENT CERVICITIS

The diagnosis of cervicitis continues to rely on symptoms, examination, and microscopic evaluation. Two simple, definitive, objective criteria have been developed to establish mucopurulent cervicitis—gross visualization of yellow mucopurulent material on a white cotton swab (Fig. 23.21) and the presence of 10 or more PMN leukocytes per microscopic field (magnification, $\times 1000$) on Gram-stained smears obtained from the endocervix. Alternative clinical criteria that may be used are erythema and edema in an area of cervical ectopy or associated with bleeding secondary to endocervical ulceration or friability when the endocervical smear is obtained. Women may also report increased vaginal discharge and intermenstrual vaginal bleeding.

The prevalence of mucopurulent cervicitis depends on the population being studied. Approximately 30% to 40% of women attending clinics for STIs and 8% to 10% of women in university student health clinics have the condition. More than 60% of women with this disease are asymptomatic. Symptoms that suggest cervical infection include vaginal discharge, deep dyspareunia, and postcoital bleeding. The physical sign of a cervical infection is a cervix that is hypertrophic and edematous.

C. trachomatis is the cause of cervical infection in many women with mucopurulent cervicitis (Fig. 23.22). Depending on the geographic region, gonorrhea is also an important cause of mucopurulent cervicitis. However, most women who have lower reproductive tract infections caused by *C. trachomatis* or *N. gonorrhoeae* do not have mucopurulent cervicitis. The corollary is that most women who have mucopurulent cervicitis are not infected by *C. trachomatis* or *N. gonorrhoeae*. Mucopurulent cervicitis is present in approximately 40% to 60% of women in whom no cervical pathogen can be identified. Thus this condition often persists following adequate broad-spectrum antibiotic

Figure 23.21 Mucopurulent cervicitis demonstrated by a cotton swab test.

Figure 23.22 Patient with *C. trachomatis* mucopurulent cervicitis with resolution post treatment.

therapy. The presence of active herpes infection is correlated with ulceration of the ectocervix but not with mucopus.

When mucopurulent cervicitis is clinically diagnosed, empirical therapy for *C. trachomatis* is recommended for women at increased risk of this common STI (age <25 years, new or multiple sex partners, unprotected sex). If the prevalence of *N. gonorrhoeae* is more than 5%, concurrent therapy for *N. gonorrhoeae* is indicated. Concomitant trichomoniasis should also be treated if detected, as should bacterial vaginosis. If presumptive treatment is deferred, the use of a sensitive nucleic acid test for *C. trachomatis* and *N. gonorrhoeae* is needed.

Recommended regimens for presumptive cervicitis therapy include azithromycin, 1 g orally in a single dose, or doxycycline, 100 mg orally twice daily for 7 days, adding gonococcal treatment if the prevalence is over 5% in the population assessed. Women treated for chlamydia should be instructed to abstain from sexual intercourse for 7 days after single-dose therapy or until completion of the 7-day regimen (Workowski, 2015).

Mycoplasma genitalium, which is noncultivable, has been associated in women with mucopurulent cervicitis by DNA testing. Empiric treatment for *M. genitalium* in cases of persistent cervicitis after standard treatment may be considered but should be done in consultation with a specialist. There is no FDA-approved diagnostic test for *M. genitalium* in the United States. Some research laboratories may have PCR-based testing. Bacterial vaginosis has also been associated with mucopurulent cervicitis; cervicitis resolved with bacterial vaginosis treatment (Workowski, 2015).

DETECTION OF PATHOGENIC CERVICAL BACTERIA

Neisseria gonorrhoeae

Nucleic acid amplification testing (NAAT) of the urine or vaginal secretions is the most sensitive and specific diagnostic tool for identifying gonorrheal infections. Urine tests should be first void (either the first void in morning or at least 1 hour since last void). This technique allows for the sensitive detection of DNA particles originating from the urethra or endocervix, which fall into the vaginal pool and vestibule.

Most women who are colonized with *N. gonorrhoeae* are asymptomatic. Therefore it is important to screen women at high risk for gonorrheal infection routinely. Screening of high-risk individuals is the primary modality to control the disease. Gonorrheal NAAT results are over 95% sensitive and specific.

Antibiotic-resistant gonorrhea culture (GC) is problematic. CDC STD Treatment Guidelines (2015) recommend dual therapy with ceftriaxone 250 mg once IM and azithromycin 1 g orally in a single dose, preferably under direct observation, for all GC infections (Boxes 23.6 and 23.7). Routine co-treatment using two antimicrobials with different mechanisms of action, such as a cephalosporin plus azithromycin, may slow the selection and spread of antibiotic-resistant GC. Based on experience with other microbes that developed antimicrobial resistance rapidly, a theoretic basis exists for combination therapy using two antimicrobials with different mechanisms of action to improve treatment efficacy and potentially delay emergence and spread of resistance to cephalosporins. Azithromycin is preferred to doxycycline because of the convenience and compliance advantages of single-dose therapy and the substantially higher prevalence of gonococcal resistance to tetracycline than to azithromycin in tracked isolates.

If the woman is asymptomatic, the CDC no longer recommends follow-up testing for a test of cure for lower tract infections (uncomplicated gonorrhea). However, studies have shown a high rate of reinfection, so rescreening patients is prudent. Women with positive cultures for gonorrhea should have a serologic test for syphilis in 4 to 6 weeks, even though patients with incubating syphilis are usually cured by antibiotic combinations of ceftriaxone and tetracycline. Similarly, patients should be offered informed consent and testing for HIV infection.

It is important to remember that *N. gonorrhoeae* attaches to the columnar epithelium, so a vaginal cuff swab in women with prior hysterectomies is not recommended (Workowski, 2015).

Chlamydia trachomatis

As with gonorrhea, the gold standard of techniques used to identify *C. trachomatis* infection is NAAT. *C. trachomatis* also

Box 23.6 Centers for Disease Control and Prevention Recommended Dual Treatment of Uncomplicated Gonococcal Infections of the Cervix, Urethra, and Rectum in Adults (2014)

Ceftriaxone, 250 mg IM, single dose
or, if not an option
Cefixime, 400 mg PO, single dose
plus
Azithromycin 1 g orally in a single doses, preferably under direct observation

Modified from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015;64(RR-03):1-137.

Box 23.7 Recommended Regimens for Treatment of Chlamydial Infection

Azithromycin, 1 g PO, single dose*
or
Doxycycline, 100 mg PO bid for 7 days
Alternative Regimens
Erythromycin base, 500 mg PO qid for 7 days
or
Erythromycin ethylsuccinate, 800 mg PO qid for 7 days
or
Ofloxacin, 300 mg PO bid for 7 days
or
Levofloxacin, 500 mg PO once daily for 7 days

Modified from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015;64(RR-03):1-137. *bid*, Twice per day; *qid*, four times per day.

*Consider concurrent treatment for gonococcal infection if prevalence of gonorrhea is high in the patient population under assessment.

attaches to the columnar epithelium. Hence, vaginal specimens should not be collected from women who have had a hysterectomy. When a culture is used for diagnosis, *C. trachomatis* is an obligatory intracellular organism; hence, it is mandatory to obtain epithelial cells to maximize the percentage of positive cultures. A Dacron, rayon, or calcium alginate swab is placed in the endocervical canal. It is rotated for 15 to 20 seconds to abrade the columnar epithelium gently. The Cytobrush, which was developed primarily to enhance sampling of endocervical cells for cytology, has been found to be the optimal instrument for appropriate sampling for *Chlamydia* culture as well. Chlamydial antigen detection is insensitive and nonspecific compared with NAAT and is no longer recommended.

C. trachomatis infection is frequently asymptomatic. Chlamydial screening programs have been successful at decreasing the prevalence of the disease. The CDC recommends annual screening of all sexually active women 25 years of age or younger and screening of older women with risk factors (e.g., those who have a new sex partner or multiple partners).

For all women with a chlamydial or gonorrheal infection, partners should be treated. Patients should be instructed to refer all sex partners of the past 60 days for evaluation and treatment and to avoid sexual intercourse until therapy is completed and they and their partner have resolution of symptoms.

If a woman is unsure whether her partner will be treated, delivery of antibiotic therapy (by prescription or medication)

is an option. Studies have demonstrated that patient-delivered partner therapy results in lower rates of chlamydial persistence or recurrence. All women with *C. trachomatis*, *N. gonorrhoeae*, or mucopurulent cervicitis of unknown origin need evaluation to rule out pelvic inflammatory disease (Workowski, 2015).

ENDOMETRITIS

Once an infection ascends through the cervix into the endometrium or into the salpinx, it is an upper genital tract infection. Nonpuerperal endometritis is infection of the uterine lining. Although endometritis commonly coexists with salpingitis, several studies have supported endometritis as a distinct clinical syndrome. In one large study of 152 women with suspected pelvic inflammatory disease (PID), all of whom underwent laparoscopy and endometrial biopsy, 43 (28%) had neither endometritis nor salpingitis, 26 (17%) had isolated endometritis, and 83 (55%) had acute salpingitis. Those with endometritis alone had distinct risk factors (douching in past 30 days, current intrauterine device [IUD] in place, and douching in days 1 to 7 of the menstrual cycle). Also, among those women with suspected PID, endometritis was associated with clinical manifestations (e.g., cervical motion tenderness, rebound, fever) and infection with *N. gonorrhoeae*, *C. trachomatis*, or both intermediate in frequency between women with salpingitis and those with neither salpingitis nor endometritis.

The gold standard diagnosis of endometritis is based on endometrial biopsy. At least one plasma cell/ $\times 120$ field of endometrial stroma combined with five or more neutrophils in the superficial endometrial epithelium/ $\times 400$ field is the histopathologic criterion for endometritis. In severe cases, diffuse lymphocytes and plasma cells in the endometrial stroma or stromal necrosis may be present.

The concept of subclinical endometritis has evolved, in part, because many women with tubal infertility have no history of clinical symptoms consistent with prior PID. Several large cross-sectional studies in various geographic regions have studied women with no symptoms or signs of acute salpingitis (no cervical motion or adnexal or uterine tenderness) to define subclinical endometritis further. Most of these studies were conducted in STI clinics or emergency rooms in women at risk for PID; endometritis is associated with young age (20 to 22 years old in most studies), abnormal uterine bleeding (menorrhagia or metrorrhagia), menstrual cycle day less than 14, douching in past 30 days, and a history of prior PID.

Lower genital tract infections with *C. trachomatis*, *N. gonorrhoeae*, bacterial vaginosis, *M. genitalium*, and *T. vaginalis* and mucopurulent cervicitis are associated with histologic endometritis with an odds ratio (OR) of 1.5 to 3.0, depending on the study. One study demonstrated that in women with current *N. gonorrhoeae* or *C. trachomatis* infection, endometritis was apparent in 43% of those with a history of prior PID and 23% of those without prior PID. This is suggestive of possible immunologic memory. Some women with endometritis do not have an isolated pathogen.

Because many of the symptoms and signs associated with endometritis are subtle, a clinician needs to have a low threshold for performing an endometrial biopsy to aid in the diagnosis.

Antimicrobial therapy for endometritis is effective. One study has demonstrated significant reduction in abnormal bleeding, cervicitis, uterine tenderness, and histologic endometritis following treatment with cefixime, 400 mg orally, azithromycin, 1000 mg, with or without metronidazole, 500 mg orally twice daily for 7 days. Endometritis in HIV-seropositive women has not been well characterized. One series of 42 seropositive women, none of whom had *C. trachomatis* or *N. gonorrhoeae*, has demonstrated a 38% prevalence of endometritis. Compared with the seropositive women without endometritis, the seropositive women with endometritis did not have increased uterine tenderness, lower counts of CD4⁺ lymphocytes, or other findings. A small subset of those with endometritis had a repeat endometrial biopsy following antimicrobial therapy, and 50% of the endometritis had resolved histologically. The authors concluded that endometritis in HIV-infected women might be related to pathogens that were not evaluated, to prior infection, or to reduced immunity from HIV.

The sequelae of endometritis distinct from salpingitis are difficult to determine. In a series of 614 women in the PID evaluation and clinical health (PEACH) study, women with endometritis, upper genital tract infection with *N. gonorrhoeae* or *C. trachomatis*, or both were compared with women without endometritis or upper genital tract infection for outcomes of pregnancy, infertility, recurrent PID, and chronic pelvic pain. The women with endometritis or upper genital tract infection had higher age- and race-specific pregnancy rates than the national average after adjusting for age, race, education, PID history, and baseline infertility. In the group with clinically suspected mild PID treated with standard antimicrobial therapy, endometritis or upper genital tract infection was not associated with reproductive morbidity.

PELVIC INFLAMMATORY DISEASE

PID is an infection in the upper genital tract not associated with pregnancy or intraperitoneal pelvic operations. Thus it may include infection of any or all of the following anatomic locations: endometrium (endometritis; see the previous section), oviducts (salpingitis), ovary (oophoritis), uterine wall (myometritis), uterine serosa and broad ligaments (parametritis), and pelvic peritoneum. Many authors prefer the term *salpingitis* because infection of the oviducts is the most characteristic and common component of PID. Importantly, most long-term sequelae of PID result from destruction of the tubal architecture by the infection. In most clinical situations, the terms acute *salpingitis* and *pelvic inflammatory disease* are used synonymously to describe an acute infection.

The incidence of PID in the United States is decreasing. However, the prevalence of STIs and corresponding PID is a major public health concern. The estimated number of cases in women 15 to 44 years of age was 189,662 in 2002 and 168,837 in 2003 (National Ambulatory Medical Care Survey [NAMCS]). The number of hospitalizations for acute PID steadily declined in the 1980s and 1990s, increased somewhat in the period from 2001 to 2004 but, by 2006, had dropped back to 50,000/year, levels consistent with those in 2000. Outpatient visits have also declined. From 2001 to 2008, the number of visits to physician's offices for PID declined from 244,000 to 104,000. Reduction of

the medical impact of acute PID requires aggressive therapy for lower genital tract infection and early diagnosis and treatment of upper genital tract infection. Public health emphasis also must be placed on primary prevention involving attempts to prevent exposure and acquisition of STIs. This includes teaching adolescents safe sex practices and promoting the use of condoms and chemical barrier methods. Secondary prevention of PID involves the universal screening of women at high risk for chlamydia and gonorrhea, screening for active cervicitis, increasing use of sensitive tests to diagnose lower genital infection, treatment of sexual partners, and education to prevent recurrent infection.

Acute PID results from ascending infection from the bacterial flora of the vagina and cervix in more than 99% of cases. This ascending infection occurs along the mucosal surface, resulting in bacterial colonization and infection of the endometrium and fallopian tubes. The process sometimes extends to the surface of the ovaries and nearby peritoneum, and rarely into the adjacent soft tissues, such as the broad ligament and pelvic blood vessels. Acute PID is rare in the woman without menstrual periods, such as the pregnant, premenarcheal, or postmenopausal woman. In less than 1% of cases, acute PID results from transperitoneal spread of infectious material from a perforated appendix or intraabdominal abscess. Hematogenous and lymphatic spread to the tubes or ovaries is another remote possibility. Unlike an infection in many other areas of the body that may be caused predominantly by one species of microorganism, acute PID is usually a polymicrobial infection that is a mixture of aerobic and anaerobic bacteria, clinically appearing as a complex infection. More than 20 species of microorganisms have been cultured from direct tubal aspiration of purulent material. Therapeutic strategies and regimens are of a broad range, seeking to suppress aerobic and anaerobic organisms.

Annually, acute PID occurs in 1% to 2% of all young, sexually active women. It is the most common serious infection of women ages 16 to 25 years. Approximately 85% of infections are spontaneous in sexually active females. The other 15% of infections develop following procedures that break the cervical mucus barrier, allowing the vaginal flora the opportunity to colonize the upper genital tract. These procedures include endometrial biopsy, curettage, IUD insertion, hysterosalpingography, and hysteroscopy.

One in four women with acute PID experiences medical sequelae. Following acute PID, the rate of ectopic pregnancy increases 6- to 10-fold, and the chance of developing chronic pelvic pain increases 4-fold. In the United States, each year, 26,100 ectopic pregnancies and 90,000 new cases of chronic abdominal pain are directly related to PID. The incidence of infertility following acute PID varies widely (6% to 60%), depending on the severity of the infection, number of episodes of infection, and age of the woman. Weström reported that hospitalized patients have an incidence of infertility caused by tubal obstruction of 11.4% after one episode of PID, 23.1% after two episodes, and 54.3% after three or more episodes. Women with one episode of acute PID are also more susceptible to developing a subsequent infection. It is difficult to distinguish whether this tendency is related primarily to mucosal damage or to reinfection by a potentially infected mate.

The clinical symptoms and signs of acute PID vary considerably and are usually nonspecific. Importantly, some patients may have very little symptomatology, a condition called silent, or asymptomatic pelvic inflammatory disease. These women

may have tubal infertility without a prior history of symptoms or signs consistent with an acute infection (see “Endometritis,” presented earlier in the chapter).

Ideally, laparoscopy with direct visualization of the internal female organs not only improves the diagnostic accuracy but also affords the opportunity for direct culture of purulent material, which might help establish optimum therapy. However, most women do not undergo this procedure because of the expense and risk.

In summary, the CDC has emphasized that physicians should treat women aggressively if there is any suspicion of the disease because the sequelae are so devastating and the clinical diagnosis made from symptoms, signs, and laboratory data is often incorrect (Workowski, 2015).

ETIOLOGY

As noted, acute PID is usually a polymicrobial infection caused by organisms ascending from the vagina and cervix along the mucosa of the endometrium to infect the mucosa of the oviduct. In many cases, no causative organism is found. The two classic sexually transmitted organisms associated with PID, *N. gonorrhoeae* and *C. trachomatis*, cause acute PID in many cases. These two organisms may frequently coexist in the same individual. Endogenous aerobic and anaerobic bacteria that originate from the normal vaginal flora are cultured from tubal fluid in approximately 50% of cases. In women with bacterial vaginosis (BV) and PID, BV-associated microorganisms have been isolated laparoscopically from the fallopian tubes, demonstrating ascension of these organisms. Direct cultures have shown that tubal infections are usually polymicrobial throughout the active infectious process. One investigator found an average of seven different species in intraabdominal cultures obtained via the laparoscope. Laparoscopic studies have demonstrated a correlation of no more than 50% between endocervical and tubal cultures. Thus endocervical cultures are, at best, a crude index of the specific cause of upper genital tract infection.

Approximately 15% of women with cervical infection by *N. gonorrhoeae* subsequently develop acute PID. The virulence of the strain or colony type of *N. gonorrhoeae* helps predict the incidence of upper genital tract infection. Transparent colonies of *N. gonorrhoeae* on culture medium attach more readily to epithelial cells and thus produce tubal infection more frequently than opaque-appearing colonies. Immunologic studies have demonstrated that an antibody against the outer membrane protein of the gonococcus develops in approximately 70% of women following severe pelvic infection. The lack of significant antibody titers may help explain why teenagers are more likely to develop upper genital tract disease than women in their late 20s.

There is an extremely wide variation in the recovery rates of *N. gonorrhoeae*, depending on the geographic location of the study (Table 23.8). However, the prevalence of *N. gonorrhoeae* cervicitis in young women is significantly increased in the South and southeastern regions of the United States. Therefore the proportion of patients with salpingitis from *N. gonorrhoeae* in these regions is likely much higher than in the Pacific Northwest or other geographic regions with a low gonorrhea prevalence.

Once the gonococcus ascends to the fallopian tube, it selectively adheres to nonciliated mucus-secreting cells. However, most damage occurs to the ciliated cells, most likely because of

an acute complement-mediated inflammatory response with the migration of polymorphonuclear leukocytes, vasodilation, and transudation of plasma into the tissues (Figs. 23.23 and 23.24). This robust inflammatory response causes cell death and tissue damage. The process of repair with removal of dead cells and fibroblast presence results in scarring and tubal adhesions.

C. trachomatis is an intracellular, sexually transmitted bacterial pathogen. A report from Edinburgh has found a ratio of chlamydial-to-gonococcal PID diagnosed by laparoscopy of 4:1. However, there is a widespread difference in isolation rates (Table 23.9). Chlamydia has become more prevalent than gonorrhea. From 20% to 40% of sexually active women have antibodies against *C. trachomatis*. From 10% to 30% of women with acute PID who do

not have cultures positive for *Chlamydia* have evidence of acute chlamydial infection by serial antibody titer testing. Approximately 30% of women with documented acute cervicitis secondary to chlamydia subsequently develop acute PID (Risser, 2007). Studies have shown that upper tract chlamydial infection increases the risk of an ectopic pregnancy by three to six times compared with women without chlamydial infection.

Whereas *N. gonorrhoeae* remains in the fallopian tubes for at most a few days in untreated patients, *Chlamydia* may remain in the fallopian tubes for months after initial colonization of the upper genital tract. Sophisticated PCR assays, in situ hybridization, and electron microscopy studies have demonstrated the persistence of the *C. trachomatis* in the fallopian tubes for years. Whether this represents persistent or recurrent infection of the upper genital tract is unknown.

Cell-mediated immune mechanisms appear to be important in tissue destruction associated with *C. trachomatis* infection. Primary infection appears to be self-limited, with mild symptoms and little permanent damage. In animals, repeat genital exposures to *C. trachomatis* can induce a chronic hypersensitivity response to chlamydial antigens. Because chlamydial 57-kDa protein and human 60-kDa heat shock protein have homologous regions, repeat exposures to *Chlamydia*, such as may occur in asymptomatic untreated *C. trachomatis* cervical infection, may lead to an autoimmune response that causes severe tubal damage, even if *C. trachomatis* is no longer present. Immunologically sensitized studies have demonstrated that women with antibodies to chlamydial heat shock protein are more likely to have severe tubal scarring and Fitz-Hugh–Curtis syndrome (adhesions between the liver and diaphragm indicating prior peritonitis) than women who do not mount this antibody response. Basic research has demonstrated a genetic modulation of the immune response to *C. trachomatis* infection, with an increased risk in women with human leukocyte antigen (HLA)-1. Preliminary evidence has suggested that the specific chlamydial strain also may be an important variable.

Atypical, or silent, PID is an asymptomatic, or relatively asymptomatic, inflammation of the upper genital tract often associated with chlamydial infection. The sequelae of repeated asymptomatic chlamydial infections are tubal infertility and ectopic pregnancy. Some investigators believe that atypical PID may be the more common form of upper tract infection, and symptomatic PID may just be the tip of the iceberg. As many

as 40% of women with cervicitis without upper tract symptoms will also have endometritis noted on endometrial biopsy. Studies of women with tubal infertility have found that many women, although not diagnosed as having had overt PID, have had symptoms of acute pelvic pain (see earlier, Endometritis).

The role of genital mycoplasmas as the cause of acute PID is unclear. Cervical cultures positive for *Mycoplasma hominis* and *Ureaplasma urealyticum* may be obtained from most young, sexually active women; the rate of isolation of genital mycoplasmas from the cervix is approximately 75% and similar in populations of women who are sexually active, with and without PID. Direct tubal cultures have demonstrated *M. hominis* in 4% to 17% and *U. urealyticum* in 2% to 20% of women with acute PID. However, serologic studies in women with acute PID have demonstrated that only one woman in four develops a significant rise in antibody titers to these organisms. Experimental inoculation of the cervix of the rhesus monkey has demonstrated that the route of spread of mycoplasmas is via the parametria rather than the mucosa. Thus the primary upper genital tract infection is in the parametria and the tissue surrounding the tubes, not in the tubal lumen. This may help explain the low success rate of direct tubal cultures. Histologically, *Mycoplasma* does not appear to produce damage to the tubal mucosa. These organisms are not highly pathogenic. In summary, in vitro and in vivo studies have suggested that *Mycoplasma* may be a commensal bacterium rather than a pathogen in the oviducts.

However, *M. genitalium*, which is noncultivable and identified by PCR, has been associated with cervicitis, endometritis,

Figure 23.25 Laparoscopic view of the pouch of Douglas with pus from acute PID.

and tubal factor infertility. In one study of 123 women with laparoscopically determined acute salpingitis, *M. genitalium* was detected in 9 (7%), including 1 woman with a positive fallopian tube specimen. In a different study, *M. genitalium* was detected in the cervix, endometrium, or both of 58 women with histologically confirmed endometritis (Workowski, 2015).

The endogenous aerobic and anaerobic flora of the vagina will frequently ascend to colonize and infect the upper reproductive tract. Direct cultures of purulent material (Fig. 23.25) from the tubal lumen or posterior cul-de-sac have demonstrated a wide range of organisms. The most common aerobic organisms are nonhemolytic *Streptococcus*, *E. coli*, group B *Streptococcus*, and coagulase-negative *Staphylococcus*. Anaerobic organisms tend to predominate over aerobes, and the most common anaerobic organisms are *Bacteroides* spp., *Peptostreptococcus*, and *Peptococcus*. Anaerobic organisms are almost ubiquitous in pelvic abscesses associated with acute PID. A tubo-ovarian complex and abscess are more common in women with concurrent bacterial vaginosis or HIV infection. The findings of concurrent bacterial vaginosis and PID, as well as the association of bacterial vaginosis with endometritis, emphasize the contributory role of these organisms in the pathogenesis of PID. Regardless of the initiating event, the microbiology of PID should be treated as mixed.

RISK FACTORS

Risk factors are important considerations in the clinical management and prevention of upper genital tract infections. There is a strong correlation between the incidence of STIs and acute PID in any given population. In epidemiologic studies, age at first intercourse, marital status, and number of sexual partners are all gross indicators of the frequency of exposure to STIs and PID. Having multiple sexual partners increases the chance of acquiring acute PID by approximately fivefold. Social factors

such as involvement with a child protective agency, prior suicide attempt, and alcohol use before intercourse have also been identified in case-control studies as risk factors for PID. The frequency of intercourse with a monogamous partner is not a risk factor.

The age distribution of uncomplicated STI is usually the same as that for acute PID. It is a condition of young women, with 75% of cases occurring in women younger than 25 years. The sexual behavior of teenagers, including lack of contraception, predisposes them to STIs and, correspondingly, acute PID. The incidence decreases with advancing age. The risk that a sexually active adolescent female will develop acute PID is 1 in 8, which decreases to 1 in 80 for women older than 25 years. For unknown reasons, young women with colonization of the cervix by *Chlamydia* have a higher incidence of upper genital tract infection than older women. A hypothesis to explain the increased infection rate in teenagers includes the comparative lack of antibody protection and the wider area of cervical columnar epithelium, which allows colonization by *C. trachomatis* and *N. gonorrhoeae*.

Stone and associates tabulated proved and hypothetical methods of preventing STIs and acute PID (Table 23.10). Clinical and laboratory studies have documented that the use of contraceptives changes the relative risk of developing acute PID. Barrier methods (e.g., condoms, diaphragms, spermicidal preparations) are effective as mechanical obstructive devices and as chemical barriers. Nonoxynol 9, the material ubiquitous in spermicidal preparations, is bactericidal and viricidal. Laboratory tests have demonstrated that nonoxynol 9 kills *N. gonorrhoeae*, genital *Mycoplasma* spp., *T. vaginalis*, *T. pallidum*, HSV, and HIV. However, doses of 100-mg gel, alone or in a contraceptive sponge, are associated with increased epithelial abrasions and ulcers. The porosity of latex in condoms is more than 1000 times smaller than viral particles. Thus routine condom use prevents the deposition and transmission of infected organisms from the semen to the endocervix. Many studies have found that women who frequently use a vaginal douche have a threefold to fourfold increased relative risk of PID over women who douche less frequently than once a month.

Multiple case-control studies carried out 20 to 30 years ago reported an increased risk of acute PID in women who were using an IUD. There has been just criticism of these early epidemiologic studies for their selection of control groups and the bias of including women with Dalkon shield IUDs in their statistics. The increase in risk for PID occurs only at the time of insertion of the IUD and in the first 3 weeks after placement. An analysis from the World Health Organization (WHO) has found the rate of PID to be 9.7/1000 woman-years for the first 20 days after insertion compared with 1.4/1000 woman-years for the next 8 years of follow-up. Studies evaluating the newer progesterone-containing IUD have not shown an increased risk of intrauterine infection. Many experts believe that IUDs may be considered in carefully selected nulliparous patients.

Acute salpingitis occurring in a woman with a previous tubal ligation is extremely rare and, when it does occur, the symptoms of the infection are less severe. Phillips and D'Ablaing reported the incidence of acute PID developing in the proximal stump of previously ligated fallopian tubes, occurring in 1 of 450 women hospitalized for acute salpingitis (Phillips, 1986).

Table 23.10 Methods of Preventing STDs, Mechanisms of Action, and Efficacy

Method	Mechanism	Efficacy in Prevention of Sexually Transmitted Diseases
Behavioral		
Monogamy	Decreases likelihood of exposure to infected persons	Not well studied; theoretic efficacy
Reducing number of partners	Decreases likelihood of contact with infectious agents	
Avoiding certain sexual practices		
Inspecting and questioning partners		
Barriers		
Condom	Protects partner from direct contact with semen, urethral discharge, or penile lesion	Effective in vitro barrier to chlamydiae, CMV, and HIV, partial protection HSV
	Protects wearer from direct contact with partner's mucosal secretions	Appears to decrease risk of acquiring urethral/cervical GC, PID, and male urethral <i>Ureaplasma</i> colonization; partial HPV protection
Spermicide	Chemically inactivates infectious agents	Effect on risk of acquiring NGU not established Nonvaginal use has not been studied Inactivates gonococci, syphilis spirochetes, trichomonads, ureaplasmas, and HIV in vitro. In vivo studies disappointing 100 mg gel dose and contraceptive sponge associated with epithelial ulcers and abrasions
Diaphragm/spermicide	Mechanical barrier covers cervix Used with spermicides	Diaphragm alone has not been studied Appears to decrease risk of acquiring cervical GC and PID
Vaccines	Induce antibody response that renders host immune to disease	Commercially available hepatitis B vaccine is safe and effective Results of clinical trials of gonococcal and herpes simplex vaccines ongoing Gonococcal, HIV, and HSV vaccines research in progress Effective quadrivalent HPV vaccine safe and effective
Oral Antibiotics		
Penicillin	Kill infectious agent on or shortly after exposure before infection is established	No studies among women or civilian men
Sulfathiazole		Appears to decrease risk of acquiring GC and hard and soft chancres, but use not recommended
Local		
Postcoital urination	Flushes infectious agents out of urethra and washes infectious agents of genital skin and mucous membrane	Poorly studied
Postcoital washing		
Postcoital antiseptic douching	Inactivates and washes infectious agents out of vagina	Poorly studied Not recommended Increases risk of endometritis

From Stone KM, Grimes DA, Magder LS. Primary prevention of sexually transmitted diseases: a primer for clinicians. *JAMA*. 1986;255(13):1763-1766. Copyright 1986, American Medical Association.

CMV, Cytomegalovirus; GC, gonorrhea; HIV, human immunodeficiency virus; HPV, human papillomavirus; HSV, herpes simplex virus; NGU, nongonococcal urethritis; PID, pelvic inflammatory disease.

Epidemiologic studies have documented that previous acute PID is a definite risk factor for future attacks of the disease. Approximately 25% of women with acute PID subsequently develop another acute tubal infection. Direct cultures have proved that the disease is another primary infection. The microscopic tubal damage produced by the initial upper genital tract infection may facilitate repeat infection. It is possible that prior infection causes an immunologic priming effect, making upper genital tract infection more likely with repeated cervical exposure (see earlier discussion of *C. trachomatis* pathology). The increased risk may also be related to an untreated male partner.

Transcervical penetration of the cervical mucus barrier with instrumentation of the uterus is a risk factor because it may initiate iatrogenic acute PID. The incidence of upper genital tract

infection associated with first-trimester terminations is approximately 1 in 200 cases. Recent practice has emphasized the use of prophylactic antibiotics to decrease the incidence of associated acute PID. Women with concurrent bacterial vaginosis have a higher risk for postabortal infection and thus should be treated with oral antibiotics with anaerobic coverage.

A growing area of research involves the identification of changes in the virulence of organisms and the host's response to the organisms. Virulence factors of an organism may explain why some lower tract infections progress to upper tract disease but others do not. The gonococcus has characteristics that may become activated in certain environments to increase the virulence of the organism. Similarly, other organisms that are usually of low virulence may have features that affect their virulence and pathogenicity. Both bacterial virulence factors, such as

hemolysin enzymes and proteases, and bacterial defense mechanisms that inhibit host responses may become activated in varying microenvironments. Genetic variation may be another risk factor. Some women may be genetically predisposed to mount a robust inflammatory process that may lead to tubal scarring (e.g., chlamydial heat shock protein).

SYMPTOMS AND SIGNS

Patients with acute PID present with a wide range of nonspecific clinical symptoms and signs. The severity of the clinical presentation of acute PID varies from lack of discernible symptoms to diffuse peritonitis and a life-threatening illness. Because the diagnosis is usually based on clinical criteria, there are high false-positive and high false-negative rates. The diagnosis of acute PID, even by experienced clinicians, is imprecise. The differential diagnosis of acute PID includes lower genital tract pelvic infection, ectopic pregnancy, torsion or rupture of an adnexal mass, acute appendicitis, gastroenteritis, and endometriosis.

Laparoscopic studies of women with a clinical diagnosis of acute PID have established the inadequacy of diagnosis by the usual criteria of history, and physical examination, and laboratory studies. In these studies, approximately 20% to 25% of women had no identifiable intraabdominal or pelvic disease. Another 10% to 15% of patients were found to have other pathologic conditions, such as ectopic pregnancy, acute appendicitis, or torsion of the adnexa (Tables 23.11 and 23.12). In one study of women in whom laparoscopy was performed because of clinically suspected acute PID, the clinical diagnosis was confirmed at laparoscopy in 532 women (65%). Laparoscopic studies also demonstrate a lack of correlation among the number and intensity of symptoms, signs, and degree of abnormality of laboratory values and the severity of tubal inflammation. Women with *C. trachomatis* infections may exhibit minor symptoms but have a severe inflammatory process visualized by laparoscopic examination. Criteria for establishing the severity of acute PID by laparoscopic examination are listed in Table 23.13.

Historically, the diagnosis of acute PID was not established unless the woman had the triad of fever, elevated erythrocyte sedimentation rate (ESR), and adnexal tenderness or a mass. Only 17% of laparoscopically identified cases have this classic triad. Thus reliance on these stringent clinical criteria generally results in most cases being overlooked and untreated. In practice, most women with acute PID do not undergo laparoscopy because of the expense of this invasive technique. Endometrial biopsy is more readily available as a diagnostic tool.

More recently, the PEACH trial found that for women with endometritis diagnosed on endometrial biopsy, the requirement of all three clinical criteria—lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness—resulted in decreased sensitivity. Hence, in 2006, the CDC treatment guidelines were changed to state that empirical therapy for PID should be initiated in sexually active young women and other women at risk for STIs with pelvic or lower abdominal pain if cervical motion tenderness, uterine tenderness, or adnexal tenderness is present. The CDC 2015 diagnostic criteria are summarized in Box 23.8 (Workowski, 2015).

Table 23.13 Severity of Disease by Laparoscopic Examination

Severity	Findings
Mild	Erythema, edema, no spontaneous purulent exudates*; tubes freely movable
Moderate	Gross purulent material evident; erythema and edema, marked; tubes may not be freely movable, and fimbria stoma may not be patent
Severe	Pyosalpinx or inflammatory complex abscess†

From Hager WD, Eschenbach DA, Spence MR, et al. Criteria for diagnosis and grading of salpingitis. *Obstet Gynecol.* 1983;61:113-114.

*The tubes may require manipulation to produce purulent exudate.

†The size of any pelvic abscess should be measured.

The most frequent symptom of acute PID is new-onset lower abdominal and pelvic pain. Typically, the pain is diffuse, bilateral, and usually described as constant and dull. It may be exacerbated by motion or sexual activity and, on occasion, the pain may become cramping. The duration of pain is usually less than 7 days. If the pain has been present for longer than 3 weeks, it is unlikely that the woman has acute PID. Approximately 75% of patients with acute PID have an associated endocervical infection or coexistent purulent vaginal discharge. Abnormal uterine bleeding, especially spotting or menorrhagia, is noted in approximately 40% of patients.

Box 23.8 Centers for Disease Control and Prevention Guidelines for Diagnosis of Acute Pelvic Inflammatory Disease: Clinical Criteria for Initiating Therapy

Minimum Criteria

Empirical treatment of PID should be initiated in sexually active young women and others at risk for STIs if the following minimum criteria are present and no other causes(s) for the illness can be identified:

- Lower abdominal tenderness *or*
- Adnexal tenderness *or*
- Cervical motion tenderness

Additional Criteria for Diagnosing PID

- Oral temperature $>38^{\circ}\text{C}$
- Abnormal cervical or vaginal discharge (mucopurulent)
- Presence of abundant WBCs on microscopy of vaginal secretions
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein
- Laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis*

Definitive Criteria for Diagnosing PID

- Histopathologic evidence of endometritis on endometrial biopsy
 - Transvaginal sonography or MRI showing thickened fluid-filled tubes, with or without free pelvic fluid or tubo-ovarian complex
 - Laparoscopic abnormalities consistent with PID
- Although initial treatment can be made before bacteriologic diagnosis of *C. trachomatis* or *N. gonorrhoeae* infection, such a diagnosis emphasizes the need to treat sex partners.

PID, Pelvic inflammatory disease; STIs, sexually transmitted infections; WBCs, white blood cells.

Data from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015;64(RR-03):1-137.

Nausea and vomiting are relatively late symptoms in the course of the disease.

The symptoms of acute pelvic infection secondary to *N. gonorrhoeae* are of rapid onset, and the pelvic pain usually begins a few days after the start of a menstrual period. Acute pelvic infection caused by *C. trachomatis* alone often may have an indolent course with slow onset, less pain, and less fever. It is important to remember that up to 50% of women with tubal damage never experience any symptoms consistent with PID.

Five percent to 10% of women with acute PID develop symptoms of perihepatic inflammation, the Fitz-Hugh–Curtis syndrome (Fig. 23.26). Persistent symptoms and signs include right upper quadrant pain, pleuritic pain, and tenderness in the right upper quadrant when the liver is palpated. The pain may radiate to the shoulder or into the back. Liver transaminase levels may be elevated. The condition is often mistakenly diagnosed as pneumonia or acute cholecystitis. Fitz-Hugh–Curtis syndrome develops from transperitoneal or vascular dissemination of the gonococcal or *Chlamydia* organism to produce the perihepatic inflammation. Other organisms, including anaerobic streptococci and coxsackievirus, have also been associated with this syndrome. When laparoscopy is performed, the liver capsule will appear inflamed, with classic violin string adhesions to the parietal peritoneum beneath the diaphragm. Women with perihepatitis have a higher prevalence of moderate to severe pelvic adhesions and a higher prevalence and titers of antibodies to

Figure 23.26 Classic violin string sign of Fitz-Hugh–Curtis syndrome in PID.

chlamydial heat shock protein 60. Treatment is the same as the treatment for acute salpingitis.

Lower abdominal and pelvic tenderness during examination is the hallmark of acute PID. On abdominal examination, patients have tenderness to direct palpation in the lower abdomen, and occasionally rebound tenderness. On pelvic examination, bilateral tenderness of the parametria and adnexa is present and may be exacerbated with movement of the uterus or cervix during the pelvic examination. An ill-defined adnexal fullness is frequently noted, which may represent edema, inflammatory adhesions to the small or large intestine, or an adnexal complex or abscess. The incidence of true adnexal abscess is approximately 10% in women with acute PID.

DIAGNOSIS

Direct visualization via the laparoscope is the most accurate method of diagnosing acute PID (Binstock, 1986). If the woman has impending septic shock, acute surgical abdomen, or a complicated differential diagnosis in a postmenopausal woman, laparoscopy or laparotomy is strongly indicated. The laparoscopy is diagnostic but also offers the additional advantage of concurrent operative procedures such as lysis of adhesions, potential drainage of an abscess, and irrigation of the pelvic cavity. To date, operative laparoscopy during acute infection has not been proved to reduce the prevalence of long-term sequelae. With the change in management toward outpatient therapy, laparoscopy is used less frequently. Acute PID should be included in the differential diagnosis of any sexually active young woman with pelvic pain.

Elevated temperature is an unreliable diagnostic sign because only one of three women with acute PID present with a temperature higher than 38°C . Laboratory tests may be ordered but are also insensitive and nonspecific. Less than 50% of women with acute PID have a white blood cell count higher than 10,000 cells/mL. Leukocytosis does not correlate with the need for hospitalization or the severity of tubal

From Peipert JF, Boardman L, Hogan JW, et al. Laboratory evaluation of acute upper genital tract infection. *Obstet Gynecol.* 1996;87(5 Pt 1):730-736. CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; NPV, negative predictive value; PID, pelvic inflammatory disease; PPV, positive predictive value; WBC, white blood cell count.

inflammation. The ESR is elevated (>15 mm/hr) in approximately 75% of women with laparoscopically confirmed acute pelvic infection. However, 53% of women with pelvic pain and visually normal pelvic organs have an elevated ESR. C-reactive protein levels have been used but are not reliable enough to guide clinical management. Combinations of positive test results improve diagnostic specificity and positive predictive value. However, this results in a diminution of sensitivity and negative predictive value (Table 23.14). Women with acute PID should have a sensitive test for human chorionic gonadotropin to help in the differential diagnosis of ectopic pregnancy. Approximately 3 to 4 of every 100 women who are admitted to a hospital with a diagnosis of acute pelvic infection have an ectopic pregnancy.

Because most cases of upper genital tract infection are preceded by lower genital tract infection, it is important to examine the endocervical mucus for inflammatory cells and perform the NAAT for *N. gonorrhoeae* and *C. trachomatis*. The presence of an increased number of vaginal white blood cells is the most sensitive laboratory indicator of acute PID. If the cervical discharge appears normal and no white blood cells are found on the wet preparation of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be considered.

Because clinical symptoms and signs are nonspecific for the disease, the false-positive and false-negative rates are high when the diagnosis is based on clinical criteria. However, because of the long-term sequelae of the disease, most clinicians maintain a low threshold in entertaining a diagnosis of acute PID, readily accepting that they are treating many women who actually do not have pelvic infection so as not to omit treating those with early or mild disease. For the CDC guidelines for the diagnosis of acute PID, see Box 23.8 (Workowski, 2015).

Figure 23.27 Transvaginal sonographic image of acute salpingitis. The central sonolucent fluid in the lumen (L) and the thickened endosalpingeal folds give this a cogwheel appearance. (From Timor-Tritsch IE, Lerner JP, Monteagudo A, et al. Transvaginal sonographic markers of tubal inflammatory disease. *Ultrasound Obstet Gynecol.* 1998;12:56-66.)

An endometrial biopsy for evidence of endometritis can be a useful tool. This test only is used to help confirm clinical suspicion because of the time required to obtain the result. Although most women with acute salpingitis have coexisting endometritis, the converse—that most women with endometritis have salpingitis—has not been established. In one study of women with biopsy-proved endometritis, the accuracy of coexistent acute PID confirmed by laparoscopy had a sensitivity of 89% and a specificity of 87%.

Ultrasonography is of limited value for patients with mild or moderate PID because of its low sensitivity, but vaginal ultrasonography is helpful in documenting an adnexal mass. It is also a noninvasive diagnostic aid for patients who are so tender during pelvic examination that the physician cannot determine the presence or absence of a pelvic mass. Although ultrasonography is neither specific nor sensitive in distinguishing the cause of a pelvic mass, findings of dilated and fluid-filled tubes, free peritoneal fluid, and adnexal masses may confirm symptoms and physical signs (Figs. 23.27 to 23.30). Thus vaginal ultrasound has a high positive predictive value when used in a high-risk population (Romosan, 2014). Magnetic resonance imaging (MRI) is sensitive, but its expense and limited acute availability in some locations have restricted its role in PID diagnosis.

The percentage of American women with acute PID who also are infected with HIV has been estimated to be 6% to 22%. Women with acute PID and HIV infection have a higher incidence of adnexal masses. However, an acute pelvic infection responds to antibiotic therapy in a similar fashion to that in women who are not infected with HIV. The CDC continues to emphasize the importance of treating partners of women with STIs (Workowski, 2015).

TREATMENT

Treatment of the woman with PID encompasses more than just prescribing the appropriate antimicrobial regimen. Determining the need for hospitalization, patient education, treatment of

Figure 23.28 Longitudinal section of a slightly dilated and fluid-filled tube (T). Its walls are slightly thickened (arrows). Endometrial biopsy showed plasma cell endometritis. F, Free fluid. Endometrial biopsy revealed plasma endometritis. (From Cacciatore B, Leminen A, Ingman-Friberg S, et al. Transvaginal sonographic findings in ambulatory patients with suspected pelvic inflammatory disease. *Obstet Gynecol.* 1992;80:912-916.)

sexual partners, and careful follow-up are key issues. The two most important goals of the medical therapy of acute PID are the resolution of symptoms and preservation of tubal function. Antibiotic therapy should be started as soon STI screening results have been obtained and the diagnosis has been suggested. Early diagnosis and early treatment will help reduce the number of women who suffer from the long-term sequelae of the disease. Women who are not treated in the first 72 hours following the onset of symptoms are three times as likely to develop tubal infertility or ectopic pregnancy as those who are treated early in the disease process. Animal and human studies have suggested that early antibiotic treatment improves long-term fertility. In the management of acute PID, one should not forget the treatment and education of the male partner for the prevention of the

Figure 23.30 Laparoscopic view of acute PID and a tubo-ovarian abscess.

disease, including the use of proper contraceptives, which help reduce the rate of upper genital tract infection.

Although the choice of antibiotic therapy for most infectious diseases is usually based on cultures and sensitivity of bacteria obtained directly from the site of the infection in PID, direct tubal cultures are not practical. Because most cases of PID are polymicrobial, broad-spectrum antibiotic coverage is indicated. Empirical antibiotic protocols should cover a wide range of bacteria, including *N. gonorrhoeae*, *C. trachomatis*, anaerobic rods and cocci, gram-negative aerobic rods, and gram-positive aerobes (Table 23.15). Selection of one antibiotic protocol over another may be influenced by the clinical history. For example, acute PID following an operative procedure is usually caused by endogenous flora of the vagina, whereas acute PID in a 19-year-old college student is likely secondary to *C. trachomatis*.

A failure of outpatient oral therapy may be related to non-compliance, reinfection, or inadequate antibiotic coverage for penicillinase-producing gonorrhea, chromosomally mediated resistant *N. gonorrhoeae*, or facultative or anaerobic organisms involved in upper genital tract infection that are resistant to the drug prescribed. It is important to know resistance profiles in your geographic region. Inpatient failure rates for resolution of acute symptoms with IV antibiotics are approximately 5% to 10%.

A variety of oral and parenteral antibiotic regimens have been effective in achieving short-term clinical and microbiologic cures in randomized clinical trials. However, there are limited data comparing the effect of various protocols on the incidence of long-term complications and elimination of bacterial infection in the endometrium and fallopian tubes. The CDC has published recommendations for the outpatient treatment of PID (Box 23.9) (Workowski, 2015). Ceftriaxone, 250 mg IM once, or cefoxitin, 2 g IM, plus probenecid, 1 g orally in a single

Ceftriaxone, 250 mg IM, single dose
or
Cefoxitin, 2 g IM, single dose, and probenecid, 1 g PO administered concurrently in a single dose
or
Other parenteral third-generation cephalosporin (e.g., ceftizoxime, cefotaxime)
plus
Doxycycline, 100 mg PO bid for 14 days
with or without
Metronidazole, 500 mg PO bid for 14 days

Modified from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(RR-03):1-137.

dose, concurrently once, or another parenteral third-generation cephalosporin such as ceftizoxime or cefotaxime together with doxycycline, 100 mg orally twice daily for 14 days, is the recommended outpatient regimen. The optimal cephalosporin choice is not known. Ceftizoxime has unparalleled coverage against *N. gonorrhoeae*; cefotaxime has better anaerobic coverage. The clinician should individualize the choice of regimens depending on his or her estimate of the need for anaerobic coverage. Importantly, if the woman has bacterial vaginosis, adding prolonged coverage with metronidazole, 500 mg orally twice daily for 14 days, is preferable.

Other regimens with at least one trial include amoxicillin-clavulanic acid and doxycycline. However, this regimen may be difficult to tolerate because of adverse gastrointestinal symptoms. Azithromycin has demonstrated short-term effectiveness in one randomized trial; another trial used azithromycin combined with ceftriaxone, 250 mg IM single dose, with azithromycin, 1 g orally once weekly for 2 weeks. Also, with these regimens, consider the addition of metronidazole, because anaerobic organisms are suspected in the cause of PID and metronidazole will also treat BV, which is frequently associated with PID. Quinolone-containing regimens are no longer routinely recommended because of gonorrhea resistance. However, if parenteral cephalosporin therapy

Box 23.10 Indications for Hospitalizing Patients with Acute Pelvic Inflammatory Disease

Surgical emergencies (e.g., appendicitis) cannot be excluded.
The patient is pregnant.
The patient does not respond clinically to oral antimicrobial therapy.
The patient is unable to follow or tolerate an outpatient oral regimen.
The patient has severe illness, nausea and vomiting, or high fever.
The patient has a tubo-ovarian abscess.

Data from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(RR-03):1-137.

is not feasible, the use of fluoroquinolones (levofloxacin, 500 mg orally once daily, or ofloxacin, 400 mg twice daily for 14 days), with or without metronidazole, may be considered if the community prevalence and individual risk of gonorrhea are low, or if the diagnostic test result for gonorrhea performed prior to instituting therapy is negative.

It is important to reexamine women within 48 to 72 hours of initiating outpatient therapy to evaluate the response of the disease to oral antibiotics. The woman should be hospitalized when the therapeutic response is not optimal. If the disease is responding well, approximately 4 to 6 weeks after therapy the woman should be reexamined to assess the resolution of clinical symptoms and establish a posttreatment baseline.

In the past, many practitioners preferred to hospitalize nulliparous women for the treatment of PID, but this is no longer recommended. A multicenter trial of 831 women has found no advantage to inpatient treatment of mild to moderate PID randomized to inpatient versus outpatient treatment. In over 84 months of follow-up, there were an equivalent number of pregnancies, live births, time to pregnancy, infertility, recurrent PID, chronic pelvic pain, and ectopic pregnancy in the inpatient and outpatient treatment groups. This was true even in teenagers and women without a previous live birth.

The CDC has established criteria for hospitalization (Box 23.10) (Workowski, 2015). These include unsure diagnosis, being too ill to tolerate oral therapy, no improvement with oral therapy, and presence of a tubo-ovarian abscess or pregnancy. Acute PID associated with the presence of an IUD may be more advanced at the time of diagnosis than infection without a foreign body. Patient and physician delays in diagnosis are not unusual. Often, women misinterpret the early signs and symptoms of an infection as being related to the IUD. Pelvic infections with an IUD in place and pelvic infections following operative or diagnostic procedures often are caused by anaerobic bacteria. Outpatient therapy leaving the IUD in situ may be attempted if close follow-up of the woman is possible. If the pelvic infection worsens or does not improve, the IUD should be removed. Concurrent immunodeficiency, especially HIV infection with a low CD4⁺ count, is another reason to consider hospitalization. If a therapeutic response or compliance with oral medications has not been optimal or is questionable, or if follow-up in 72 hours is not possible, the woman should be admitted for IV antibiotic therapy.

The 2014 CDC guidelines for inpatient treatment of acute PID with parenteral therapy are listed in Box 23.11. The

Box 23.11 Inpatient Management of Acute Pelvic Inflammatory Disease

Parenteral Regimen A

Cefotetan, 2 g IV every 12 hr

or

Cefoxitin, 2 g IV every 6 hr

plus

Doxycycline, 100 mg PO or IV every 12 hr

Note: Because of pain associated with infusion, doxycycline should be administered orally when possible, even when the patient is hospitalized. PO and IV administration of doxycycline provide similar bioavailability.

Parenteral Regimen B

Clindamycin, 900 mg IV every 8 hr

plus

Gentamicin, loading dose IV or IM (2 mg/kg of body weight) followed by a maintenance dose (1.5 mg/kg) every 8 hr. Single daily dosing may be substituted.

Alternative Parenteral Regimens

Limited data support the use of other parenteral regimens. The following regimen has been investigated in a least one clinical trial, and has broad-spectrum coverage:

Ampicillin-sulbactam, 3 g IV every 6 hr

plus

Doxycycline, 100 mg PO or IV every 12 hr

One trial has demonstrated high short-term clinical cure rates with azithromycin, either as monotherapy for 1 wk (500 mg IV \times one or two doses followed by 250 mg PO, 5-6 days) or combined with a 12-day course of metronidazole.

Modified from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015;64(RR-03):1-137.

protocols stress the polymicrobial origin of acute pelvic infection, increasing importance of *C. trachomatis*, and emergence of penicillin-resistant *N. gonorrhoeae*. With IV protocols, the CDC recommends that IV antibiotics be continued for at least 24 hours after substantial improvement in the patient. When the woman has a mass, we add ampicillin to clindamycin and gentamicin. However, for patients without a mass, we switch to oral antibiotics when the symptoms have diminished and the woman has been afebrile for 24 hours. In both regimens, doxycycline is continued for a total of 14 days.

Regimen A is a combination of doxycycline and IV cefoxitin. It is excellent for community-acquired infection. Doxycycline and cefoxitin provide excellent coverage for *N. gonorrhoeae*, *C. trachomatis*, and penicillinase-producing *N. gonorrhoeae*. Cefoxitin is an excellent antibiotic against *Peptococcus* and *Peptostreptococcus* spp. and *E. coli*. The disadvantage of this combination is that the two drugs are less than ideal for a pelvic abscess or anaerobic infections. To date, cefotetan has been found to be as effective as cefoxitin. There is no clinically significant difference in the bioavailability of doxycycline whether it is given by the oral or IV route. Thus doxycycline should be administered orally whenever possible because of the marked superficial phlebitis produced by IV infusion.

Doxycycline should be included in the regimen of follow-up oral therapy. Sweet and associates have observed 17 women with PID who initially had endometrial cultures positive for *Chlamydia*. Clinically, 16 of 17 women responded to treatment

with cephalosporins alone. However, posttreatment endometrial cultures remained positive for *Chlamydia* in 12 of 13 women. Therefore without tetracycline or erythromycin, a woman may appear free of symptoms but may still be harboring *Chlamydia*. Antibiotics active against *C. trachomatis* must be present in effective dosages for at least 7 days for clinical and microbiologic cures to occur. *C. trachomatis* has a 48- to 72-hour life cycle inside the mucosal cell. Thus prolonged therapeutic levels of the antichlamydial antibiotic are imperative.

Regimen B is a combination of clindamycin and an aminoglycoside (gentamicin). It has the advantage of providing excellent coverage for anaerobic infections and facultative gram-negative rods. Therefore it is preferred for patients with an abscess, IUD-related infection, and pelvic infection after a diagnostic or operative procedure. Studies have demonstrated that high IV levels of clindamycin, such as 900 mg every 8 hours, provide activity against 90% of bacterial strains of *Chlamydia*. Most infectious disease experts recommend the use of a single daily dose of gentamicin rather than a dose given every 8 hours. The initial once-daily aminoglycoside dosage is based on nomograms that take body weight into consideration. The advantages of a once-daily aminoglycoside program are decreased toxicity, increased efficacy, and decreased cost. Also, no serum drug levels must be measured. Aztreonam, a monobactam, has an antibiotic spectrum similar to that of the aminoglycosides but without renal toxicity but is much more expensive. It may be given in a dose of 2 g IV every 8 hours. Also, a third-generation cephalosporin may be used instead of an aminoglycoside in a woman with renal disease. Parenteral antibiotic therapy may be discontinued when the woman has been afebrile for 24 hours, and oral therapy with doxycycline (100 mg twice daily) should continue to complete 14 days of therapy.

Alternative inpatient regimens include ampicillin-sulbactam plus doxycycline because they have excellent anaerobic coverage and would be a good choice for women with a tubo-ovarian complex. The alternative regimen has less extensive clinical trials.

In summary, no regimen is uniformly effective for all patients. To date, there are insufficient clinical data to suggest the superiority of one regimen over another with respect to initial response or subsequent fertility.

Operative treatment of acute PID has decreased markedly since the 1990s. Operations are restricted to life-threatening infections, ruptured tubo-ovarian abscesses, laparoscopic drainage of a pelvic abscess, persistent masses in some older women for whom future childbearing is not a consideration, and removal of a persistent symptomatic mass. Because of the techniques of in vitro fertilization, every effort is made to perform conservative surgery and preserve ovarian and uterine function in women who are not done with childbearing. Unilateral removal of a tubo-ovarian complex or an abscess is a frequent conservative procedure for acute PID. Similarly, drainage of a cul-de-sac abscess via percutaneous drainage or a colpotomy incision results in preservation of the reproductive organs.

Rigorously defined, an abscess is a collection of pus within a newly created space. In contrast, a tubo-ovarian complex is a collection of pus within an anatomic space created by the adherence of adjacent organs. Abscesses caused by acute PID contain a mixture of anaerobes and facultative or aerobic organisms (Figs. 23.31 and 23.32). The environment of an abscess cavity results in a low level of oxygen tension. Therefore

anaerobic organisms predominate and have been cultured from 60% to 100% of reported cases. Basic studies have discovered that clindamycin penetrates the human neutrophil, and it is possible that this property facilitates the level of clindamycin within the abscess. Clindamycin is also stable in the abscess environment, which is not true of many other antibiotics. Thus a combination of clindamycin and an aminoglycoside is considered the standard for treatment of a tubo-ovarian abscess. This combination does not treat *Enterococcus*, and ampicillin should be added if there is suspicion that this organism is involved. Metronidazole alone is an effective alternative to clindamycin for anaerobic infections but does not provide gram-negative coverage. If abscesses do not respond to parenteral broad-spectrum antibiotics, drainage is imperative.

Transvaginal or transabdominal percutaneous aspiration or drainage of pelvic abscesses may be accomplished under ultrasonic or computed tomography (CT) guidance. This technique has shown excellent results. In one small, randomized trial, early transvaginal drainage and intensive antibiotic therapy were compared with intensive antibiotic therapy alone. A favorable

short-term outcome occurred in 90% of those who underwent ultrasound-guided transvaginal drainage in contrast to 65% of the control group. However, fertility and ectopic pregnancy rates after percutaneous drainage are unknown at this time. Long-term recurrence and sequelae must be evaluated before this technique is accepted as a therapeutic standard. A strong contraindication to percutaneous aspiration is any suspicion of an infected carcinoma in the differential diagnosis. Laparoscopic aspiration of tubo-ovarian complexes is another alternative. This procedure has shown good results but does not have greater benefit than percutaneous ultrasound-guided aspiration of abscess cavities. Laparoscopic aspiration obviously carries more operative risks than ultrasound-guided aspiration.

Postmenopausal women with suspected PID should have appropriate imaging studies to rule out other concurrent diseases, especially malignancies. The bacterial cause in postmenopausal women does not usually include a sexually transmitted microorganism, but rather bacteria from the intestinal tract or normal vaginal flora. The disease process involves tubo-ovarian complexes and abscesses. Medical treatment should emphasize broad-spectrum antibiotic regimens with adequate anaerobic coverage. Operative intervention in a postmenopausal woman should be considered early in the disease, especially if the condition does not improve rapidly with medical treatment.

Figure 23.32 Pyosalpinx. The right tube is markedly enlarged and contains 50 mL of creamy pus. The tubal wall is thickened. (From Janovski NA, ed. *Color Atlas of Gross Gynecologic and Obstetric Pathology*. New York: McGraw-Hill; 1969:131.)

SEQUELAE

Approximately 25% of women experience recurrent acute PID. Younger women become reinfected twice as often as older women. A great challenge to health care providers is to educate women with PID to reduce their chances of a second episode of infection. It is essential and imperative for preventive medicine to include treatment and education of the male partner. Liberal prescriptions for treatment of lower genital tract disease and selection of contraceptives that will reduce the chance of upper genital tract infections are also important for these women. Because sequelae to PID, overt and silent, are related to the number of infections, prevention cannot be overemphasized. Because most PID in the United States is related to STIs, increased attention to partner treatment and education is appropriate.

The morbidity, suffering, and cost of PID arise from the scarring and adhesion formation that accompany healing of damaged tissues after the infection itself is eradicated. These effects result in ectopic pregnancy, chronic pain, and infertility. Approximately 10% to 15% of pregnancies will be ectopic after laparoscopically mild to moderate PID, and almost 50% after severe PID. The number of hospitalizations for ectopic pregnancies peaked around 1989 at 90,000 and declined to 20,000 in 2009. This decline is partially a result of outpatient management of ectopic pregnancies but is mostly a result of successful chlamydia screening and prevention programs. One case-control study has suggested that chlamydia-associated PID alone causes almost half of all ectopic pregnancies (Table 23.16).

Studies have found that chronic pain is a common sequela of a symptomatic pelvic infection. In one study, the chance that a woman will develop chronic pelvic pain following acute salpingitis was four times greater than the risk for control subjects. Approximately 20% of women with acute pelvic infections subsequently developed chronic pelvic pain versus approximately 5% in controls without pelvic infection. Other studies

have found similar results (Table 23.17). Among women with chronic pelvic pain, approximately two of three are involuntarily infertile, and a similar percentage of these women have deep dyspareunia. In a study from Oxford of 1355 women with PID and 10,507 controls, chronic abdominal pain

developed 10 times more commonly in those who had PID (Table 23.18). Chronic pelvic pain may be caused by a hydrosalpinx, a collection of sterile watery fluid in the fallopian tube. A hydrosalpinx (Fig. 23.33) is the end-stage development of a pyosalpinx. Chronic pain often develops in a woman, even though she may have had a normal pelvic examination when examined 4 to 8 weeks following her acute infection. The pain may result from adhesions and the resultant fixation or tethering of organs intended to have freedom of movement during physical activity, coitus, and ovulation (Table 23.19). Women with chronic pelvic pain and a history of acute PID may benefit from laparoscopy to establish the diagnosis and rule out other diseases, such as endometriosis.

Acute pelvic infection is one of the major causes of female infertility. Epidemiologic studies have estimated that between 4% and 13% of women are infertile or undergo an operative procedure secondary to acute PID.

The sequelae of infections include a damaged yet patent oviduct, peritubular and periovarian adhesions that may hinder ovum pickup, and finally complete tubal obstruction. Tubal obstructions secondary to infection are commonly found at the fimbrial end or cornual region of the oviduct. An alarming factor that has been documented with chlamydial infection is the tubal damage from subacute PID. Patton and colleagues found almost equally severe tubal damage, adhesion, degeneration of endosalpingeal structures, and cilia dysfunction in women with acute chlamydial PID and women with silent chlamydial infection.

Infertility rates were significantly lower in younger women than in older women following a single episode of infection

*After admission with acute pelvic inflammatory disease or a control event in cohorts of women in the Oxford Record Linkage Study followed from 1970 to 1985. Number of women shown in parentheses.

(Table 23.20). The milder the episode of acute PID, the less likely a woman was to suffer tubal obstruction and infertility. The infertility rate also increased directly with the number of episodes of acute pelvic infection. These data are not surprising because the prevalence of long-term sequelae is directly proportional to the number and severity of the episodes of acute PID. Lepine and coworkers reported additional data from the largest and longest prospective cohort study of women with acute PID. They found that increasing severity

of the initial episode of acute pelvic infection correlates with a longer low-term probability of live birth. The cumulative proportion of women achieving a live birth after 12 years was 90% for women whose initial infection was mild, 82% for women with moderate disease, and 57% for women with severe PID. Subsequent episodes of pelvic infection had a greater effect on women whose initial episode was judged as severe as for those with milder disease.

Figure 23.33 Hydrosalpinx with marked dilation of the fallopian tube and blunting of the fimbriated end. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby; 1997:107.)

ACTINOMYCES INFECTION

Actinomyces is a rare cause of upper genital tract infection. *Actinomyces israelii*, the most common species found, is a gram-positive anaerobic bacterium that is difficult to culture. To culture this organism successfully, an anaerobic environment must be maintained for 2 to 3 weeks.

A. israelii is discovered by histologic examination or culture from women with tubo-ovarian abscesses. There are many large series of tubo-ovarian abscesses without a single case of *A. israelii* described. Most cases described have been in women chronically wearing an IUD for an average of 8 years. Usually, *A. israelii* is part of a polymicrobial infection, and whether its role is primary or secondary in the infectious process is unknown.

There is controversy about the significance of discovering actinomycetes on a Pap smear of women wearing an IUD. The contrasting, relatively high detection rate of actinomycetes observed on Pap smears from IUD users, and extreme rarity of subsequent development of pelvic actinomycosis, has led most experts to conclude that progression to upper tract infection is

Table 23.19 Associations among History of Acute Pelvic Inflammatory Disease and Adnexal Adhesions, Distal Tubal Occlusion, or Perihepatic Adhesions

Laparoscopic Findings	PELVIC INFLAMMATORY DISEASE		OR	95% CI	P
	Yes (N = 22)	No (N = 90)			
Distal tubal occlusion	4 (18.2%)	7 (7.8%)	2.6	0.7-10.0	0.14
Tubal adhesions	8 (36.4%)	21 (23.3%)	1.9	0.7-5.1	0.16
Ovarian adhesions	9 (40.9%)	21 (23.3%)	2.3	0.9-6.5	0.08
Perihepatic adhesions	3/21 (14.3%)	2/84 (2.4%)	6.8	1.1-43.9	0.05
Any adhesions	11 (50.0%)	25 (27.8%)	2.6	1.0-6.8	0.04

Table 23.20 Percentage and Number of Patients Attempting to Conceive*

No. of Episodes of PID	AGE (YEARS)		Total % (n/N)
	<25 % (n/N)	≥25 % (n/N)	
One	7.7 (59/771)	9.1 (20/220)	8.0 (79/991)
Mild	0.8 (2/241)	0.0 (0/71)	0.6 (2/312)
Moderate	6.4 (23/361)	5.6 (5/89)	6.2 (28/452)
Severe	20.1 (34/169)	25.0 (15/60)	21.4 (49/229)
Two	18.4 (29/158)	25.9 (7/27)	19.5 (36/185)
Three or more	37.7 (23/61)	75.0 (3/4)	40.0 (26/65)
Total	11.2 (111/990)	12.0 (30/251)	11.4 (141/1241)

From Weström L, Joesoef R, Reynolds G, et al. Pelvic inflammatory disease and fertility: a cohort study of 1,844 women with laparoscopically verified disease and 657 control women with normal laparoscopic results. *Sex Transm Dis.* 1992;19(4):185-192.
*Women had tubal factor infertility by age, number of acute PID episodes, and severity of PID, excluding those with nontubal factor infertility and with incomplete infertility examinations.
n, Total number of cases followed; N, total number of evaluable cases; PID, pelvic inflammatory disease.

highly unlikely to be related. The decision to remove the IUD to treat a woman is influenced by the presence or absence of clinical symptoms. Unless there are associated symptoms, such as fever, abdominal pain, or abnormal uterine bleeding, the identification of the organism in any cervical smear should not prompt antibiotic therapy or IUD removal.

Actinomycetes may produce a chronic endometritis, with an associated foul-smelling discharge. The clinical infection may be manifest by widespread adhesions, induration, and fibrosis. The diagnosis of *Actinomyces* infection is usually not made until a tubo-ovarian abscess is examined by the pathologist. Then, the classic sulfur granules are observed histologically, along with gram-positive filaments.

Although much has been written about chronic draining sinuses with *Actinomyces* infection, this complication is unusual in gynecology. However, when this organism is present in a tubo-ovarian abscess, the woman should receive oral penicillin, doxycycline, or a fluoroquinolone for 12 weeks following an operative procedure (Evans, 1993).

TUBERCULOSIS

Tuberculosis of the upper genital tract, primarily chronic salpingitis and chronic endometritis, is a rare disease in the United States. Most gynecologists may never encounter a single case. However, pulmonary tuberculosis has been steadily increasing in the United States and it is likely that the incidence of pelvic tuberculosis also may rise. Tuberculosis is a frequent cause of chronic PID and infertility in other parts of the world. Thus it should be suspected in immigrants, especially those from Asia, the Middle East, and Latin America. Although the disease is usually found in premenopausal women, it occurs in postmenopausal women 10% of the time.

Pelvic tuberculosis may be produced by *Mycobacterium tuberculosis* or *Mycobacterium bovis*. The primary site of infection for tuberculosis is usually the lung. Early in the course of pulmonary infection, the bacteria spread hematogenously and the infection becomes located in the oviducts, which are the primary and predominant site of pelvic tuberculosis. Subsequently, the bacilli usually spread to the endometrium and, less commonly, to the ovaries. In developing countries without pasteurization of milk, bovine tuberculosis produces primary infections in the human gastrointestinal tract. Subsequent lymphatic or hematogenous dissemination results in pelvic tuberculosis. Autopsy studies published 25 years ago demonstrated that 4% to 12% of women who died of pulmonary tuberculosis concurrently had evidence of upper genital tract infection. In a large study from India, 117 women had tubal blockage secondary to tuberculosis. When these women underwent laparoscopy, the findings were 50% simple tubal blockage, 15% tubo-ovarian masses, and 24% a frozen pelvis.

In general, extrapulmonary tuberculosis may present as an insidious or rapidly progressing disease. The clinical symptoms and signs of pelvic tuberculosis are similar to the chronic sequelae of nontuberculous acute PID. The predominant presentations of this chronic infection are infertility and abnormal uterine bleeding. Mild to moderate chronic abdominal and pelvic pain occur in 35% of women with the disease. Advanced cases are often accompanied by ascites. Some women may be asymptomatic.

The findings at pelvic examination are normal in approximately 50% of cases. The remaining patients have mild adnexal tenderness and bilateral adnexal masses, with an inability to manipulate the adnexa because of scarring and fixation.

Tuberculous salpingitis may be suspected when a woman is not responding to conventional antibiotic therapy for acute bacterial PID. Results of a tuberculin skin test will be positive. However, approximately one in three women does not have evidence of pulmonary tuberculosis on chest radiographic films. The diagnosis may be established by performing an endometrial biopsy late in the secretory phase of the cycle. A portion of the endometrial biopsy should be sent for culture and animal inoculation and the remaining portion should be examined histologically. The findings of classic giant cells, granulomas, and caseous necrosis confirm the diagnosis (Fig. 23.34). Approximately two of three women with tuberculous salpingitis will have concomitant tuberculous endometritis. Pelvic tuberculosis may not be diagnosed until laparotomy or celiotomy, when the characteristic changes may be visualized. The distal ends of the oviduct remain everted, producing a tobacco pouch appearance. When the diagnosis has been established, the woman should have a chest radiographic examination, IV pyelography, serial gastric washings, and urine cultures for tuberculosis. Approximately 10% of women with pelvic tuberculosis have concomitant urinary tract tuberculosis.

The treatment of pelvic tuberculosis is medical. Not uncommonly, patients will be admitted to the hospital for initiation of therapy, for observation, and to ensure appropriate compliance. Initial therapy in a woman with newly diagnosed tuberculosis usually will include five drugs because of the emergence of multidrug-resistant organisms. Multidrug-resistant (MDR) tuberculosis is defined as infection from a strain of *M. tuberculosis* that is resistant to two or more agents, including isoniazid. The mortality rate in HIV-negative patients who develop MDR infection may be as high as 80%. Often, health care workers become infected during outbreaks of MDR tuberculosis. The CDC has recommended starting a woman on a

Figure 23.34 Tuberculous salpingitis—Langerhans giant cell granuloma. (From Gompel C, Silverberg SG, eds. *Pathology in Gynecology and Obstetrics*. 2nd ed. Philadelphia: JB Lippincott; 1977:258.)

multidrug regimen until the culture results yield specific sensitivity. At that time, medications may be decreased to two or three agents. Patients who have infection from MDR strains are usually kept on a five-drug regimen. Operative therapy for pelvic tuberculosis is reserved for women with persistent pelvic

masses, some women with resistant organisms, women older than 40 years, and women whose endometrial cultures remain positive. Although the major sequela of pelvic tuberculosis is infertility, occasionally a woman will become pregnant after medical therapy (Chow, 2002; Ilhan, 2004).

KEY POINTS

- The CDC regularly revises its treatment protocols for STIs. This information may be accessed online at www.cdc.gov/publications.
- Pediculosis pubis, an infestation by the crab louse *Phthirus pubis*, is characterized by constant itching, predominantly vulvar involvement, and the finding of eggs and lice by visual inspection. It may be treated by topical application of 1% permethrin cream rinse (Nix) or 1% lindane shampoo (Kwell).
- Scabies, an infection by the itch mite *Sarcoptes scabiei*, is characterized by intermittent pruritus, most commonly in the hands, wrists, breasts, vulva, and buttocks. It may be treated by a topical application of 5% permethrin cream (Nix) or 1% lindane lotion or 30 g of cream.
- Genital herpes is a recurrent incurable STI. Approximately 80% of individuals are unaware that they are infected. It is usually transmitted by individuals who are asymptomatic and unaware that they have the infection at the time of transmission.
- Nonspecific tests for syphilis, the VDRL and RPR, have a 1% false-positive rate. Therefore specific tests such as the *Treponema pallidum* immobilization (TPI), FTA-ABS, and MHA-TP must be used when a positive nonspecific test result is encountered.
- In women in the reproductive age range, bacterial vaginosis represents approximately 50% of vaginitis cases and candidiasis and *Trichomonas* infection represent approximately 25% each. HIV acquisition is increased in women with bacterial vaginosis and *T. vaginalis* infection.
- *T. vaginalis* infection is a highly contagious STI. It is the most prevalent nonviral, nonchlamydial STI of women. An asymptomatic female who has *Trichomonas* identified in the lower female genital urinary tract should definitely be treated.
- Symptoms that suggest cervical infection include vaginal discharge, deep dyspareunia, and postcoital bleeding. Most women who have lower reproductive tract infections caused by *C. trachomatis* or *N. gonorrhoeae* do not have mucopurulent cervicitis. The corollary is that most women who have mucopurulent cervicitis are not infected by *C. trachomatis* or *N. gonorrhoeae*.
- Acute PID is usually caused by a polymicrobial infection of organisms ascending from the vagina and cervix, traveling along the mucosa of the endometrium to infect the mucosa of the oviduct. It should be diagnosed with a minimum of suspicion with the knowledge that overtreatment is preferable to missed diagnosis.
- Approximately one in four women with acute PID experiences further medical sequelae, including recurrent acute PID, ectopic pregnancy, and chronic pelvic pain.

Preoperative Counseling and Management Preoperative Evaluation, Informed Consent, Perioperative Planning, Surgical Site Infection Prevention, and Avoidance of Complications

Jamie N. Bakkum-Gamez, Sean C. Dowdy, Fidel A. Valea

Preoperative evaluation can involve both the art and science of clinical medicine. Optimal preparation for the operation facilitates a successful result and protects the patient and the physician.

In regard to the task of obtaining preoperative information, there are two goals. The first is to ensure that the procedure is appropriate for the patient's diagnosis. The content of this part of the clinician's task is covered elsewhere in this text; the process of the task involves the physician-patient relationship. Just as crucial is the second goal, ensuring that the patient is safe for the procedure and that comorbidities are appropriately addressed. Some comorbidities will require further consultation with other specialists, and it is important for the gynecologic surgeon to recognize when consultation is needed.

The gynecologic surgeon, as leader of the surgical team, has a responsibility to prepare the patient, her family, and the surgical team for the surgical procedure. Even in emergency situations, preoperative preparation should be detailed and complete. Almost any surgical procedure is a major event in a patient's life that can be accompanied by anxiety and apprehension of the anticipated surgical procedure. Among elective procedures, there may also be ambivalence in deciding whether to have the operation. In all cases, it is important for the surgeon to outline the natural history of the gynecologic disease and options for management. The risks, benefits, and alternatives must be discussed. The impact of a surgical intervention on normal body function, sexuality, and cosmesis must also be addressed. If the patient is ambivalent concerning the need for a surgical procedure, a second opinion may be warranted and should be offered. Some third-party payer programs may require patients to obtain a second opinion before elective gynecologic operations.

It is the surgeon's responsibility to protect his or her patient's privacy and dignity throughout the perioperative period. The surgeon must appreciate that the preoperative period may be one of great psychological stress for the patient and her support team. Emotional responses may include vulnerability and helplessness, and grief associated with loss of a reproductive organ. The surgeon-patient relationship is far more than the legally

described contractual one. An important aspect of the relationship is that the surgeon and patient partner in joint decision making. Trust in a surgeon's care is established via mutual respect and open communication.

Preoperative consultation with the surgeon is a crucial first step in successful surgery. Ideally, the surgeon, patient, and her selected support team meet for a confidential consultation.

A thorough and detailed history and physical examination should be performed during the surgical consultation. A number of studies have demonstrated that the most significant risk factors for postoperative morbidity are preoperative conditions. Known or unsuspected medical illnesses may affect the operation, anesthesia, and postoperative course and may preclude the procedure altogether. Also, it is important to evaluate the impact of the gynecologic diagnosis on other organ systems, such as a pelvic mass on the ureters or menorrhagia on hemoglobin level.

This chapter outlines the preoperative preparations for gynecologic surgery and perioperative management considerations. The preparations and plans for surgery extend into the postoperative period in a continuous spectrum. Thus several topics will be introduced here and discussed further in [Chapter 25](#). Emphasis is placed on obtaining a standard complete history, performing an adequate physical examination, counseling the patient, establishing informed consent, and perioperative planning to reduce complications associated with gynecologic surgery.

PREOPERATIVE HISTORY

A detailed complete history not only obtains information but may also help relieve the patient's fears and anxieties. When the history is obtained in an unhurried manner, the process can be reassuring. The extent and depth of the general history should be tailored to the age and general health of the woman and the surgical procedure that is being recommended. However, even minor operations may have major complications, so it is important to be prepared for all possibilities.

Obtaining a detailed and comprehensive preoperative history includes the use of open-ended questions as well as directed questions to complete the preoperative picture. A standardized historical questionnaire prior to the initial consultation is often requested by the surgeon or even required by the surgeon's institution. Each surgeon develops his or her method of preparation for consultation. Review of the patient's medical record, obtaining outside records and prior operative reports, and pertinent imaging and pathology can be done prior to the in-person consultation. This can allow for efficient evaluation, consultation, and preoperative referrals if needed.

Although this chapter does not review all the components of a complete history, which are discussed further in [Chapter 7](#), it may be advantageous to group questions under the specific organ systems. Specific questions should be included to cross-check the review of symptoms. Questions should be included that address prior problems with surgery, anesthesia, or bleeding in the woman or her family. Medication allergies and current medications should be reviewed. Reconciliation of prescribed and over-the-counter (OTC) medications as well as vitamins, herbal medications, and supplements is critical, as some have the potential to affect surgery through coagulation, healing, and cross-reactivity with other medications. Approximately 0.5% of the general population and 1.5% of women older than 55 years are receiving continuous glucocorticoids. Thus a specific question about glucocorticoid therapy for chronic medical problems should be included. The patient's primary care physician should be involved in the decision to temporarily stop certain medications prior to surgery, and he or she may also be able to provide guidance regarding anticoagulation bridging and stress-dose steroid dosing, if either are needed.

Patients often do not consider aspirin or oral contraceptives as medication; therefore specific questions regarding these substances are needed. General questions regarding smoking, alcohol, exercise tolerance, and recent upper respiratory infections should also be included. Specific questions should be directed toward sensitivity to iodine or latex. Latex allergy is directly responsible for 12% of the perioperative anaphylactic reactions in adult women and for 70% in children. Health care workers are particularly prone to latex allergy. Women with spinal cord injuries, or those who have had to perform self-catheterization, are at higher risk for latex allergy.

The patient's contraceptive history, including any recent change, must be known. Ensuring that pregnancy is excluded either through the preoperative history or a pregnancy test is critical prior to gynecologic surgery. Included with the contraceptive history are key questions concerning possible exposure to viruses such as hepatitis B, hepatitis C, and human immunodeficiency virus (HIV). Also, the surgeon should discuss the possibility and risks of blood transfusion and learn whether there are religious objections if a blood transfusion is needed during surgery.

PHYSICAL EXAMINATION

The preoperative physical examination should answer three basic questions:

1. Has the primary gynecologic disease process changed since the initial diagnosis?
2. What is the effect of the primary gynecologic disease on other organ systems?
3. What deficiencies in other organ systems may affect the proposed surgery and hospitalization?

Observations and findings in the physical examination may prompt further laboratory and diagnostic tests. One of the most important features of the preoperative physical exam is that it should be performed in a thorough and compulsive manner. One should use the same sequence every time to help focus attention on the evaluation of each organ system and to prevent omissions. Two important axioms should be stressed. First, even in emergency situations, it is imperative to perform a thorough physical examination. This should include an evaluation of blood pressure and pulse in the recumbent and sitting positions; orthostatic hypotension and tachycardia are crude indices of a decrease in circulating intravascular volume. Second, although it is important to perform a pelvic examination during the initial consultation, it can also be informative to perform a pelvic examination in the operating room immediately before the surgical incision. An exam while the patient is under anesthesia may provide additional information, help avoid intraoperative surprises, and affect the surgical plan.

LABORATORY AND PREOPERATIVE DIAGNOSTIC PROCEDURES

The general purpose of preoperative laboratory testing is to identify conditions that will alter or aid in perioperative management. Screening tests are used to find unsuspected asymptomatic conditions that may affect the anticipated surgical procedure. Preoperative laboratory tests may also help establish the extent of known disease and may influence the scheduling of elective surgery. Being selective in ordering preoperative tests avoids unnecessary costs associated with test results that would otherwise not affect the surgical plan. Additionally, special imaging procedures may be needed to determine the effects of pelvic disease on other organ systems.

Age-appropriate screening tests should be reviewed with each patient prior to gynecologic surgery. Papanicolaou (Pap) smears should be up to date prior to gynecologic surgery. Mammograms should at least be discussed with women ≥ 40 years of age, and colonoscopy, should be discussed with women older than 50 years.

Presently, there is debate over which preoperative laboratory procedures should be standard. Attention has been drawn to the cost-benefit ratio of preoperative screening. Although the cost of each individual test is usually low, the aggregate costs can be substantial. In a classic study, Kaplan and colleagues retrospectively studied the usefulness of preoperative laboratory procedures. They estimated that 60% of routinely ordered tests, such as differential cell count, platelet count, and 12-factor automated body chemistry analyses, would not have been performed if tests had been ordered only for an indication discovered by history or physical examination. Most important, only 0.22% of these tests demonstrated an abnormality that might influence perioperative management ([Fig. 24.1](#)). The final conclusion in their assessment of 2000 patients undergoing elective operations was that in the absence of specific indications, most routine

preoperative laboratory tests do not significantly contribute to patient care and could be eliminated (Kaplan, 1985). Additionally, the current American Society of Anesthesiologists (ASA) Practice Advisory for Preanesthesia Evaluation states that routine preoperative tests, defined as a test ordered in the absence of a clinical indication or purpose, should not be ordered. Preoperative tests should be ordered for indicated purposes that guide or optimize perioperative care (Committee on Standards and Practice Parameters, 2012).

However, a preoperative complete blood count and blood type and antibody screen should be performed prior to most gynecologic surgeries. In the setting of anemia, the risks and benefits of proceeding with gynecologic surgery should be considered. It is important that the blood bank have the capability of providing cross-matched blood within a reasonable time period if serious intraoperative bleeding were to occur. Routine coagulation studies are not cost effective and rarely provide useful clinical information unless indicated by history and physical examination, as the patient's menstrual history should identify women with bleeding disorders.

Other individualized preoperative laboratory testing should be determined based on the age of the woman, extent of the surgical procedure, and findings at the time of complete history and physical examination. It may be indicated to order limited blood screening tests for women older than 40 years or who

have positive family histories or questionable past histories of hepatic or renal disease. Determining the preoperative creatinine or blood urea nitrogen (BUN) level is especially important if the woman is going to be treated with antibiotics excreted by the kidneys. A pregnancy test may be appropriate, depending on contraceptive and sexual history, but it should almost always be performed if the patient is a teenager, as menstrual history is at best an imperfect indication of an early pregnancy. Serum electrolyte levels are ordered for women taking diuretics or those with a history of renal disease or heart disease. Also, serum electrolyte levels should be evaluated in women with vomiting, diarrhea, ileus, bowel obstruction, or any condition that affects electrolyte balance. Ideally, abnormal results from any laboratory test ordered preoperatively should result in some change in perioperative management.

Routine chest x-rays on all patients often do not affect perioperative management in elective gynecologic surgery. A history and physical examination are sufficient for screening, and chest x-rays should be obtained in patients with positive findings. A meta-analysis of studies of routine preoperative chest x-rays demonstrated that false-positive results leading to invasive procedures and associated morbidity are more frequent than the discovery of new findings leading to a change in management. However, chest films should be ordered for women who are 20-pack/year smokers, women with cardiac or pulmonary symptoms, immigrants who have not had a recent chest film, and women older than 70 years (Qaseem, 2006). Interestingly, there appears to be a great deal of institutional variability regarding the absolute age cutoff.

A baseline preoperative electrocardiogram (ECG) has been found to be cost effective in asymptomatic women ≥ 60 years without a history of cardiac disease or significant risk factors. An ECG may also be indicated in younger women with a history of smoking and those with diabetes or renal disease, depending on the severity.

Based on the complete history, physical examination, and preoperative testing, the gynecologic surgeon should determine whether consultation with other specialists is necessary. This decision should take into account the severity of comorbidities and the complexity of the proposed operation.

Figure 24.1 Proportions of indicated and unindicated preoperative tests, drawn to scale. Numbers in parentheses represent sample sizes used. CBC, Complete blood count; automated multiple analysis is the sixth factor; PT/PTT, prothrombin time/partial thromboplastin time. (From Kaplan EB, Scheiner LB, Boeckmann AJ, et al. The usefulness of preoperative laboratory screening. *JAMA*. 1985;253[24]:3576-3581.)

PATIENT EDUCATION AND INFORMED CONSENT

One of the primary responsibilities of the gynecologic surgeon is to educate the patient and her support team about the anticipated surgical procedure, hospitalization, and recovery. Informed consent is an important principle to ensure that the patient's right to self-determination is respected. The ethical concept of the process of informed consent includes two components, comprehension and free consent. Throughout the educational process, questions from the patient or her support team should be welcomed. Educating the patient can also address anxiety. Written information, when available, can be helpful. Psychological preparation of the patient's support team is equally important, and arrangements for appropriate communication with the patient's family or support team during the operation should be made.

Few concepts bring more ambivalence and concern to the physician than the doctrine of informed consent. In the present

medicolegal climate, the absence of informed consent is cited as a major problem in many lawsuits. Some of these issues are discussed further in [Chapter 6](#). It is important to differentiate between the concepts of consent and informed consent. Consent involves a simple yes-no decision, but informed consent is an educational process. To obtain informed consent, the surgeon must explain the following to the patient in understandable terms: the nature and extent of the disease process; the nature and extent of the contemplated operation; the anticipated benefits and results of the surgery, including a conservative estimate of successful outcome; the risks and potential complications of the operative procedure; alternative methods of therapy; and any potential changes in sexual, reproductive, and other functions. The surgeon should also discuss with the patient what the operation will not accomplish. Questions from the patient should be encouraged and addressed. Any details specific to the situation should be clarified in the consent note in addition to stating that the procedure, alternative treatments, and risks have been discussed and questions have been answered. The possibility of unanticipated pathologic conditions should be discussed with the woman and permission obtained on the written consent form for the most extensive operative procedure that may be necessary.

One of the greatest dilemmas in the doctrine of informed consent is the extent and depth of discussions concerning potential complications of an operation. Attorneys who specialize in defending gynecologic surgeons in medical malpractice litigation strongly advise discussing all major complications, including death from surgery and rare, serious complications, such as urinary tract fistulas following hysterectomy. Studies have documented that approximately 70% of patients do not read the consent form before signing it. Ideally, to protect the surgeon, another member of the health care delivery team should witness the final discussion of the informed consent process. The surgeon should document critical highlights of this discussion in the patient's medical record.

The gynecologic surgeon must not only educate his or her patient but must be prepared to discuss other information that the patient has received, including information from the lay press and Internet. During the preoperative educational process, so much information may be given that it causes confusion. Studies have noted that the more information given, the less information is actually retained, much less correctly retained. A study by Sandberg and colleagues has noted that during the preoperative evaluation, information given by anesthesiologists and other health care providers vastly exceeds the short-term capacity of patients ([Sandberg, 2008](#)). Thus it is extremely helpful to provide written preoperative instructions and important information.

PREOPERATIVE PREPARATION

Because of the increasing emphasis on same-day admission to the hospital, most procedures and orders are accomplished on an outpatient basis. Preoperative orders should be standardized to avoid omissions and electronic order sets are standard at most institutions. Orders individualized to a patient should be written in specific detail to avoid confusion by nursing and other hospital personnel.

Prior to presentation to the hospital, the patient should be provided with a list of specific instructions for the 24 hours

before surgery. If an enhanced recovery pathway is being utilized, the patient can usually eat solid food up until midnight and clear liquids until 30 minutes prior to presenting to the hospital. To avoid hypoglycemia, most enhanced recovery after surgery protocols allow patients to eat solid food up to 6 hours before surgery. Clear liquids are emptied from the stomach within minutes; however, fatty foods delay gastric emptying. Incomplete preparation of the upper gastrointestinal tract increases the risk of aspiration. Studies have documented the safety of allowing inpatients and outpatients to ingest clear liquids up until two hours before elective surgery. Interestingly, the extent of preoperative anxiety does not influence gastric fluid volume or acidity.

CONSULTATION WITH ANESTHESIOLOGY

Among patients with no or limited comorbidities, the consultation with their anesthesiologist may occur in the preoperative area on the day of surgery. During this time, the anesthesiologist reviews and obtains any additional medical information, evaluates the patient's airway, determines the American Society of Anesthesiologists (ASA) risk score for the patient, and writes any preoperative medication orders. Among patients with complex medical histories or comorbidities, prior complications with anesthesia, family history of anesthesia complications, or planned high complexity surgery, a preoperative evaluation with an anesthesiologist in an outpatient clinic a day or more prior to surgery is warranted. The goal for this evaluation is to ensure all preoperative assessments needed to optimize anesthesia safety have been performed.

Surgeons and anesthesiologists frequently have to determine whether to continue or interrupt medications during the perioperative period. If the medication is prescribed for a chronic medical illness, it is likely best to continue the drug throughout the perioperative period. However, it is essential to determine whether the drug will adversely affect the course of the anesthesia or surgery and whether it will interact with other drugs to be given during the procedure. It is acceptable for the patient to take oral medications the morning of surgery. The 30 to 60 mL of water needed to swallow the oral medication is negligible compared with gastric fluid volumes.

Anesthesiologists classify surgical procedures according to the patient's risk of mortality. In 1961, Dripps first published guidelines to determine the risk of death related to major operative procedures. This physical status scale ([Table 24.1](#)) has been

Table 24.1 American Society of Anesthesiologists (ASA) Physical Status Classification

ASA Physical Status Class	Description
1	A normal healthy patient
2	A patient with mild systemic disease
3	A patient with severe systemic disease
4	A patient with severe systemic disease that is a constant threat to life
5	A moribund patient who is not expected to survive without the operation

From Koo CY, Hyder JA, Wanderer JP, et al. A meta-analysis of the predictive accuracy of postoperative mortality using the American Society of Anesthesiologists' Physical Status Classification System. *World J Surg.* 2015;39(1):88-103.

adopted by the ASA and has been revalidated many times over the years. With minor modifications, these anesthetic risk classes are still widely used. An emergency operation doubles the mortality risks for classes 1, 2, and 3; produces a slightly increased risk in class 4; and does not change the risk in class 5 (Koo, 2015).

PERIOPERATIVE MANAGEMENT

ENHANCED RECOVERY

Enhanced recovery refers to a bundled process with the aim of attenuating pathophysiologic changes and the stress response occurring with surgery. These processes replace traditional but untested practices of perioperative care with the primary goal of hastening recovery. This challenge to traditional surgical paradigms—such as mechanical bowel preparation, the overnight fasting rule, delayed postoperative feeding, hypervolemia, and intravenous narcotics—was first described in Europe in the 1990s (Kehlet, 1997). There has been widespread uptake of formalized evidence-based enhanced recovery after surgery (ERAS) protocols internationally, particularly in colorectal surgery. Adoption of enhanced recovery has resulted in an average reduction in length of stay of 2.5 days (Chambers, 2014; Varadhan, 2010) and a decrease in complications by as much as 50%. Similarities between gynecologic oncology procedures and those performed in surgical specialties such as colorectal surgery suggest that patients with gynecologic cancer may obtain comparable benefits.

In one investigation of patients undergoing gynecologic surgery, 241 (81 complex cytoreductive, 84 staging, and 76 vaginal surgery cases) were managed with an enhanced recovery protocol and compared with 235 historical controls matched by procedure (Kalogera, 2013). The protocol included omission of preoperative fasting (Brady, 2003), use of carbohydrate loading (Mathur, 2010; Nygren, 1995), omission of mechanical bowel preparation (Güenaga, 2011), use of preemptive analgesia, nausea and vomiting prophylaxis, and maintenance of perioperative euvolemia (Brandstrup, 2003). Laparotomy wounds were injected with bupivacaine, as epidural analgesia was not utilized for patients undergoing laparotomy in this series. Intrathecal analgesia was utilized in more than 40% of vaginal cases in this series. Nasogastric tubes (Nelson, 2007), surgical drains (Kalogera, 2012), and intravenous patient-controlled analgesia was avoided or omitted, whereas early feeding (Charoenkwan, 2007; Cutillo, 1999; Minig, 2009), laxative use, and early mobilization were encouraged (Table 24.2). Enhanced recovery achieved the greatest benefit in patients undergoing complex cytoreduction for ovarian cancer, of whom 57% underwent colonic or small bowel resection. Patient-controlled anesthesia use decreased from 99% to 33%, and total opioid use decreased by 80% in the first 48 hours with no increase in pain scores. Hospital stay was reduced by four days with 30-day cost savings of more than \$7600 per patient (18.8% reduction). In benign vaginal cases, mean pain scores significantly improved and hospital stay was significantly reduced by one day with the use of intrathecal analgesia. Ninety-five percent of patients rated satisfaction with perioperative care as excellent or very good. Other investigations in patients undergoing gynecologic surgery have shown that enhanced recovery is safe and confers significant benefits in hospital length of stay, pain control, and overall recovery (Carter, 2012; Chase, 2008;

Eberhart, 2008; Gerardi, 2008; Kalogera, 2013; Marx, 2006; Wijk, 2014).

The popularity of thoracic epidural anesthesia (TEA) following major open gynecologic surgery is due to its effectiveness in controlling pain and the quicker return of bowel function seen in patients with epidural anesthetics (Ferguson, 2009). However, the role of TEA in an ERAS care plan is less clear, as it can compete at times with some of the ERAS goals such as early ambulation and voiding. The use of TEA has been associated with more interventions to treat hypotension, longer length of hospital stay, as well as more complications in one series of early stage endometrial cancer patients (Belavy, 2013). The estimated length of stay in most ERAS pathways for simple hysterectomy is approximately 1 to 2 days. The use of TEA in this setting not only is a poor utilization of resources but also will likely interfere with the expected expedient discharge from the hospital. Further study is needed to determine if TEA or other local or regional analgesic approaches in radical abdominal procedures such as ovarian cancer debulking improve the return of bowel function or shorten hospital stay.

GASTROINTESTINAL TRACT CONSIDERATIONS

If gastrointestinal symptoms are present prior to gynecologic surgery, preoperative endoscopy or imaging studies of the gastrointestinal tract should be considered to better understand the etiology of these symptoms. The effect of nausea, vomiting, or diarrhea on serum electrolyte levels and on the nutritional status of the patient also needs to be evaluated. The evaluation should be individualized to determine whether a primary gynecologic process is causing the gastrointestinal symptoms.

If a bowel preparation is felt to be necessary, a single day of an oral solution can be used. Magnesium citrate, sodium phosphate (Fleet phospho-soda), and polyethylene glycol (PEG; GoLYTELY) are the three most commonly used agents. Oliveria and colleagues reported a large randomized trial comparing sodium phosphate and PEG-based oral lavage solutions. The efficacy of the two preparations was similar. However, there was superior subjective patient tolerance to the 90-mL dose of sodium phosphate (Oliveira, 1997). Care must be taken in selecting patients who are to receive oral sodium phosphate as a bowel preparation because it may lead to hypokalemia, has been associated with acute phosphate nephropathy, and is contraindicated in women with hepatic, renal, or heart disease. As a result, the U.S. Food and Drug Administration (FDA) issued a warning in late 2008 regarding the use of all oral sodium phosphate preparations when used as a bowel cleanser. Special care must be taken in patients over the age of 55 or younger than 18, patients taking medications that can affect kidney function, or patients who are dehydrated.

REDUCING POSTOPERATIVE COMPLICATIONS

Site Marking and Universal Protocol

Depending on the surgical procedure being performed, operative site marking may be required. Most institutions mandate site marking to be performed in the setting of surgical procedures that involve or remove one or both organs or structures that are paired. This is controversial in gynecologic surgery, as

Table 24.2 Evidence-Based Enhanced Recovery after Surgery (ERAS) Protocol for Gynecologic Surgery Patients

Preoperative	
Diet	<p>Evening before surgery: carbohydrate-loading drink; may eat until midnight</p> <p>May ingest fluids up to 4 hours before procedure</p> <p>Eliminate use of mechanical bowel preparation; rectal enemas still performed</p>
Intraoperative	
Analgesia before OR entry	<p>Celecoxib 400 mg PO once</p> <p>Acetaminophen 1000 mg PO once</p> <p>Gabapentin 600 mg PO once</p>
Postoperative nausea and vomiting prophylaxis	<p>Before incision (\pm 30 min): dexamethasone 4 mg IV once + droperidol 0.625 mg IV once</p> <p>Before incision closure (\pm 30 min): granisetron 0.1 mg IV once</p>
Fluid balance	<p>Goal: maintain intraoperative euolemia</p> <p>Decrease crystalloid administration</p> <p>Increase colloid administration if needed</p>
Analgesia	<p>Opioids IV at discretion of anesthesiologist supplemented with ketamine or ketorolac</p> <p>After incision closure: injection of bupivacaine at incision site</p>
Anesthesia in complex vaginal surgery	<p>Subarachnoid block containing bupivacaine and hydromorphone (40–100 μg)</p> <p>Sedation versus “light” general anesthetic at the discretion of the anesthesiologist</p> <p>Ketorolac 15 mg at the end of the procedure for patients able to tolerate it</p> <p>No wound infiltration with bupivacaine in this cohort</p>
Postoperative	
Activity	<p>Evening of surgery: out of bed greater than 2 hours, including 1 or more walks and sitting in chair</p> <p>Day after surgery and until discharge: out of bed greater than 8 hours, including 4 or more walks and sitting in chair</p> <p>Patient up in chair for all meals</p>
Diet	<p>No nasogastric tube (NGT); if NGT used intra operatively, remove at extubation</p> <p>Patient encouraged to start low-residue diet 4 hours after procedure</p> <p>Day of surgery: 1 box of liquid nutritional supplement. Encourage oral intake of at least 800 mL of fluid, but no more than 2000 mL by midnight.</p> <p>Day after surgery until discharge: 2 boxes of liquid nutritional supplement. Encourage daily oral intake of 1500–2500 mL of fluids.</p>
Analgesia	<p>Osmotic diarrhetics: senna and docusate sodium; magnesium oxide; magnesium hydroxide prn</p> <p>Goal: no IV patient-controlled analgesia (PCA)</p> <p>Oral opioids</p> <p>Oxycodone 5–10 mg PO every 4 hours as needed for pain rated 4 or greater or greater than patient stated comfort goal (5 mg for pain rated 4–6 or 10 mg for pain rated 7–10). For patients who received intrathecal analgesia start 24 hours after intrathecal dose given.</p> <p>Scheduled acetaminophen*</p> <p>Acetaminophen 1000 mg PO every 6 hours for patients with no or mild hepatic disease; acetaminophen 1000 mg PO twice daily for patients with moderate hepatic disease; maximum acetaminophen should not exceed 4000 mg per 24 hours from all sources.</p> <p>Scheduled NSAIDs</p> <p>Ketorolac 15 mg IV every 6 hours for 4 doses (start no sooner than 6 hours after last intra-operative dose); then, ibuprofen 800 mg PO every 6 hours (start 6 hours after last Ketorolac dose administered)</p> <p>If patient unable to take NSAIDs</p> <p>Tramadol 100 mg PO four times a day (start at 6 a.m. day after surgery) for patients less than 65 years of age and no history of renal impairment or hepatic disease; tramadol 100 mg PO twice daily (start at 6 a.m. day after surgery) for patients 65 years of age or older or creatinine clearance less than 30 mL/min or history of hepatic disease.</p> <p>Breakthrough pain (pain greater than 7 more than 1 hour after receiving oxycodone)</p> <p>Hydromorphone 0.4 mg IV once if patient did not receive intrathecal medications; may repeat once after 20 minutes if first dose ineffective.</p> <p>IV PCA</p> <p>Hydromorphone PCA started only if continued pain despite two doses of IV hydromorphone</p>
Fluid balance	<p>Operating room fluids discontinued upon arrival to floor</p> <p>Fluids at 40 mL/hour until 8:00 a.m. on day after surgery, then discontinued</p> <p>Peripheral lock IV when patient had 600 mL PO intake or at 8:00 a.m. on day after surgery, whichever came first.</p>

PO, Administered orally.

From Kalogera E, Bakkum-Gamez JN, Jankowski CJ, et al. Enhanced recovery in gynecologic surgery. *Obstet Gynecol.* 2013;122(2 Pt 1):319–328.

*Doses for patients greater than 80 kg and less than 65 years of age; doses adjusted as appropriate for patients less than 80 kg and/or 65 years of age or older.

the preoperative determination of adnexal laterality is not always reliable. If site marking is done, it should be performed in the preoperative area while the patient is awake and nonsedated. The patient should participate in Universal Protocol and confirm which organ(s) will undergo surgery. Universal Protocol and site marking reduces the risk of wrong site, wrong procedure, and wrong person operations (Knight, 2010).

Preoperative Briefing

It is now common practice to perform a preoperative briefing, or “huddle,” prior to bringing the patient to the operating room. Usually performed in the preoperative area, the entire surgical team should be briefed on the patient’s diagnosis, surgical plan, positioning, relevant comorbidities, intraoperative orders, and perioperative considerations. Medications to be administered, including antibiotics, prophylactic dose heparin, local analgesics, and specialty medications such as local or systemic dye injections or vasoactive medications should be discussed. The anesthesia plans and estimated blood loss for the procedure should be reviewed. Special equipment needed for the procedure should be noted so that it is immediately available when needed. The anticipated wound classification should be noted so that it is accurately documented in the patient’s medical record. Ideally, the entire operating room team should be present for the briefing, including the surgeon, resident/fellow, nurse, surgical assistant and tech, and anesthesia team. All team members’ questions should be answered prior to bringing the patient to the operating room.

Positioning for Surgery

After anesthesia has taken effect and the abdominal wall is relaxed, a preoperative pelvic examination may be indicated depending on the surgical procedure planned. The findings may influence the choice of incision or operative approach. Additionally, the surgeon should supervise the positioning of the patient to ensure that she is properly positioned for the procedure being performed. Pressure points should be avoided to protect against neuromuscular and skin injury, especially over bony prominences (Irvin, 2004).

Surgical Site Infection Prevention

The occurrence of a surgical site infection (SSI) is one of the most common complications after surgery. SSIs dissatisfy patients and providers, but they also increase the cost of surgical care, increase morbidity, and can increase mortality (Bakkum-Gamez, 2013; Tran, 2015). Additionally, SSIs associated with hysterectomies performed through abdominal incisions (laparotomy, laparoscopy, or robotics) are reported to the Centers for Medicare and Medicaid Services (CMS) and are utilized to compare hospitals to the national benchmark for surgical quality. Ultimately, the occurrence of an SSI after hysterectomy will likely influence third-party reimbursement. As such, there are multiple reasons to reduce SSI occurrences.

SSIs are multifactorial in etiology. There are host and endogenous flora factors that may or may not be modifiable. Additionally, surgical procedures, the surgical team, hospital practice factors, and prophylactic interventions will influence the risk of SSI (Fig. 24.2). SSIs are categorized into three classifications

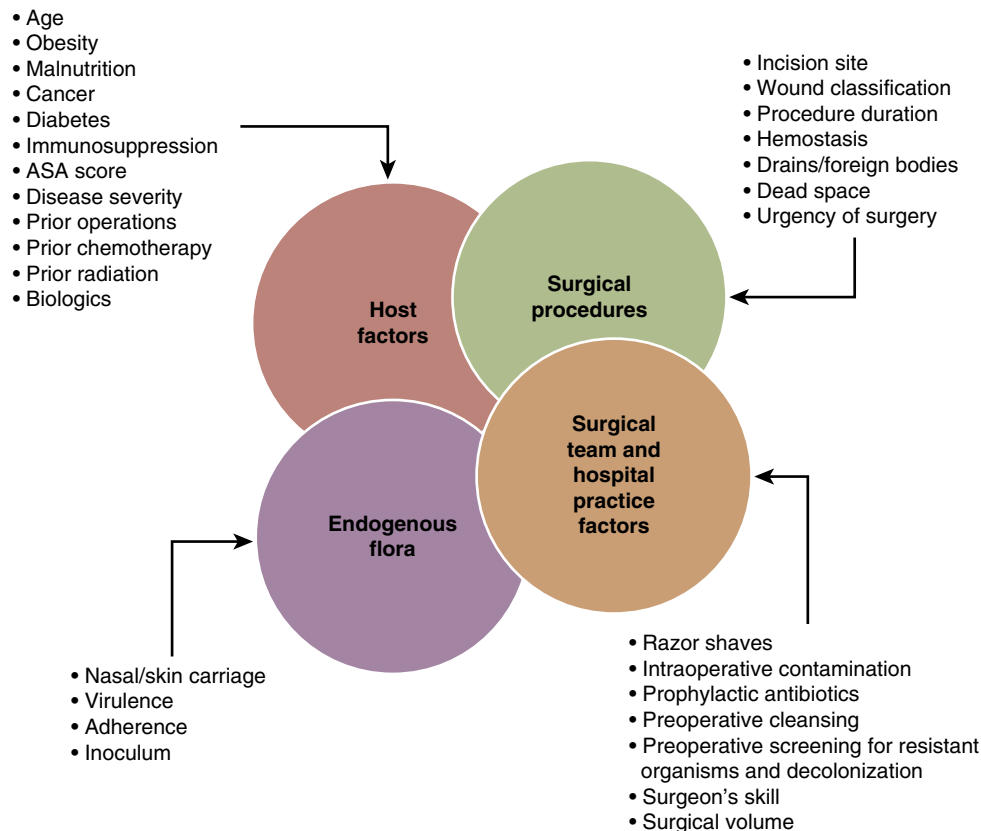

Figure 24.2 Surgical site infections are multifactorial in etiology.

by the Centers for Disease Control and Prevention (CDC) and the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP): (1) superficial incisional, (2) deep incisional, and (3) organ/space (ACS NSQIP, 2011) (Box 24.1); each has different risk factors (Bakkum-Gamez, 2013). Given the implications of an SSI diagnosis, it is important to ensure that if a wound complication occurs, the surgeon classifies it appropriately.

Surgical Site Infection Reduction Bundles

In approaching the challenge of reducing SSIs, the combination of evidence-based medicine with consensus best practices into “bundles” of interventions has been shown to have some of the greatest impacts. The term *bundle* has been defined by the Institute for Healthcare Improvement (IHI) as a structured way of improving the processes of care and patient outcomes or a small, straightforward set of evidence-based practices that, when performed collectively and reliably, have been proved to improve patient outcomes. Elements shown to decrease SSI that are often included in reduction bundles include preoperative nicotine cessation (Sørensen, 2012), preoperative antiseptic showering (Webster, 2007) and chlorhexidine preparation (Darouiche, 2010), using hair clippers instead of a razor (Cruse, 1980; Kjønnsen, 2002), appropriate preoperative antibiotic selection (Bratzler, 2013), normothermia (Rajagopalan, 2008; Scott, 2006; Warttig, 2014), and glycemic control (Kwon, 2013). SSI reduction bundles that include various combinations of these elements

as well as additional evidence-based and best practices have been shown to decrease SSI after hysterectomy by 40% (Revolus, 2014) and by more than 50% in general surgery and colorectal surgery (Cima, 2013; van der Slegt, 2013; Waits, 2014). The colorectal surgery SSI reduction bundle at the Mayo Clinic (Fig. 24.3) has been validated in the gynecologic surgery practice as well (Cima, 2013). Additionally, in at least one study of patients undergoing colorectal surgery, there was an inverse association with SSI and the number of bundle elements utilized (Waits, 2014), which suggests it is the combination of interventions rather than one element alone yielding the impact.

Prophylactic Antibiotics

The use of prophylactic antibiotics in gynecologic surgical procedures has become standard. Rigidly defined, prophylactic antibiotic use involves the administration of antibiotics to patients without evidence of current infection to prevent postoperative morbidity related to infection. The goal of antibiotic therapy is to prevent SSI by the endogenous flora of the lower female reproductive tract. There is abundant literature supporting the use of prophylactic antibiotics in gynecology. The incidence of febrile morbidity may be reduced from 40% to 15%, and the incidence of pelvic infection decreased from 25% to 5%. The current guidelines for antimicrobial prophylaxis for vaginal or abdominal hysterectomy include the first- or second-generation cephalosporins of cefazolin, cefotetan, cefoxitin, or ampicillin-sulbactam. Among women with a β -lactam allergy, the recommended combinations are (1) clindamycin or vancomycin plus an aminoglycoside, or (2) aztreonam, or (3) a fluoroquinolone, metronidazole, and aminoglycoside, or (4) a fluoroquinolone alone (Bratzler, 2013).

Emphasis has focused on short duration of therapy for prophylactic antibiotics. Comparative studies have documented that single-dose therapy is as effective as 24 hours of antibiotics. No advantage exists to continuing prophylactic antibiotics beyond the immediate operative period. This short duration of administration also reduces cost and complications. The incidence of serious complications, such as drug allergy and resistant bacteria, is directly related to the length of administration of the antibiotic.

The Surgical Care Improvement Project (SCIP) implemented by CMS focused on appropriate antibiotic selection and timing of administration with the goal of reducing SSI rates by 25% between 2006 and 2010. Despite high compliance to SCIP measures, which later included normothermia, glucose control, and hair removal guidelines, SSI rates do not correlate with SCIP compliance (Hawn, 2011). So although antibiotic prophylaxis is an important element in SSI reduction, antibiotics alone cannot mitigate the SSI risk.

Minimally Invasive Surgery

With the introduction of laparoscopy and robotic surgery, the armamentarium of minimally invasive gynecologic surgery approaches changed dramatically. Vaginal surgery continues to carry the lowest risks of SSI (Lake, 2013) and should remain the preferred surgical approach when feasible. However, when minimally invasive approaches to hysterectomy replace laparotomy, the risk of SSI can be reduced by up to 16-fold (Bakkum-Gamez,

Box 24.1 Classification of Surgical Site Infections (SSI) by the Centers for Disease Control and Prevention (CDC) and American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP)

Superficial Incisional SSI*

1. Purulent incisional drainage from above the fascia
2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
3. Pain/tenderness, wound swelling, redness, or heat and the superficial incision is deliberately opened by the surgeon (unless it is culture negative)

Deep Incisional SSI* (involves deep soft tissues, such as the fascia or muscle layers of the incision)

1. Purulent drainage from the deep incision
2. Spontaneous dehiscence or deliberate opening of the fascia in the setting of fever or localized pain/tenderness (unless it is culture negative)
3. An abscess is found involving the deep incision via physical examination, reoperation, or radiologic examination

Organ/Space SSI*

1. Purulent drainage from an intraperitoneal drain
2. Presence of organisms in culture of fluid obtained aseptically from an organ or space
3. Abscess or other infection involving an organ or space on physical examination, reoperation, histopathologic or radiologic examination

From ACS NSQIP. Classic, essential, small-rural, targeted, and Florida variables & definitions. *American College of Surgeons National Surgical Quality Improvement Program Operations Manual*. Chicago: ACS; 2011:24-26.

*Surgeon diagnosis of any of the three types of SSI also meets NSQIP criteria.

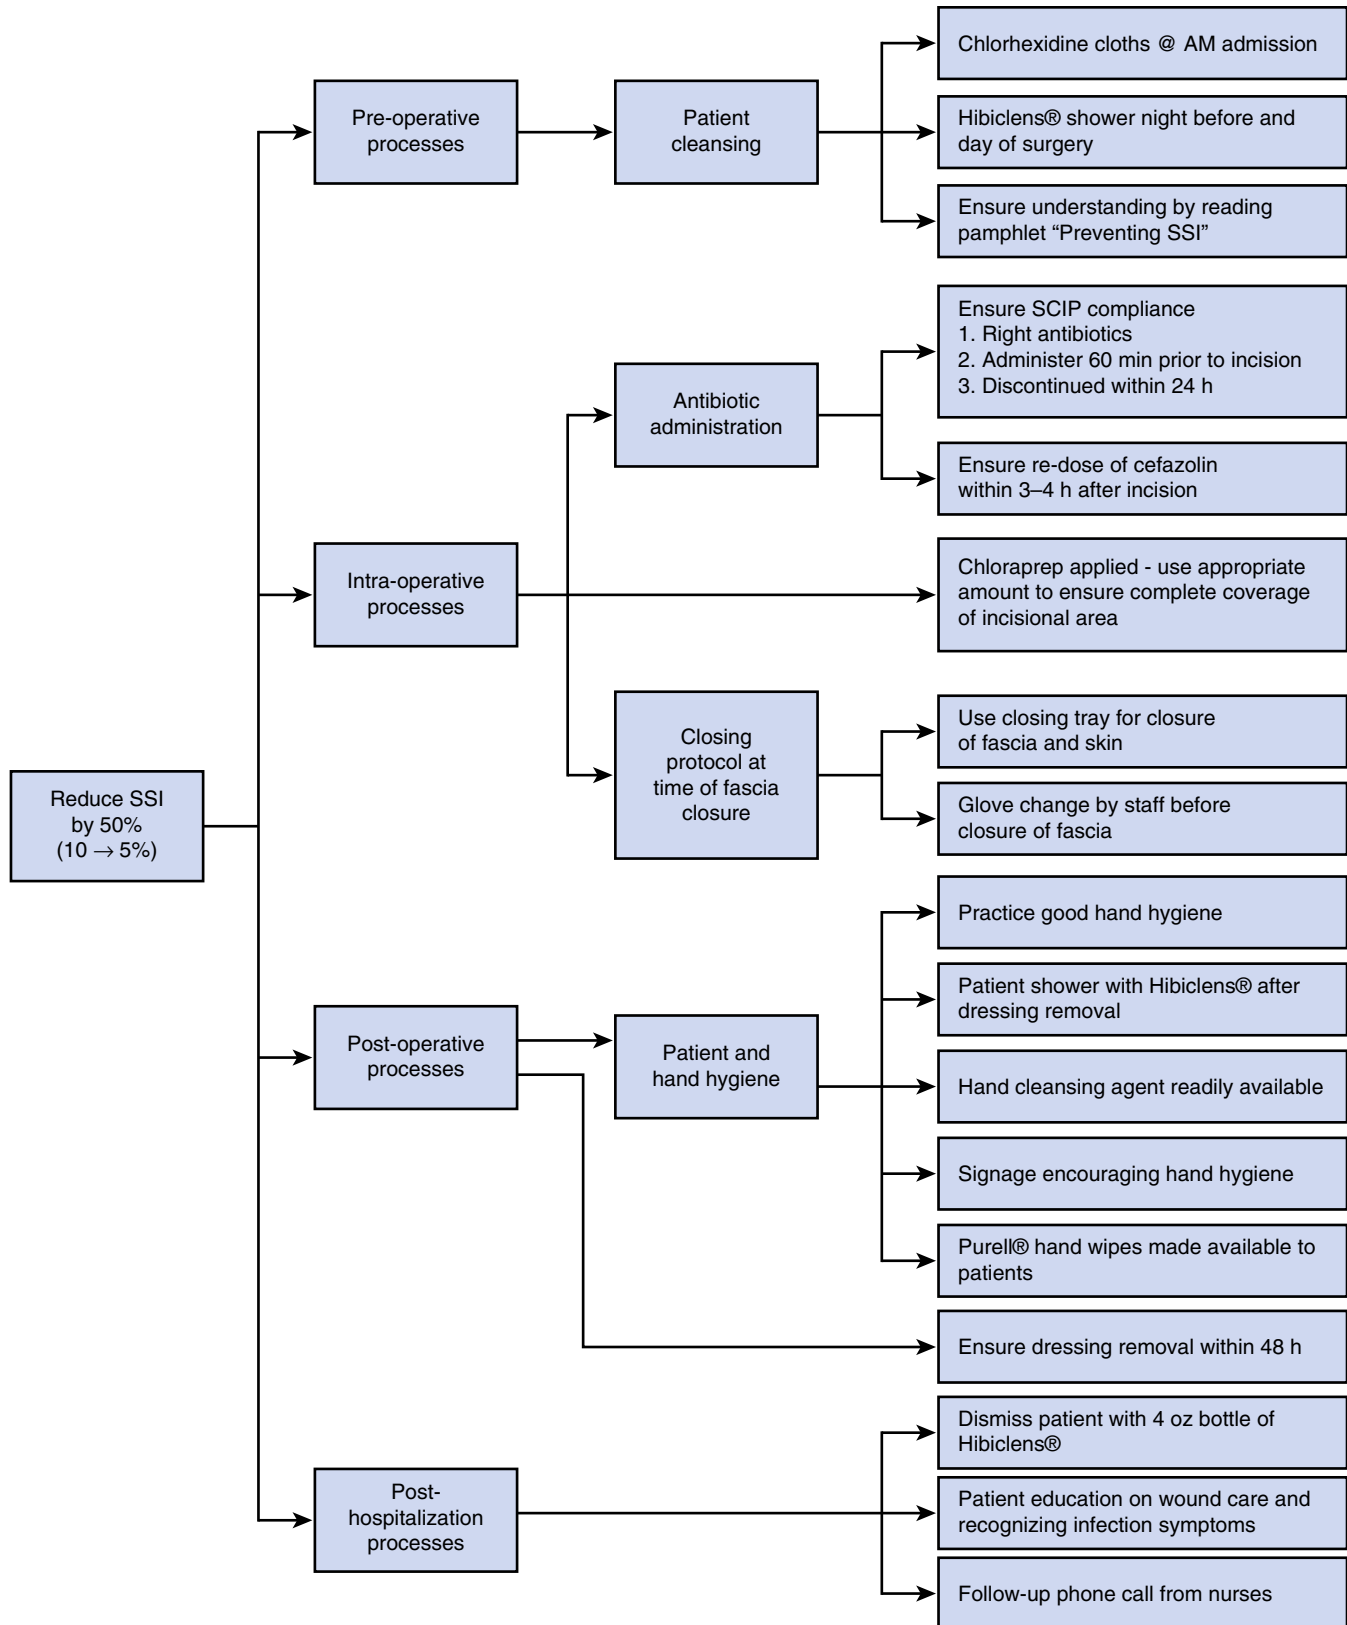

Figure 24.3 Surgical site infection reduction bundle in colorectal surgery at Mayo Clinic. Surgical site infection was reduced by >50% with the implementation of this full bundle. (From Cima R, Dankbar E, Lovely J, et al. Colorectal surgery surgical site infection reduction program: a national surgical quality improvement program-driven multidisciplinary single-institution experience. *J Am Coll Surg*. 2013;216[1]:23-33.)

2013; Colling, 2015). As such, the utilization of minimally invasive surgery is a critical modifiable factor in the SSI prevention bundle.

Hair Removal

Multiple studies have documented a two- to threefold increase in SSI rate directly related to perioperative shaving. Cruse and Foord studied approximately 63,000 operations over a 10-year period and found a 0.9% incidence of SSI when patients were not shaved as opposed to 2.5% when they were shaved (Cruse, 1980). Razors produce macroscopic and microscopic nicks and cuts that allow a protective environment for colonization by skin bacteria. Depilatory agents often produce intense burning if used on the perineum. A systematic review by Kjønniksen and associates has concluded that if the hair is mechanically in the way, it should be clipped just before the operation (Kjønniksen, 2002). Patients should also be advised not to shave themselves prior to surgery for this reason.

Chlorhexidine/Alcohol Skin Preparation

A randomized trial comparing chlorhexidine gluconate with 70% isopropyl alcohol versus an aqueous solution of 10% povidone-iodine for skin cleansing showed a 40% reduction in SSIs in clean contaminated (type II) wound types (Darouiche, 2010). The solution is highly flammable, and care must be taken to ensure adequate drying time in order to avoid a fire when electrocautery is used.

Smoking

The risk of an SSI is significantly increased in the setting of smoking (van Walraven, 2013). Ideally, patients should stop smoking for at least 8 weeks prior to surgery. However, abstinence from cigarettes for 2 to 4 weeks preoperatively is still beneficial. Providing nicotine replacement is helpful in alleviating the symptoms of acute nicotine withdrawal. Referral to preoperative smoking cessation programs not only decreases smoking around the time of surgery and related perioperative complications but also leads to an increased incidence of long-term smoking cessation. In one multicenter study, Lindström and associates noted that the patients in a smoking cessation program had perioperative complication rates of 21% versus 41% in controls (Lindström, 2008).

Normothermia

Hypothermia, frequently defined as a core body temperature less than 36° C, has been shown to increase the incidence of wound infection and postoperative myocardial events, increase perioperative blood loss, impair drug metabolism, and prolong postoperative recovery (Rajagopalan, 2008; Scott, 2006; Warttig, 2014). Patients undergoing major surgery are at high risk of hypothermia due to prolonged periods with an open abdomen. Furthermore, general anesthesia induces peripheral vasodilation leading to accelerated heat loss. The use of esophageal probes is frequently used to monitor temperature. Methods to maintain normothermia include the use of forced air devices (Galvão, 2010), underbody warming mattresses (Perez-Protto, 2010), and warmed intravenous fluids (Campbell, 2015). Whichever method is used, it is important to understand that preventing intraoperative hypothermia improves surgical outcomes.

Glucose Control in the Diabetic and Nondiabetic

The prevalence of diabetes is approximately 10% in women <65 years of age, and the incidence increases rapidly as women get older. The stress of surgery often produces changes in glucose tolerance and insulin resistance. Because pancreatic reserve is a continuum, even women who are not diabetic by standard blood glucose criteria may develop detrimental hyperglycemia secondary to the physiologic stresses of surgery. Glucose levels >180 mg/dL among diabetics and nondiabetics increase the risk of SSI by twofold (Kwon, 2013). Perioperative blood glucose levels among both diabetics and nondiabetics should be maintained at <200 mg/dL. Category 1A evidence has demonstrated that strict glucose control (80 to 130 mg/dL) in both diabetics and nondiabetics does not improve SSI rates over glucose levels <200 mg/dL (Chan, 2009), and strict control may have detrimental effects on postoperative outcomes (Gandhi, 2007).

In 2004, the American College of Endocrinology published a position paper, "Inpatient Diabetes and Metabolic Control," emphasizing not only the effects of elevated blood glucose levels but the beneficial effects of adequate insulin (Box 24.2). Insulin decreases lipolysis. Elevated free fatty acid levels are associated with arrhythmias. Insulin inhibits several inflammatory mediators, especially the proinflammatory cytokines. Adequate insulin also leads to an increase in nitric oxide levels in the endothelium, inducing vasodilation.

The principal postoperative complications in diabetic women are increased risk of cardiac morbidity, SSI, and wound disruptions. The increase in SSI rate is believed to be secondary to a decrease in cellular and humoral responses to bacteria. Women with diabetes have approximately a fivefold increase in incidence of SSI compared with age-matched controls. The increased incidence of wound disruptions is caused by a decreased tensile strength during healing associated with insulin resistance and an elevated blood sugar level.

Important questions during the preoperative evaluation focus on the severity of the diabetes, types of medications, and recent diabetic control. Recent blood glucose and hemoglobin A1c (HbA1c) levels may be helpful predictors of perioperative

Box 24.2 Mechanisms Causing Adverse Outcomes from Poorly Controlled Diabetes

Hyperglycemia

- Dehydration
- Acidemia from keto acids and lactate
- Nonenzymatic glycosylation of proteins central to immune function: complement, impaired IgG, inhibited neutrophil activity
- Fatigue and muscle wasting from lipolysis and protein catabolism
- Increased circulating fatty acids
- Increased skeletal muscle breakdown
- Cell membrane instability
- Decline in myocardial contractility and increased cardiac arrhythmias
- Inhibited endothelial function
- Insulin resistance
- Increased lipolysis
- Presence of insulin inhibits inflammatory factors
- Decreased endothelial-derived relaxing factor—nitric oxide
- Insulin and glucose inhibit proinflammatory cytokines

Modified from the American College of Endocrinology. Position statement on inpatient diabetes and metabolic control. *Endocr Pract.* 2004;10(1):77-82.

Table 24.3 Caprini Score Risk Assessment Model for Venous Thromboembolism

1 Point	2 Points	3 Points	5 Points
Age 41-60	Age 61-74	Age ≥75	Stroke (<1 mo)
Minor surgery	Arthroscopic surgery	History of VTE	Elective arthroplasty
BMI >25 kg/m ²	Major open surgery (>45 min)	Family history of VTE	Hip, pelvis, or leg fracture
Swollen legs	Laparoscopic surgery (>45 min)	Factor V Leiden	Acute spinal cord injury (<1 mo)
Varicose veins	Malignancy	<i>Prothrombin 20210A</i> mutation	
Pregnancy or postpartum	Confined to bed (>72 h)	Lupus anticoagulant	
History of unexplained or recurrent spontaneous abortion	Immobilizing plaster cast	Anticardiolipin antibodies	
Oral contraceptives or hormone replacement	Central venous access	Elevated serum homocysteine	
Sepsis (<1 mo)		Heparin-induced thrombocytopenia	
Serious lung disease, including pneumonia (<1 mo)		Other congenital or acquired thrombophilia	
Abnormal pulmonary function			
Acute myocardial infarction			
Congestive heart failure (<1 mo)			
History of inflammatory bowel disease			
Medical patient at bed rest			

From Gould MK, Garcia DA, Wren SM, et al. Prevention of VTE in nonorthopedic surgical patients: *Antithrombotic Therapy and Prevention of Thrombosis*, 9th ed. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. *Chest*. 2012;141(2 Suppl):e227S-e277S.

morbidity, even if they are not modifiable. At the very least, their severity should be documented in the medical record to ensure accurate accounting of perioperative morbidity.

Screening for *Staphylococcus aureus*

Approximately 25% of all SSIs are caused by *Staphylococcus aureus*. Patients at high risk for *S. aureus* SSI (previous *S. aureus* infection or colonization, obesity, or diabetes) likely benefit from preoperative *S. aureus* screening by nasal culture. If positive cultures are documented, eradication of colonization with chlorhexidine baths and twice-daily intranasal mupirocin has been shown to decrease the rate of SSI. Bode and colleagues demonstrated a decrease in SSI from 7.7% to 3.4% when *S. aureus* was detected and decolonization performed (Bode, 2010).

Venous Thromboembolism Prevention

Venous thromboembolism (VTE) of the pelvic or leg veins is a frequent complication of gynecologic surgery. Studies using ¹²⁵I-fibrinogen scanning techniques have documented that approximately 15% of women having gynecologic surgery for a benign disease and approximately 22% of women having surgery for malignant disease develop VTE (Bonnar, 1985). Most of these women will be asymptomatic. Several aspects of pelvic surgery predispose women to VTE, including venous stasis, surgical injury to the walls of large veins, associated anaerobic infection, and hormonal status. Gynecologic malignancy also increased the risk of VTE.

Approximately 40% of deaths following gynecologic surgery are related to pulmonary emboli. Although the initial venous injury most often occurs at the time of the operation, approximately 15% of symptomatic emboli cases do not present until the first week following discharge from the hospital. Because of the significant morbidity and mortality associated with a postoperative pulmonary embolus, every effort should be made to reduce the incidence of thrombophlebitis.

One method commonly used to determine the VTE risk for an individual patient is to calculate the Caprini score, which

takes into consideration risk factors such as a history of previous VTE and personal or family history of hypercoagulability. The presence of such a history should also prompt an evaluation for a thrombophilia. Other risk factors for VTE include active malignancy, previous radiation therapy, congestive heart failure, chronic pulmonary disease, nephrotic syndrome, morbid obesity, venous disease, edema of the legs, active pelvic infection, age older than 40 years, current use of oral contraceptives or hormone replacement therapy up to the time of the operation, length of immobilization or preoperative hospitalization, and the length of the planned surgical procedure (Table 24.3). A Caprini score of 0 is very low risk for VTE, 1 to 2 is low risk, 3 to 4 is moderate risk, and ≥5 is considered high risk for VTE. Women in the very low-risk group have less than a 3% risk of VTE, women in the moderate group have a 10% to 30% risk, and women in the high-risk groups have a more than 30% risk of a VTE. The American College of Chest Physicians have published evidence-based clinical practice guidelines aimed at mitigating VTE risk in the setting of abdominal-pelvic surgery that vary by risk stratification (Table 24.4) (Gould, 2012). The utilization of an inferior vena cava (IVC) filter for primary VTE prevention is not recommended. (The use of IVC filters is currently limited to secondary prevention in patients who cannot be anticoagulated or in patients with a “breakthrough” pulmonary embolism on anticoagulation.) Additionally, surveillance with lower extremity Doppler ultrasound for asymptomatic VTE is not recommended (Gould, 2012). These guidelines are widely accepted for VTE prevention.

The main complication from heparin prophylaxis is bleeding. Some women are transiently anticoagulated by the heparin and may experience excessive bleeding during or following the operative procedure. This complication is rare and experienced by approximately 2% of women. The risk of bleeding is significantly lower with low-molecular-weight heparin (LMWH). Obese or extremely thin women should have their dosage of heparin adjusted accordingly.

Table 24.4 Venous Thromboembolism Prophylaxis Recommendations for Abdominal-Pelvic Surgery

Risk Stratification	Prophylaxis Measures
Very low risk (Caprini score 0)	Early ambulation
Low risk (Caprini score 1-2)	Mechanical prophylaxis with SCDs
Moderate risk (Caprini score 3-4)	Daily prophylactic dose LMWH or thrice-daily prophylactic dose LDUH or SCDs
Not at high risk for bleeding	
Moderate risk (Caprini score 3-4)	Mechanical prophylaxis with SCDs
High risk for bleeding or consequences of bleeding severe	
High risk (Caprini score ≥ 5)	Daily prophylactic dose LMWH or thrice-daily prophylactic dose LDUH + elastic stockings or SCDs
Not at high risk for bleeding	
High risk (Caprini score ≥ 5)	Daily prophylactic dose LMWH or thrice-daily prophylactic dose LDUH + elastic stockings or SCDs
Undergoing surgery for cancer	Extended duration (4 weeks) daily prophylactic dose LMWH
	Low-dose aspirin or fondaparinux or SCDs
High risk (Caprini score ≥ 5)	
LMWH and LDUH contraindicated	

Data from Gould MK, Garcia DA, Wren SM, et al. Prevention of VTE in nonorthopedic surgical patients: *Chest*. 2012;141(2):e227S-e277S.

LDUH, Low-dose unfractionated heparin; LMWH, low-molecular-weight heparin; SCDs, sequential compression devices.

LMWH is superior to standard unfractionated heparin because it has a longer half-life, almost 100% bioavailability, dose-independent clearance, and a more consistent anticoagulation effect from dose to dose. Most studies have reported significantly fewer hemorrhagic complications with LMWH than with unfractionated heparin. Also, the incidence of heparin-induced thrombocytopenia is significantly lower in women given LMWH than in those receiving unfractionated heparin. In the gynecologic surgical community there are two major “protocols” for the timing of pharmacologic prophylaxis. One uses a dose 1 to 2 hours before surgery and postoperatively, and the other begins the pharmacologic prophylaxis between 6 and 12 hours after surgery. A meta-analysis of studies summarizing 1600 surgeries for elective hip repair, as high risk as gynecologic procedures, has found perioperative and postoperative LMWH administration to be equally effective. The rates of deep vein thrombosis were 12.4% and 14.4%, respectively. The risks of bleeding were higher in the perioperative protocol groups, 6.3% versus 2.5% for postoperative dosing. It was concluded that dosing may begin 12 hours after the procedure in most cases and no less than 6 hours after the procedure (Raskob, 2003).

CHRONIC ANTICOAGULATION AND BLEEDING DISORDERS

In women who are currently taking full anticoagulation because of an active VTE or cardiac indication, short-term interruption of blood thinning is indicated for surgical procedures that pose a greater risk of bleeding than a dilation and curettage (D&C). Bridging with LMWH preoperatively and postoperatively may be indicated, and oral anticoagulants should be restarted shortly after surgery. The physician

managing the patient’s anticoagulation should be part of the team guiding bridging and oral agent interruption. In general, warfarin should be held for at least 5 days prior to surgery, and the international normalized ratio (INR) should be <1.5 prior to incision. Therapeutic dose aspirin should be held for 7 days prior to surgery. Once-daily dosing of baby aspirin (81 mg/day) can usually be continued. There are novel oral anticoagulants (NOACs) that are becoming more common; these are factor Xa inhibitors and direct thrombin inhibitors, such as fondaparinux, which inactivates factor Xa by binding antithrombin. Factor Xa inhibitors should be held for 2 to 3 days before surgery, depending on the individual drug’s half-life. Direct thrombin inhibitors should be held for 2 to 4 days prior to surgery, depending on renal function. Depending on the indication for full anticoagulation, bridging with LMWH may be required, and this should be guided by the patient’s primary prescribing physician. Factor Xa inhibitors and direct thrombin inhibitors should be resumed when the surgeon feels the patient is stable and at low risk for postoperative bleeding from full anticoagulation; these oral anticoagulants have a short half-life and effectively fully anticoagulate within a matter of hours (Robertson, 2015). Also of note, patients with an acute VTE who cannot have their surgery delayed may require placement of a temporary IVC filter.

Bleeding disorders usually cause symptomatic issues in most patients earlier in their lives, and it is estimated that approximately 1% to 2% of patients in the United States have some type of bleeding diathesis. The most common is von Willebrand disease. Patients who have had symptoms of easy bruising, frequent nosebleeds, anemia, menorrhagia, and excessive bleeding with surgical procedures should be considered for a hematologic assessment. Any positive test result should be followed by consultation with a hematologist, as supplementation with coagulation factors in the perioperative period may be required. Women with already confirmed bleeding problems should have a consultation for appropriate prophylaxis, and factor replacement should be guided by a hematologist.

STRESS-DOSE STEROIDS

Glucocorticoids are prescribed for a variety of illnesses. Exogenous glucocorticoids will blunt the natural response of the hypothalamic-pituitary-adrenal (HPA) axis in the necessary response to stress. Steroid use for longer than a 2-week period within the year prior to surgery necessitates augmented steroid administration during the perioperative period. Even if the dosing was small (as little as 5 to 7.5 mg of daily prednisone), adrenal insufficiency may occur. In fact, any patient who has received the equivalent dose of 20 mg of daily prednisone for more than 5 days is at risk for HPA suppression (Axelrod, 2003). Supplemental stress-dose corticosteroids should be given at the time of surgery. Minor surgery will only necessitate one dose; major surgeries require dosing for the surgery and may require up to 24 hours of additional treatment postoperatively. If on chronic corticosteroids, the patient should resume preoperative dosing immediately after surgery.

Assessment of Cardiopulmonary Comorbidities

Most healthy patients planning gynecologic surgery will not require extensive preoperative testing beyond a complete history,

physical examination, and the basic preoperative testing described earlier. However, a patient with significant medical comorbidities will likely require more extensive testing and consultation with other specialties to optimize the patient's perioperative outcome. It is beyond the scope of this book to cover the full evaluation of the various medical comorbidities one will encounter in clinical practice, but a basic understanding of what the consulting physician will consider in his or her evaluation of the patient is important to help counsel the patient and set proper expectations.

Pulmonary Disease

Pulmonary complications are a frequent form of postoperative morbidity experienced by approximately 5% of women following gynecologic surgery. The goals of the preoperative assessment of the respiratory system are to identify women at risk for developing postoperative pulmonary complications and prescribe appropriate preoperative therapy to reduce these risks. Similar to the evaluation of other organ systems, the history and physical examination are the most important parts of the pulmonary evaluation. Pulmonary function tests of lung volumes and flow rates are only indicated to evaluate women with a history or physical findings suggestive of restrictive or obstructive pulmonary disease. Pulmonary function tests help assess the pulmonary reserve and identify the extent to which the dysfunction is reversible. These tests measure lung volumes, forced vital capacity (FVC), and flow rates, forced expiratory volume in 1 second (FEV₁), to help distinguish restrictive defects from obstructive defects. Women who have compromised preoperative pulmonary function are especially susceptible to develop clinically significant postoperative atelectasis, which occurs following approximately 10% of gynecologic operations. Predisposing factors that increase the incidence of atelectasis include morbid obesity, smoking, pulmonary disease, and advanced age. Increased pain, the supine position, abdominal distention, impaired function of the diaphragm, and sedation also contribute to decreased lung volumes and reduced dynamic measurements of pulmonary function postoperatively. Women with chronic lung disease often have shunting of blood in the lungs and arterial hypoxemia. A preoperative arterial blood gas may be able to demonstrate if the patient is hypoxic or hypercarbic, a serious sign, as the patient's respiratory drive may be refractory to hypercarbia. Hence, oxygen therapy for women who are morbidly obese or with symptoms of sleep apnea should be done with care, as these conditions may further suppress respiratory drive.

Asthma increases the incidence of perioperative respiratory problems approximately fourfold. Asthmatic women are susceptible to perioperative respiratory complications secondary to bronchial hyperresponsiveness, airflow obstruction, and hypersecretion of mucus. Ideally, an asthmatic woman should have elective surgery when she is free of wheezing and her pulmonary function is optimal.

Cardiovascular Disease

Cardiac complications are the leading cause of postoperative deaths. Approximately 1.5% of adults who undergo inpatient noncardiac surgery die in during the first 30 postoperative days. (Devereaux, 2015). Unstable angina of less than 3 months'

duration is a strong contraindication to an elective operation. After a myocardial infarction, it is important to delay an elective operation for approximately 6 months. The excessive mortality rate associated with a noncardiac operative procedure within 3 months of an acute myocardial infarct is 27% to 37%. Following a 6-month interval, the chance of a reinfarction is 4% to 6% with elective operations.

The accurate assessment of cardiac risk is important for several reasons. First, it permits the patient to make an informed decision when weighing the risks and benefits of the proposed surgery. Second, the accurate estimation of cardiac risk can also guide preoperative interventions and postoperative care, including the intensity of monitoring. Finally, it allows for more accurate reporting of outcomes that are linked to the intensity of comorbid conditions. There are currently two cardiac risk indexes that are commonly used: the Revised Cardiac Risk Index (RCRI) is the most validated, and the National Surgical Quality Improvement Program risk index for Myocardial Infarction and Cardiac Arrest (NSQIP MICA) has the best predictive performance (<http://www.surgicalriskcalculator.com/miocardiacarrest>). Both models assign points based on risk factors, but each defines a cardiac event a little differently, making direct comparisons difficult. For example, the RCRI assigns 1 point for each of the following: high-risk surgery; prior congestive heart failure, stroke, or transient ischemic attack; ischemic heart disease; use of insulin therapy; and creatinine level >2 mg/dL. The risk of a myocardial infarction is 0.5% with 0 points, 1.3% with 1 point, 3.6% with 2 points, and 9.1% with ≥3 points. Unfortunately, clinical risk indexes tend to underestimate risk in patients who are immobile prior to surgery, as they may lack some of the symptoms of cardiac disease simply because they are immobile. It is in this setting that noninvasive cardiac testing is used such as stress nuclear scintigraphy, which missed 30% of postoperative myocardial infarctions in one series or preoperative coronary computed tomographic angiography, which tends to overestimate cardiac risk.

One of the more common practices used to limit cardiac complications was the routine use of beta-blockers perioperatively as an attempt to blunt the sympathetic stress response. Unfortunately, the use of beta-blockers perioperatively reduced the risk of nonfatal myocardial infarction but increased the risk of death, nonfatal stroke, hypotension, and bradycardia. As a result, the common practice of perioperative beta-blockade has given way to its selective use to treat ischemia and tachycardia that can be safely and accurately identified by means of noninvasive cardiac monitoring.

PROPHYLAXIS AGAINST INFECTIVE ENDOCARDITIS

The indications for prophylactic antibiotic use for the prevention of infective endocarditis (IE) have changed considerably since the American Heart Association guidelines were first published in 1955. In the most recent version of the guidelines, the indications for prophylaxis are very limited compared with prior guidelines (Wilson, 2007). The impetus behind the change is that the risk of IE is greater from random spontaneous bacteremias associated with daily activities than from invasive gastrointestinal (GI), genitourinary (GU), or even dental procedures.

There is a lack of published data convincingly demonstrating that prophylaxis actually prevents IE. In addition, the use of prophylactic antibiotics may prevent a very small number of IEs, at the expense of more adverse antibiotic-associated events, tilting the risk-benefit scale in the wrong direction. As a result, the guidelines no longer recommend IE prophylaxis based solely on an increased lifetime risk of acquisition of IE. They restrict the use of prophylactic antibiotics only for patients who are planning invasive, higher risk procedures (Wilson, 2007). They do not recommend any prophylaxis to prevent IE for elective, noninfected genitourinary GU or GI invasive procedures. They acknowledge that there may be a very small number of IE cases, if any, that could be prevented with prophylactic antibiotics use in this patient population. However, with no proved benefit, the administration of prophylactic antibiotics solely to prevent endocarditis is not recommended for patients who undergo GU or GI tract procedures.

SUMMARY

In summary, it is the gynecologic surgeon's responsibility to ensure his or her patient is adequately informed of the risks, benefits, and alternative treatments for each recommended surgical procedure. Caring for the patient as a team by involving her primary care provider or other long-term specialty physicians to guide management of medical conditions and long-term medications that may affect the surgical procedure or anesthesia is essential. Early consultation with an anesthesiologist is important for patients with multiple comorbidities, prior anesthesia complications, or patients undergoing complex gynecologic operations, as this improves the preparation and safety of the procedure. Universal Protocol, guidelines to prevent VTE, pathways to enhance postoperative recovery, and surgical site infection prevention bundles improve the quality of gynecologic surgical care and should be used routinely.

KEY POINTS

- Optimal preparation for an operation facilitates a successful result and protects the patient and physician.
- The most significant risk factors for postoperative morbidity are preoperative conditions. They may affect the operation, anesthesia, and postoperative course and may preclude the procedure altogether.
- Approximately 0.5% of the general population and 1.5% of women older than 55 years are receiving continuous glucocorticoids.
- Latex allergy is directly responsible for 12% of the perioperative anaphylactic reactions in adult women and for 70% in children. Health care workers, women with spinal cord injuries, or those who have had to perform self-catheterization are at higher risk for latex allergy.
- The preoperative physical examination should answer three basic questions:
 - Has the primary gynecologic disease process changed since the initial diagnosis?
 - What is the effect of the primary gynecologic disease on other organ systems?
 - What deficiencies in other organ systems may affect the proposed surgery and hospitalization?
- An exam while the patient is under anesthesia may provide additional information, help avoid intraoperative surprises, and affect the surgical plan.
- It is estimated that 60% of routinely ordered tests would not have been performed if tests had been ordered only for an indication discovered by history or physical examination.
- The American Society of Anesthesiologists (ASA) Practice Advisory for Preanesthesia Evaluation states that routine preoperative tests, defined as a test ordered in the absence of a clinical indication or purpose, should not be ordered.
- A preoperative complete blood count and blood type and antibody screen should be performed prior to most gynecologic surgeries.
- Other individualized preoperative laboratory testing should be determined based on the age of the woman, extent of the surgical procedure, and findings at the time of complete history and physical examination.
- Determining the preoperative creatinine or blood urea nitrogen (BUN) level is especially important if the woman is going to be treated with antibiotics excreted by the kidneys.
- A pregnancy test may be appropriate, depending on contraceptive and sexual history, but it should almost always be performed if the patient is a teenager, as menstrual history is at best an imperfect indication of an early pregnancy.
- Serum electrolyte levels are ordered for women taking diuretics or those with a history of renal disease or heart disease. Also, serum electrolyte levels should be evaluated in women with vomiting, diarrhea, ileus, bowel obstruction, or any condition that affects electrolyte balance.
- Routine chest x-rays on all patients often do not impact perioperative management in elective gynecologic surgery, but they should be ordered for women who are 20-pack/year smokers, women with cardiac or pulmonary symptoms, immigrants who have not had a recent chest film, and women older than 70 years.
- A baseline preoperative ECG has been found to be cost effective in asymptomatic women ≥ 60 years without a history of cardiac disease or significant risk factors.
- In the present medicolegal climate, the absence of informed consent is cited as a major problem in many lawsuits.
- Preoperative orders should be standardized to avoid omissions, and electronic order sets are standard at most institutions.
- If an enhanced recovery pathway is being utilized, the patient can usually eat solid food up until midnight and clear liquids until 30 minutes prior to presenting to the hospital.
- To avoid hypoglycemia, most enhanced recovery after surgery protocols allow patients to eat solid food up to 6 hours before surgery.
- Anesthesiologists classify surgical procedures according to the patient's risk of mortality using the ASA risk class stratification (classes 1-5).

Continued

KEY POINTS—cont'd

- An emergency operation doubles the mortality risks for ASA classes 1, 2, and 3; produces a slightly increased risk in class 4; and does not change the risk in class 5.
- Enhanced recovery refers to a bundled process with the aim of attenuating pathophysiologic changes and the stress response occurring with surgery. These processes replace traditional but untested practices of perioperative care with the primary goal of hastening recovery.
- Adoption of enhanced recovery has resulted in an average reduction in length of stay of 2.5 days and a decrease in complications by as much as 50%.
- Enhanced recovery achieved the greatest benefit in patients undergoing complex cytoreduction for ovarian cancer, of whom 57% underwent colonic or small bowel resection.
- The popularity of TEA following major open gynecologic surgery is due to its effectiveness in controlling pain and the quicker return of bowel function seen in patients with epidural anesthetics.
- The role of TEA in an ERAS care plan is less clear, as it can compete at times with some of the ERAS goals and its use. TEA has been associated with more interventions to treat hypotension, longer length of hospital stay, and more complications in one series of early stage endometrial cancer patients.
- An SSI is one of the most common complications after surgery. SSIs dissatisfy patients and providers, but they also increase the cost of surgical care, increase morbidity, and can increase mortality.
- SSIs are categorized into three classifications by the CDC and the ACS NSQIP: (1) superficial incisional, (2) deep incisional, and (3) organ/space.
- Elements shown to decrease SSI that are often included in reduction bundles include preoperative nicotine cessation, preoperative antiseptic showering and chlorhexidine preparation, using hair clippers instead of a razor, appropriate preoperative antibiotic selection, normothermia, and glycemic control.
- There is abundant literature supporting the use of prophylactic antibiotics in gynecology. The incidence of febrile morbidity may be reduced from 40% to 15% and the incidence of pelvic infection decreased from 25% to 5%.
- The current guidelines for antimicrobial prophylaxis for vaginal or abdominal hysterectomy include the first- or second-generation cephalosporins of cefazolin, cefotetan, cefoxitin, or ampicillin-sulbactam.
- Among women with a β -lactam allergy, the recommended combinations are (1) clindamycin or vancomycin plus an aminoglycoside, or (2) aztreonam, or (3) a fluoroquinolone, metronidazole, and aminoglycoside, or (4) a fluoroquinolone alone.
- Comparative studies have documented that single-dose therapy is as effective as 24 hours of antibiotics. No advantage exists to continuing prophylactic antibiotics beyond the immediate operative period.
- Vaginal surgery continues to carry the lowest risks of SSI and should remain the preferred surgical approach when feasible. However, when minimally invasive approaches to hysterectomy replace laparotomy, the risk of SSI can be reduced by up to 16-fold.
- Multiple studies have documented a two- to threefold increase in the SSI rate directly related to perioperative shaving; if the hair is mechanically in the way, it should be clipped just before the operation.
- The use of chlorhexidine gluconate with 70% isopropyl alcohol as a skin preparation demonstrated a 40% reduction in SSIs in clean contaminated (type II) wound types compared with a 10% povidone-iodine solution.
- The risk of an SSI is significantly increased in the setting of smoking, and patients should be encouraged to stop as patients in a smoking cessation program had perioperative complication rates of 21% versus 41% in controls.
- Hypothermia has been shown to increase the incidence of wound infections, postoperative myocardial events, and perioperative blood loss; impair drug metabolism; and prolong postoperative recovery. Preventing intraoperative hypothermia improves surgical outcomes.
- Glucose levels >180 mg/dL among diabetics and nondiabetics increase the risk of SSI by twofold. Perioperative blood glucose levels should be maintained at <200 mg/dL for all patients.
- Category 1A evidence has demonstrated that strict glucose control (80 to 130 mg/dL) in both diabetics and nondiabetics does not improve SSI rates over glucose levels <200 mg/dL. Strict control may have detrimental effects on postoperative outcomes.
- Approximately 25% of all SSIs are caused by *Staphylococcus aureus*.
- Approximately 40% of deaths following gynecologic surgery are related to pulmonary emboli. Although the initial venous injury most often occurs at the time of the operation, approximately 15% of symptomatic emboli do not present until the first week following discharge from the hospital.
- Using the “Caprini score,” women in the very low risk group have less than a 3% risk of VTE, women in the moderate group have a 10% to 30% risk, and women in the high risk groups have a more than 30% risk of a VTE.
- LMWH is superior to standard unfractionated heparin because it has a longer half-life, almost 100% bioavailability, dose-independent clearance, and a more consistent anticoagulation effect from dose to dose.
- A meta-analysis of studies evaluating high-risk procedures found perioperative and postoperative LMWH administration to be equally effective.
- In general, warfarin should be held for at least 5 days prior to surgery and the INR should be <1.5 prior to incision.
- Therapeutic dose aspirin should be held for 7 days prior to surgery. Once-daily dosing of baby aspirin (81 mg/day) can usually be continued.
- Factor Xa inhibitors should be held for 2-3 days before surgery, depending on the individual drug's half-life. Direct thrombin inhibitors should be held for 2-4 days prior to surgery, depending on renal function.
- Patients with bleeding disorders usually present early in their lives with bleeding. It is estimated that approximately 1% to 2% of patients in the United States have some type of bleeding diathesis, the most common of which is von Willebrand disease.

KEY POINTS—cont'd

- Steroid use for longer than a 2-week period within the year prior to surgery necessitates augmented steroid administration during the perioperative period.
- Pulmonary function tests of lung volumes and flow rates are only indicated to evaluate women with a history or physical findings suggestive of restrictive or obstructive pulmonary disease.
- Predisposing factors that increase the incidence of atelectasis include morbid obesity, smoking, pulmonary disease, and advanced age. Increased pain, the supine position, abdominal distention, impaired function of the diaphragm, and sedation also contribute to decreased lung volumes and reduced dynamic measurements of pulmonary function postoperatively.
- The excessive mortality rate associated with a noncardiac operative procedure within 3 months of an acute myocardial infarct is 27% to 37%. Following a 6-month interval, the chance of a reinfarction is 4% to 6% with elective operations.
- The routine use of beta-blockers perioperatively to reduce the risk of nonfatal myocardial infarction is no longer practiced due to the increased risk of death, nonfatal stroke, hypotension, and bradycardia. As a result, the common practice of perioperative beta-blockade has given way to its selective use.
- The administration of prophylactic antibiotics solely to prevent endocarditis is no longer recommended for patients who undergo GU or GI tract procedures.

Perioperative Management of Complications

Fever, Respiratory, Cardiovascular, Thromboembolic, Urinary Tract, Gastrointestinal, Wound, and Operative Site Complications; Neurologic Injury; Psychological Sequelae

Leslie Clark, Paola Alvarez Gehrig

The goal of postoperative care is the restoration of a woman's normal physiologic and psychological health. The postoperative period includes the time from the end of the procedure in the operating room until the woman has resumed her normal routine and lifestyle.

Postoperative complications may occur at any time; however, early recognition and management will often preclude larger problems. Thus attention to postoperative details cannot be overemphasized. Complications increase the duration of the postoperative stay in the hospital. In a study of women readmitted for postoperative complications, approximately 40% had been discharged earlier than the mean length of stay for the corresponding operative procedure (Meeks, 1992). Because many procedures are now performed using minimally invasive techniques, patients will usually leave less than or close to 24 hours after surgery. Prior to discharge, it is important that the patient receive education regarding expectations, signs and symptoms of infection and other complications, and contact information.

Significant risk factors in any surgical population include underlying cardiac and pulmonary disease, smoking, obesity, prior or current abdominal/thoracic surgery, and type of anesthesia. General caveats of postoperative management emphasize attention to the particular needs of each woman. Studies conflict on whether age alone is an independent risk factor for perioperative morbidity and mortality. Older patients tend to have more underlying disease, placing them at higher risk for perioperative complications. Unfortunately, this alone does not completely account for their worse outcomes. In one large population-based study, even *healthy* elderly patients continued to have higher morbidity and mortality. It is likely that elderly patients respond differently to perioperative physiologic stressors and pharmacologic interventions. Individualization is especially important in the postoperative care of geriatric women. Special nursing attention and minimal doses of narcotics help prevent confusion and disorientation.

Ongoing verbal communications with the nursing staff help eliminate misunderstandings that might result in less than ideal postoperative care.

Surgical stress invokes several physiologic responses meant as the body's defenses. Many of these responses may be more problematic than the actual surgery. For example, some women will respond to the insulin resistance of surgical trauma with severe hyperglycemia, which is detrimental to healing. Peri- and postoperative management strategies are aimed at minimizing or preventing these adverse effects, such as prevention of thromboembolism, or selective use of beta blockade in older patients to prevent cardiac complications (Fig. 25.1) (Kehlet, 2003).

This chapter discusses major issues of management during the period from the end of surgery until the return to normal physiologic and psychological function. However, much of the data regarding postoperative complications only involve the period up through postoperative day 30. Problems and complications arise over the whole spectrum of the postoperative time frame and are interrelated. Thus the clinician must be aware at all times of a woman's changing status during recovery. For simplicity, this chapter is organized around organ systems and their potential complications.

POSTOPERATIVE FEVER

The exact definition of postoperative febrile morbidity varies greatly among authors. Diurnal fluctuations are characteristic of the normal daily body temperature patterns of humans. Most definitions use a temperature greater than 38° C 24 hours after surgery as the indicator of febrile morbidity. It is not unusual for gynecologic patients to have a mild temperature elevation during the first 72 hours of the postoperative period, especially during the late afternoon or evening. Up to 75% of patients develop a temperature greater than 37° C, which is usually not associated

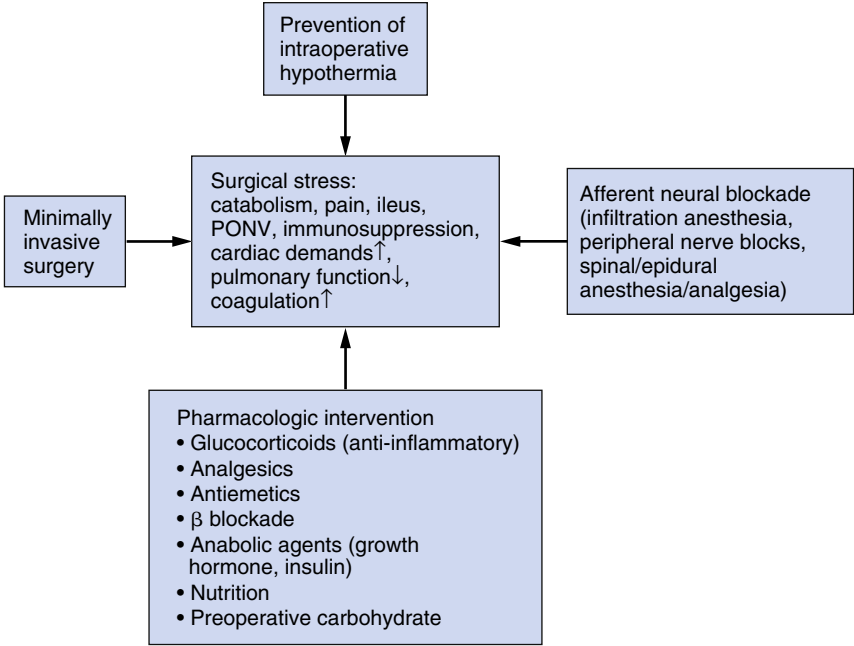

Figure 25.1 Stresses of surgery and interventions to counteract adverse responses. (Modified from Kehlet H, Dahl JB. Anaesthesia, surgery, and challenges in postoperative recovery. *Lancet*. 2003;362[9399]:1921-1928.)

with an infectious process. The incidence of postoperative febrile morbidity following benign hysterectomy ranges from 14% to 16% (Kendrick, 2008; Peipert, 2004).

Fever is the most common morbidity in the postoperative patient. Common causes of a fever include atelectasis, pneumonia, urinary tract infection (UTI), nonseptic phlebitis, wound infection, and operative site infection. Two intraoperative factors that dramatically increase the risk of postoperative fever are an operative time longer than 2 hours and the necessity for intraoperative transfusion. Increased intraoperative blood loss is associated with a 3.5 relative risk (relative risk [RR]; 95% confidence interval [CI]: 1.8-6.8) of developing a postoperative fever (Peipert, 2004).

The physician’s primary goal in examining the postoperative febrile patient is to determine the etiology of the fever. Approximately 20% of postoperative fevers are directly related to infection and 80% are related to noninfectious causes (Schey, 2005). Some conditions necessitate active intervention, whereas others are self-limiting. Thus it is imperative not to treat a postoperatively febrile patient empirically with broad-spectrum antibiotics. Protocols limiting antibiotic use to high-risk patients (bowel operation, preoperative infection, immunodeficiency, indwelling vascular access, mechanical heart valves, or intensive care unit [ICU] admission) or those with persistent fevers over 101° F for more than 48 hours have been shown to be safe (Kendrick, 2008).

The pathophysiology of postoperative fever is primarily related to the release of cytokines. The cause of a postoperative fever may be simple and common, such as atelectasis or dehydration, or unusual, such as malignant hyperthermia or septicemia. The temporal relationship of the onset of a woman’s febrile response to common postoperative complications is depicted in Table 25.1.

Table 25.1 Onset of Fever for Various Postoperative Complications

Causes	Day						1 Week or Longer
	1	2	3	4	5	6	
Atelectasis				→			
Pneumonia				→	→	→	→
Wound infection							
Streptococcal or clostridial		→					
Other bacterial							
Ovarian abscess					→		→
Cuff cellulitis						→	→
Phlebitis							
Superficial					→		→
Deep					→		→
Urinary tract infection							→
Ureteral or bladder injury							→

WORKUP FOR FEVER

The initial workup for a postoperative fever should focus on the most common problems. Medical students memorize the “five Ws” in the differential diagnosis of a postoperative fever: *w*ind (atelectasis), *w*ater (UTI), *w*ound (infection or hematoma), *w*alk (superficial or deep vein phlebitis), and *w*onder drugs (drug-induced fever). The proper workup of a postoperative fever, similar to that of any problem in medicine, involves the three classic steps of history, physical examination, and laboratory evaluations, with major emphasis placed on the physical examination. The physical examination emphasizes the following:

examination of the lungs for atelectasis and pneumonia; the wound and operative site for infection or hematoma formation; the costovertebral angles for tenderness, which may suggest pyelonephritis; and superficial veins in the arms for superficial phlebitis and deep veins in the legs for deep vein phlebitis.

The findings of the history and especially the physical examination will influence the extent of laboratory tests ordered. The three most commonly ordered laboratory tests are complete blood count, chest radiography, and urinalysis. A study by Schwandt and colleagues has emphasized that chest radiography and urine cultures are best ordered only for specific clinical signs not as reflex orders (Schwandt, 2001). Other common tests include culture and Gram stains of body fluids, including sputum, urine, and blood. One study of over 300 women who were febrile following hysterectomy did not identify a single positive blood culture, while another study found a 9.7% positive blood culture rate in over 500 patients, suggesting a role for judicious use of blood cultures (Kendrick, 2008; Schey, 2005). Women with persistent and undiagnosed fevers may need imaging studies, such as pelvic ultrasound or computed tomography (CT) to detect problems such as compromised ureters, abscesses, or foreign bodies.

Each major complication will be discussed in detail later in the chapter. However, several specific generalizations concerning the type and characteristics of fever patterns should be emphasized. Fever is a common postoperative finding and rarely is the cause of the fever a serious infection. Microatelectasis is thought to be the cause of approximately 90% of fevers occurring in the first 48 hours after operation. Patients who develop fever as a result of an indwelling catheter, such as intravenous (IV) lines or Foley catheters, are afebrile for several days and then experience an abrupt temperature spike. In contrast, wound or pelvic infections, which are usually clinically diagnosed from the fourth to seventh postoperative days, usually are associated with a low-grade fever that begins early in the postoperative period. An empiric trial of IV heparin for 72 hours is often a diagnostic and therapeutic trial for pelvic thrombophlebitis in refractory cases of postoperative fever of unknown origin.

Importantly, infection in the older woman will not always present with classic findings. The amount of temperature elevation may not reflect the severity of the infection. Not uncommonly, the first signs of infection in older adults will be mental status changes. Additionally, the degree of leukocytosis, being blunted or absent may not reflect infection.

A woman with a drug-induced fever feels better and does not look as ill as her temperature course indicates. The tachycardia associated with the elevated temperature is usually much less than usually anticipated with a similar temperature elevation secondary to inflammation or infection. The presence of eosinophilia suggests a drug-induced fever. However, drug fever is rare and is usually a diagnosis of exclusion. Presumptive evidence of a drug-induced fever is established when the fever disappears after discontinuation of the drug. The most commonly implicated drugs include allopurinol, carbamazepine, lamotrigine, phenytoin, sulfasalazine, vancomycin, minocycline, dapsone, and sulfamethoxazole. The risk of developing a drug-induced fever is higher in elderly and HIV-infected patients.

Superficial thrombophlebitis often produces an enigmatic fever. Often, there is tenderness at the IV site. IV catheters should be removed at the first sign of tenderness or erythema,

but routine replacement to prevent thrombophlebitis is not indicated (Webster, 2013). Transfusion reactions can also cause febrile events. Leukocyte or platelet antibodies usually cause these reactions. As long as a major blood type incompatibility is not found, treatment is usually conservative.

It is common practice to repeat the basic fever workup at regular intervals until the diagnosis is established. The woman should be reexamined and selective laboratory tests reordered. Rare causes of postoperative fever include pulmonary embolism (PE), thyroid storm, and malignant neoplasms. These diagnoses usually present with other signs and symptoms as well as temperature elevation. It is important to consider that fever is a potentially beneficial physiologic response of the patient. Therefore unless the woman is symptomatic secondary to the elevated temperature, it is not necessary to order antipyretic medications. Cellular damage usually occurs when the core temperature exceeds 41° C. Active cutaneous cooling does not reduce core temperature effectively and may have undesirable effects, such as increasing the metabolic rate and activating the autonomic nervous system.

MANAGEMENT OF FALLING HEMOGLOBIN

Bleeding is one of the most worrisome postoperative complications. Significant arterial bleeding in the first 24 hours often necessitates reoperation. This complication is discussed later in the chapter, along with the management of shock and pelvic hematoma.

Vital signs should be ordered at frequent intervals during the first 24 hours to detect hypovolemia. Most institutions have standard postoperative monitoring floor orders of at least every 4 hours. Most women will have sufficient intravascular volume to compensate (during the early phases of hemorrhage) through the redistribution of blood flow from less vital to more vital organs. As a result, low urine output may be the earliest sign of a decrease in intravascular volume. Thus following an operation, sizable amounts of unrecognized intraperitoneal or retroperitoneal bleeding are sometimes present without the woman having subjective symptoms or appreciable changes in her vital signs. This may be the case particularly in young, healthy women. Minimum urine output should be 0.5 mL/kg/hr. A consistent orthostatic decrease in blood pressure of more than 10 mm Hg may indicate a decrease of 20% of the blood volume. Thus measuring hemoglobin at two intervals during the postoperative course is helpful. Hemoglobin drawn 24 hours following an operation may not truly reflect postoperative blood loss, thus a repeat hemoglobin measurement could be evaluated at 48 to 72 hours postoperatively to identify the nadir if indicated.

The normal physiologic response to the stress of the operation and tissue destruction is a release of increased levels of aldosterone, cortisol, and antidiuretic hormone (ADH). The higher levels of aldosterone produce an increase in sodium and water retention, whereas increased levels of ADH promote free water retention. This has been called the *ebb phase* of postoperative physiology. It is common for women to have notable lower extremity edema for the first few postoperative days, because they are often given significant amounts of IV fluids. Depending on the type and amount of intraoperative and postoperative IV fluids, the hemoglobin on the first postoperative day may be

Figure 25.2 Graphic illustration of lung volumes and capacities. (From Wellman JJ. Respiratory care in the surgical patient. In: Lubin MF, Walker HD, Smith RB, eds. *Medical Management of the Surgical Patient*. Stoneham, MA: Butterworth; 1982.)

misleading and reflect fluid changes rather than intraoperative or postoperative hemorrhage. The hemoglobin from the third postoperative day is a more accurate measurement of postoperative change. If the patient is doing well, stress hormone levels decline, and water retention stops, the patient will begin to experience a brisk diuresis beginning around the third postoperative day. Hemoglobin samples should be obtained in a standard fashion to eliminate sampling errors. For example, samples drawn from central lines or during blood gas determinations often give false values because of the heparin or saline flush solutions.

After the effects of the operative blood loss are subtracted from the preoperative hemoglobin, each further reduction in hemoglobin of 1 to 2 points reflects a postoperative hemorrhage of approximately 250 to 500 mL. The safe level of postoperative anemia is a controversial issue. Historically, patients were transfused to maintain hemoglobins greater than 10, but mounting evidence supported the role of individualized treatment in consideration for transfusion. In hemodynamically stable patients a hemoglobin of <7 is usually an indication for transfusion. Postoperative patients with a hemoglobin of 7 to 8 should be considered for transfusion if cardiovascular disease is present. In a patient with a hemoglobin of 8 to 10 transfusion is not indicated unless symptomatic anemia, ongoing bleeding, or concern for acute coronary syndrome is noted (Klein, 2007). The morbidity and mortality associated with a surgical procedure are directly related to the amount of intraoperative and postoperative blood loss and not the corresponding level of preoperative anemia.

RESPIRATORY COMPLICATIONS

Alterations of pulmonary function are an expected physiologic change in women having general anesthesia and operations that enter the peritoneal cavity. Of importance, respiratory

complications contribute to up to 25% of deaths in women who die during the first 7 postoperative days. Respiratory problems may arise secondary to inadequate ventilation by women as they try to minimize acute pain from the operative incision.

ATELECTASIS

The term *atelectasis* is derived from two Greek words that mean “imperfect expansion.” The severity of atelectasis ranges from lack of expansion of a small group of terminal bronchioles and alveoli to complete collapse of a lung. In most patients, atelectasis is the failure to maintain patency of the small pulmonary airways and alveoli. Atelectasis is the most common cause of postoperative temperature elevations. Studies have demonstrated that there is no association between fever and the amount of atelectasis seen radiographically. The incidence of atelectasis depends on the number of predisposing risk factors and the vigor with which the clinical diagnosis is established.

Of all postoperative respiratory complications, 90% are related to atelectasis. The immediate postoperative period is characterized by a decrease in functional residual capacity and lung compliance (Fig. 25.2). Thus the work of breathing is increased. Micro atelectasis is most common when small airways (<1 mm in diameter) become blocked by secretions. When small airways remain closed by a combination of mucous plugs and bronchospasm, the gas distal to the obstruction is absorbed. This process results in atelectasis. These changes occur during the first 72 hours following an operation. When atelectasis becomes progressive and involves a large area of lung tissue, there is an associated decrease in oxygen saturation and a decrease in arterial oxygen pressure (PO_2). This is associated with a normal to low arterial carbon dioxide pressure (PCO_2).

Pulmonary and nonpulmonary factors that favor premature airway closure and development of atelectasis are listed in

Box 25.1 Nonpulmonary and Pulmonary Factors Favoring Premature Airway Closure and Atelectasis

Nonpulmonary Factors

Supine position
Obesity
Increased abdominal girth (ileus, pneumoperitoneum)
Breathing at low lung volumes
 Bindings around the chest and abdomen
 Incisional pain
 Sedative narcotic drugs
 Prolonged effect of paralyzing drugs
 Immobility
 Excessively high concentrations of oxygen for prolonged periods

Pulmonary Factors

Interstitial edema
Loss of surfactant with air space instability
Airway obstruction
 Inflammatory with swelling of bronchial and interbronchial tissue
 Constriction of bronchial smooth muscle
 Retained secretions

From Wellman JJ. Respiratory care in the surgical patient. In: Lubin MF, Walker HK, Smith RB, eds. *Medical Management of the Surgical Patient*. Stoneham, MA: Butterworth; 1982.

Box 25.1. The supine position decreases the functional residual capacity by approximately 20% compared with the erect position. Obesity, smoking, age older than 60 years, prolonged operative time, presence of a nasogastric tube, and coexisting medical conditions, such as cardiac or lung disease and pulmonary infection, all predispose women to atelectasis. Insufflation of the abdomen for laparoscopic and robotic surgery also contributes to postoperative atelectasis by collapsing the dependent portion of the lung bases if adequate ventilation pressures are not used.

In normal breathing, periodic, involuntary, deep inspirations help expand all areas of the lung. Incisional pain, the supine position, narcotics, and abdominal distention contribute to a pattern of monotonous shallow breathing without spontaneous deep sighs in the postoperative period. As a result of the incisional pain, chest wall breathing dominates over abdominal breathing. The resultant decrease in the movement of the diaphragm contributes to the development of atelectasis. A further decrease in functional residual capacity, a decrease in surfactant, and a depression of mucociliary transport, all contribute to ventilation-perfusion (\dot{V}/\dot{Q}) mismatches and reduced \dot{V}/\dot{Q} ratios. The results are gas trapping, atelectasis, and vascular shunting. In most individuals, microatelectasis is patchy and localized to small areas. However, the severity of atelectasis varies and may involve a complete lung. Distribution of pulmonary blood flow is influenced by gravity. A greater proportion of pulmonary blood flows to dependent areas of the lungs in the supine patient. This increased blood flow, combined with the atelectasis in dependent areas, results in an increased impairment of oxygenation, as well as a decrease in the elimination of carbon dioxide. Obese patients, in general, should be kept slightly upright, not prone, for the first 24 hours to improve vital capacity and ventilation, thus decreasing atelectasis.

Atelectasis may present as the classic triad of fever, tachypnea, and tachycardia developing within the first 72 hours following

an operation. On physical examination, tubular breathing, decreased breath sounds, and moist inspiratory rales may be heard. These findings are most prominent over the bases of the lung. If the condition progresses, an increase in productive cough and leukocytosis results. Chest radiographic films may demonstrate a patchy infiltrate with elevations of the diaphragm.

Atelectasis usually resolves spontaneously by the third to fifth postoperative day. Nevertheless, major efforts are made to prevent atelectasis, especially in high-risk individuals. The foundations of prevention of atelectasis are the encouragement of uneven ventilation and the production of episodes of prolonged inspiration to increase functional residual capacity. Thus the patient is encouraged to walk, take deep breaths, cough, turn from side to side, remain semierect rather than supine, and use the incentive spirometer regularly. Early mobilization and ambulation have been documented to be as effective as chest physical therapy in the prevention of pulmonary complications. Keeping pain relief to a level at which the woman will be able to cooperate and not have monotonous shallow breathing is also helpful. Although the use of neither postoperative continuous positive airway pressure (CPAP) nor incentive spirometry has been shown to reduce postoperative pulmonary morbidity, simple bedside incentive spirometry can be used to prevent and reverse atelectasis (Nascimento, 2014; Ireland, 2014). Many women need encouragement by the hospital staff to use these devices effectively. The primary risk of atelectasis is progression to pneumonia.

PNEUMONIA

Postoperative pneumonia is commonly associated with atelectasis because bacterial infections often begin in collapsed areas of the lungs. Predisposing factors to the development of pneumonia include chronic pulmonary disease, heavy cigarette smoking, alcohol abuse, obesity, advanced age, nasogastric tubes, long operative procedures, gram-negative bacterial infections, postoperative peritonitis, and debilitating illnesses.

The symptoms and signs of pneumonia are fever, cough, dyspnea, tachypnea, and purulent sputum. When pain occurs, it may be felt in the back or chest. The classic physical finding of pneumonia is coarse rales over the infected area. The patient usually has a higher temperature and more systemic toxicity than a woman with atelectasis. Leukocytosis is pronounced in most patients, although it may be delayed or attenuated in older women. Chest radiographs often demonstrate diffuse patchy infiltrates of the lung. Radiographic diagnoses are approximately 60% accurate for bacterial or viral pneumonia in women with laboratory-proved pneumonia. Gram staining of the sputum helps differentiate between bacterial colonization and infection. In cases of pneumonia, the smear contains a large number of inflammatory cells with both intracellular and extracellular bacteria.

The management of pneumonia is similar to the management of atelectasis, with the addition of parenteral antibiotics. Antibiotic choice is based on the type of pneumonia diagnosed. Most postoperative patients will fall into one of the following categories: hospital-acquired pneumonia (HAP) occurring 48 hours or more after hospital admission, ventilator-acquired pneumonia (VAP) developing 48 to 72 hours after endotracheal intubation, or health care-associated pneumonia (HCAP) occurring in a nonhospitalized patient with extensive health care contact. HCAP was

added as a category in 2005, as individuals with extensive health care contact are at an increased risk for developing pneumonia with multidrug resistant bacteria. Patients meet the definition of HCAP if they are not hospitalized, develop pneumonia, and have one of the following: IV therapy, wound care, or IV chemotherapy in the prior 30 days; reside in a nursing facility or long-term care facility or have been hospitalized for 2 or more days in the past 90 days; or attended a hospital or hemodialysis clinic in the prior 30 days. Most patients with HAP, HCAP, and VAP who do not have significant risk factors for multidrug resistance and can be treated with empiric antibiotics using one of the following regimens: (1) ceftriaxone 2 gm IV daily, (2) ampicillin-sulbactam 3 gm IV every 6 hours, (3) levofloxacin or moxifloxacin 750 mg IV daily or 400 mg IV daily, or (4) ertapenem 1 gm IV daily. However, in the setting of risk factors for multidrug resistance (antibiotics in the past 90 days, current hospitalization >5 days, high frequency of resistance in the community or hospital unit, immunosuppression due to therapy or disease), one should choose one of the following: (1) an antipseudomonal cephalosporin (such as cefepime 2 gm IV every 8 hours or ceftazidime 2 gm IV every 8 hours), (2) an antipseudomonal carbapenem (such as meropenem 1 gm IV every 8 hours or imipenem 500-1000 mg every 6 hours), or (3) piperacillin-tazobactam 4.5 gm IV every 6 hours. In patients with severe penicillin allergies who cannot have these regimens, aztreonam 2 gm IV every 6 to 8 hours should be used. In addition, the provider should add either an antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin) or aminoglycoside (gentamycin, tobramycin, or amikacin). Finally, methicillin-resistant *Staphylococcus aureus* (MRSA) coverage should be provided with linezolid (600 mg every 12 hours), vancomycin (15 to 20 mg/kg IV every 8 to 12 hours), or telavancin (10 mg/kg IV every 24 hours).

Postoperative patients can also develop aspiration pneumonia due to loss of protective airway reflexes during intubation and extubation, or related to postoperative nausea and vomiting. The most common pathogens in aspiration pneumonia are upper airway pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus aureus*, and gram-negative rods. Aspiration pneumonia is best treated with clindamycin 600 mg IV every 8 hours, followed by 300 mg PO four times daily or 450 mg PO three times daily. Alternative regimens include amoxicillin-clavulanate 875 mg twice daily or amoxicillin 500 mg three times daily with metronidazole 500 mg three times daily.

Approximately 1 in 3000 surgical procedures are complicated by aspiration pneumonitis produced by the aspiration of gastric fluid (sterile and highly acidic). The aspiration produces a severe chemical pneumonitis. Aspiration and its complications are a cause of approximately 30% of anesthetic mortalities. Risk factors for aspiration pneumonia include older age, obesity, hiatal hernia, or emergency surgery associated with a full stomach. The morbidity from aspiration is secondary to both particulate matter entering into the lungs and the caustic nature of gastric acid. The combination of these insults leads to a destructive inflammatory response. When aspiration is significant and severe, adult respiratory distress syndrome often develops. Secondary infection usually complicates aspiration pneumonitis, and broad-spectrum antibiotics should be given when this diagnosis is entertained. Preventive measures include early removal of nasogastric suction, antacid ingestion, and H₂ blockers in the perioperative period, as well as careful use of narcotics and sedatives.

SLEEP APNEA

Sleep apnea has become a significant concern because of the rising incidence of obesity and morbid obesity in the United States. The increased soft tissues of the head and neck can lead to airway compromise that leads to intermittent apnea and hypoventilation while a woman sleeps. The increased weight of the extra adipose tissue on the neck, chest, and abdominal wall lead to a decrease in pulmonary compliance. As a result, the relative hypoxia may induce systemic as well as pulmonary hypertension. Patients may also develop chronic hypercapnia as the respiratory drive shifts from a CO₂-driven response to a hypoxia-driven response in patients with sleep apnea. It is important to note that when morbidly obese patients are given higher levels of oxygen, as well as narcotics, they are at increased risk for apnea. These patients develop an increased sensitivity to narcotics that shuts down the respiratory drive. Patients with chronic hypoxia from any cause will often have an increased sensitivity to narcotics, but it is particularly problematic in the obese patient who is dependent on low levels of oxygen for respiratory stimulation. These patients should be given oxygen as needed. However, during the postoperative period, when narcotics are given, the goal should be to keep the oxygen saturation in the 94% range. At saturation levels of 96% to 99% these patients may lose respiratory drive and become hypercarbic and acidotic (Ahmad, 2008).

Preoperatively patients who are thought to be at risk for sleep apnea may be queried by asking them the "STOP-BANG" questions. These eight questions can predict sleep apnea with a high degree of sensitivity. The questions include the following: Do you snore? Do you often feel tired? Has anyone observed you stop breathing? Are you being treated for high blood pressure? Is your body mass index >35? Are you older than age 50? Is your neck size >16 inches for a woman? Gender-male? A "yes" answer to zero to two questions implies that one is low risk for obstructive sleep apnea (OSA); three to four "yes" answers places one at intermediate risk for OSA; six to eight "yes" answers places one at high risk for OSA (Chung, 2008).

CARDIOVASCULAR PROBLEMS

HEMORRHAGIC SHOCK

Shock is defined as a condition in which circulatory insufficiency prevents adequate vascular perfusion of vital organs. Systemic hypotension results in poor tissue perfusion and reduced capillary filling. If this pathophysiologic state is neglected, prolonged hypotension results in oliguria, progressive metabolic acidosis, and multiple organ failure. Shock may be produced by hemorrhage, cardiac failure, sepsis, and anaphylactic reactions. Hypovolemic shock is the most common cause of acute circulatory failure in gynecologic patients. Cardiogenic shock and septic shock are less common. Shock from postoperative hemorrhage is usually seen in the first several hours following surgery. In the perioperative period, hypovolemia may be secondary to several factors, including preoperative volume deficiency, under-replaced blood loss during surgery, extracellular fluid loss during surgery, inadequate fluid replacement and, most commonly, continued blood loss following the surgical procedure. Tachycardia is the classic cardiovascular physiologic response to hypotension. Progressive hypovolemia results in diminished urine output.

The majority of perioperative cases of shock are related to hemorrhage secondary to inadequate hemostasis. The development of shock from acute blood loss depends on the rate of bleeding; for example, slow venous oozing may produce a large amount of blood loss but not produce shock. Rapid loss of 20% of a woman's blood volume produces mild shock, whereas a loss of greater than 40% of blood volume results in severe shock. Even with the extensive use of suction equipment, the actual measurement of intraoperative blood loss is imprecise. Massive blood loss has been defined as hemorrhage that results in replacement of 50% of the circulating blood volume in less than 3 hours.

Hypotension in the immediate postoperative period may be secondary to the residual effects of anesthesia or over sedation. For example, older patients often experience prolonged vasodilation secondary to the sympathetic blockade produced by epidural or spinal anesthesia. The most common cause of postoperative bleeding is a less than ideal ligature or hemorrhage from a vessel that has retracted during the operation. Bleeding may come from an isolated artery or vein or may be more generalized when the bleeding is secondary to a clotting abnormality. The differential diagnosis of postoperative hemorrhagic shock includes conditions such as pneumothorax, PE, massive pulmonary aspiration, myocardial infarction, and acute gastric dilation. However, in the postoperative period the index of suspicion would be highest for bleeding.

The differential diagnosis of ineffective coagulation includes sepsis, fibrinolysis, diffuse intravascular coagulation, and a previously unrecognized coagulation defect, such as von Willebrand disease. Coagulopathies can also develop from excessive transfusion and dilution of fibrinogen and other clotting factors. The progressive acidosis associated with shock increases hemostatic problems by interfering with assembly of coagulation factor complexes. Hypothermia further complicates hemostasis because it produces platelet dysfunction and coagulopathy secondary to decreased activity of thromboxanes. Thrombocytopenia, impaired platelet function, and a decrease in factors V, VIII, and XI commonly occur with massive transfusions, of more than 5 units of packed red blood cells (PRBCs). Hypofibrinogenemia is the first to develop, followed by deficiencies of other coagulation factors. Thrombocytopenia is frequently the last defect to be recognized in the coagulopathy cascade. However, the timing of its development varies among individuals. Thus transfusion of platelets should be determined by serial platelet counts (Box 25.2). Similarly, preset formulas for the transfusion of fresh-frozen plasma (FFP), such as 2 units of FFP for every 5 units of PRBCs, should be replaced by selective transfusion of plasma as needed to match a clotting deficiency as measured by the prothrombin time (PT) and activated partial thromboplastin time (aPTT). Each unit of FFP can be expected to raise increase clotting protein levels by 2.5% to 10%.

Two early signs of hypovolemia caused by hidden internal bleeding include tachycardia and decreased urine output. The body's adrenergic response to hemorrhage includes perspiration, tachycardia, and peripheral vasoconstriction. Urine output decreases to less than 0.5 mL/kg/hr (20 to 25 mL/hr) as a result of poor perfusion of the kidneys. With further loss of blood, agitation, weakness, and skin pallor can appear, the extremities may feel cold and clammy, and, ultimately, systolic blood pressure drops below 80 mm Hg. Again, because of adaptive cardiovascular changes, it takes a rapid loss of approximately one third of the blood volume to produce significant hypotension.

Box 25.2 Suggested Transfusion Guidelines for Platelets

- Recent (within 24 hr) platelet count $<10,000/\text{mm}^3$ (for prophylaxis)
- Recent (within 24 hr) platelet count $<50,000/\text{mm}^3$ with demonstrated microvascular bleeding (oozing) or a planned surgical/invasive procedure
- Demonstrated microvascular bleeding and a precipitous fall in platelet count
- Adult patients in the operating room who have had complicated procedures or have required more than 10 units of blood *and* have microvascular bleeding. Giving platelets assumes that adequate surgical hemostasis has been achieved.
- Documented platelet dysfunction (e.g., prolonged bleeding time >15 min, abnormal platelet function tests) with petechiae, purpura, microvascular bleeding (oozing), or surgical or invasive procedure
- Unwarranted indications:
 - Empirical use with massive transfusion when patient is not having clinically evident microvascular bleeding (oozing)
 - Prophylaxis in thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, or idiopathic thrombocytopenic purpura
 - Extrinsic platelet dysfunction (e.g., renal failure, von Willebrand disease)

From Rutherford EJ, Skeet DA, Schooler WG. Hematologic principles in surgery. In: Townsend CM, Beauchamp RD, Evers BM, eds. *Sabiston Textbook of Surgery*. 17th ed. Philadelphia, Saunders; 2004.

Box 25.3 Management Priorities in Massive Transfusion

- Restore circulating blood volume.
- Maintain oxygenation.
- Correct coagulopathy.
- Maintain body temperature.
- Correct biochemical abnormalities.
- Prevent pulmonary and other organ dysfunction.
- Treat underlying cause of hemorrhage.

From Donaldson MDJ, Seaman MJ, Park GR. Massive blood transfusion. *Br J Anaesth*. 1992;69(6):621-630.

*The exact priority depends on the circumstances.

Postoperatively, occult intraperitoneal and retroperitoneal bleeding often occurs without significant local symptoms. Extraperitoneal bleeding may present as bleeding from the vaginal cuff. Abdominal distention, muscle rigidity, and shoulder pain are late signs of intraperitoneal hemorrhage. The diagnosis of clinically significant postoperative bleeding may be confirmed by serial changes in hemoglobin levels. However, it is important to caution that marked changes in hematocrit and hemoglobin levels require time to develop. Imaging studies may demonstrate hematomas or increased intraperitoneal free fluid.

The management goals of postoperative shock are to replace, restore, and maintain the effective circulating blood volume and establish normal cellular perfusion and oxygenation (Box 25.3). To accomplish this goal, an adequate cardiac output and appropriate peripheral vascular resistance must be maintained. The first priority is to provide adequate ventilation because poor respiratory gas exchange is the most frequent cause of death in these patients. The second, almost simultaneous, priority is rapid fluid replacement with adequate amounts of blood and crystalloid solution (normal saline or lactated Ringer solution). The 3:1 rule suggests a ratio of 3 mL of crystalloid solution for every 1

mL of blood loss. The optimal fluid replacement is a fluid evenly distributed throughout multiple body compartments. Randomized trials of crystalloid and colloid resuscitation solutions have shown no clear survival benefit to the use of colloids (albumin, gelatin, dextran, and hydroxyethyl starch), but a reduced rate of tissue edema, abdominal compartment syndrome, and hyperchloremic metabolic acidosis is demonstrated. The substantial cost of these agents should be weighed against potential benefits (Bougle, 2013). Crystalloids should be considered the initial resuscitation fluid of choice in hemorrhagic shock; colloids are appropriate for resuscitation in conjunction with crystalloids when blood products are not immediately available. Guidelines for transfusion of PRBCs are listed in Box 25.4.

Box 25.4 Suggested Transfusion Guidelines for Red Blood Cells

Hemoglobin <8 g/dL or acute blood loss in an otherwise healthy patient with signs and symptoms of decreased oxygen delivery with two or more of the following:

- Estimated or anticipated acute blood loss of >15% of total blood volume (750 mL in 70-kg man)
- Diastolic blood pressure <60 mm Hg
- Systolic blood pressure drop >30 mm Hg from baseline
- Tachycardia (>100 beats/min)
- Oliguria, anuria
- Mental status changes

Hemoglobin <10 g/dL in patients with known increased risk of coronary artery disease or pulmonary insufficiency who have sustained or are expected to sustain significant blood loss

Symptomatic anemia with any of the following:

- Tachycardia (>100 beats/min)
- Mental status changes
- Evidence of myocardial ischemia, including angina
- Shortness of breath or dizziness with mild exertion
- Orthostatic hypotension

Unfounded or questionable indications:

- To increase wound healing
- To improve the patient's sense of well-being
- 7 g/dL < hemoglobin < 10 g/dL (or 21% < hematocrit < 30%) in otherwise stable, asymptomatic patient
- Mere availability of predesignated autologous blood without medical indication

From Rutherford EJ, Skeet DA, Schooler WG. Hematologic principles in surgery. In: Townsend CM, Beauchamp RD, Evers BM, eds. *Sabiston Textbook of Surgery*. 17th ed. Philadelphia: Saunders; 2004.

The goals of fluid replacement are to obtain and maintain a systolic blood pressure that is similar to preoperative readings and maintain urine output greater than 0.5 mL/kg/hr (usually, >30 mL/hr). Table 25.2 lists types of blood components used for replacement therapy. Traditionally in massive hemorrhage replacement a ratio of 2 units of packed red blood cells to 1 unit of fresh-frozen plasma is desirable, but resuscitation should be tailored to the clinical scenario. For every 6 units of packed red blood cells, a six-pack of platelets may be required. Each unit or pack of platelets will raise the platelet level by 15,000/mm³. The platelet count should be maintained above 50,000/mm³ in a woman who is bleeding (Stronckek, 2007). The importance of adequate transfusion is not only support of intravascular volume but also supply of oxygen.

Coagulation studies, prothrombin time, and activated prothrombin time should be obtained regularly during the bleeding episode. The term *washout* is used to describe the loss of clotting factors as a woman uses up her blood volume and is replaced with PRBCs and crystalloid. Disseminated intravascular coagulation (DIC) is an intravascular consumption and is different than washout. However, both conditions require replacement and ongoing evaluation. Importantly, with continued severe bleeding, the use of recombinant factor VIIa (70 to 90 µg/kg) should be considered. Although expensive, factor VIIa initiates a rapid burst of thrombin production and stimulates the entire clotting cascade. Many studies have shown it to be very effective in situations of continued bleeding from small vessels (Bougle, 2013).

The decision to return to the operating room to control hemorrhage is commonly difficult to make as the offending artery or vein is often unable to be identified at the time of reoperation. Additionally, friable inflamed postoperative tissues can result in further bleeding. If ongoing postoperative bleeding requires reoperation, this decision should not be postponed. It should be performed expediently after volume replacement and sometimes concomitantly. During this second operation, excellent anesthesia, a full selection of surgical instruments, and the value of good assistance cannot be overemphasized. Proper exposure is paramount for the success of this operation. Initially the old clots are removed and further bleeding is reduced by direct pressure over the presumed bleeding vessels while a systematic search is conducted in an effort to identify the individual vessels that are bleeding.

Bilateral ligation of the anterior divisions of the hypogastric arteries distal to the posterior parietal branch is an effective

Table 25.2 Indications for Administration of Various Blood Products

Product	Content	INDICATION	
		Acceptable	Unacceptable
Red blood cells	Red cells	To increase oxygen-carrying capacity in anemic women; for orthostatic hypotension secondary to blood loss	For volume expansion; to enhance wound healing; to improve general well-being
Platelet concentrates	Platelets	To control or prevent bleeding associated with deficiencies in platelet number or function	In patients with immune thrombocytopenic purpura (unless bleeding is life-threatening)
Fresh-frozen plasma	Plasma, clotting factors	To increase the level of clotting factors in patients with demonstrated deficiency	For volume expansion; as a nutritional supplement; prophylactically with massive blood transfusion
Cryoprecipitate	Factors I, V, VIII, XIII, von Willebrand factor, fibronectin	To increase the level of clotting factors in patients with demonstrated deficiency of fibrinogen, factor VIII, factor XIII, fibronectin, or von Willebrand factor	Prophylactically with massive blood transfusion

From American Congress of Obstetricians and Gynecologists. *ACOG Tech Bull*. 1994;199:1.

operation to control persistent postoperative pelvic hemorrhage. This procedure results in a reduction of pulse pressure, which allows a stable clot to form at the site where the pelvic vessels are injured. Classically, two ligatures are placed and tied around each hypogastric artery (Fig. 25.3). The major potential complication of this procedure is injury to the hypogastric vein. If there is generalized oozing, thrombocytopenia, DIC, or factor VIII deficiency should be suspected. If these conditions are excluded, venous oozing from small vessels in the pelvis may be controlled by the local application of microfibrillar collagen compounds (e.g., Avitene, Gelfoam, FloSeal).

Intraoperative rapid autologous blood transfusion is a technique that is used extensively in cardiovascular and trauma surgery. Regrettably, it is underused or rarely performed by

Figure 25.3 Ligation of internal iliac artery. Double loop is being directed toward bifurcation of common iliac artery. (From Breen JL, Gregori CA, Kindzierski JA. Hemorrhage in gynecologic surgery. In: Shaefer G, Graber EA, eds. *Complications in Obstetric and Gynecologic Surgery*. Hagerstown, MD: Harper & Row, 1981.)

gynecologists. The major complication of rapid autologous transfusion is a 10% hemolysis rate. The risks of air embolism or infusion of particulate matter are minimal. Obviously, autologous blood does not contain platelets or clotting factors, so platelets and fresh-frozen plasma will have to be given concurrently for severe hemorrhage. Rapid autologous transfusion is contraindicated in advanced pelvic infection or malignancy.

In many cases, angiographic embolization, instead of exploratory laparotomy, is preferable (Fig. 25.4). Introduction of digital road mapping technology has improved the rapid identification of bleeding vessels. Similarly, treatment of recurrent postoperative hemorrhage or hemorrhage late in the postoperative course (7 to 14 days) may be performed with angiographic arterial embolization. Absorbable gelatin sponges, which produce vascular occlusion for 10 to 30 days, or metal coils with Dacron fibers, which produce permanent occlusion, may be used.

HEMATOMAS

This section describes the management of wounds or pelvic hematomas that develop slowly and are diagnosed after the first postoperative day. Proper management of postoperative hematomas is challenging and controversial. The incidence of hematomas is inversely related to the extent to which meticulous hemostasis is obtained intraoperatively. Women who are given low-dose heparin or who take aspirin chronically are at a slightly higher risk of hematoma formation. Women on antiplatelet medication or anticoagulation are also at risk. Hematomas result from intermittent or slow, continuous venous bleeding and are almost always self-limiting. Eventually, the pressure of the expanding hematoma will exceed the venous pressure and a stable clot will form.

The extent of the hematoma is determined partially by the potential size of the compartment into which the bleeding occurs. Retroperitoneal, or broad ligament, hematomas may

Figure 25.4 **A**, Anteroposterior digital subtraction pelvic angiogram in 37-year-old woman with persistent pelvic bleeding after surgical myomectomy for uterine leiomyomas demonstrates contrast pooling (arrows) from branches of left uterine artery, consistent with active hemorrhage. **B**, Postembolization left uterine arteriogram shows occluded left uterine artery (long arrows) with no evidence of active bleeding. (From Vedantham S, Goodwin SC, McLucas B, et al. Uterine artery embolization: an underused method of controlling pelvic hemorrhage. *Am J Obstet Gynecol*. 1997;176[4]:938-948.)

contain several units of blood. The diagnosis of a wound, or pelvic, hematoma is usually suspected when the patient's hemoglobin on postoperative day 3 is unexpectedly low. The woman may have mild to moderate tenderness over the affected area. By the fifth postoperative day, the hematoma liquefies and may be easier to outline during bimanual examination. Distinguishing between an uninfected hematoma and a hematoma that has become secondarily infected is difficult before incision and drainage. Both clinical situations produce tenderness and fever secondary to the inflammation surrounding the hematoma. The diagnosis of a retroperitoneal hematoma may be made by physical examination; most helpful is a careful rectovaginal examination. However, radiologic imaging studies are indicated when a hematoma is suspected and cannot be palpated. Imaging is commonly used to make the diagnosis of a postoperative hematoma.

Hematomas smaller than 5 cm in diameter may be treated conservatively. Larger hematomas may be drained transcutaneously with CT or ultrasound guidance. If not treated, most large hematomas will become secondarily infected, even if treated with parenteral antibiotics. Effective drainage of most pelvic and broad ligament hematomas usually can be accomplished vaginally or radiographically. Small subcutaneous hematomas or fascial hematomas usually resolve. However, they are associated with an increased incidence of wound infection and pain.

RETAINED FOREIGN BODY

With any operation there is the potential risk of an unrecognized retained foreign body, sponge, or laparotomy pad. The exact incidence of this worrisome complication is difficult to establish but is estimated to be from 1 in 1200 to 1500 laparotomies, typically with correct sponge counts at the time of surgery. When this complication is discovered during the first postoperative week, the woman usually has a tender pelvic mass that is infected. When this mass is discovered after the immediate postoperative course, patients are often asymptomatic or exhibit minimal tenderness. The possibility of a retained foreign body should be considered in the differential diagnosis of pelvic hematomas and abscesses. A retrospective study of retained sponges by Gawande and associates noted that retained foreign bodies are more commonly associated with a higher body mass index (BMI), emergency surgeries, and an intraoperative change in the type of procedure to be performed (Gawande, 2003).

THROMBOPHLEBITIS AND PULMONARY EMBOLUS

Surgery is a time of hypercoagulability secondary to the stress response. As such, the surgeon must be aware of the potential complications of thromboembolism throughout the postoperative course. Prophylaxis against deep vein thrombosis (DVT) is discussed in [Chapter 24](#). However, prophylaxis must be continued throughout the hospital stay and, in certain high-risk cases, even after discharge. For example, patients with malignancy who undergo laparotomy, patients with previous blood clot or personal history of thrombophilia, and those who will have decreased ambulation may benefit from up to 4 weeks of low-molecular-weight heparin (LMWH) after leaving the hospital. Studies in patients with hip replacements and with abdominal pelvic malignancies have shown significant reductions (50% to

66%) in the incidence of DVT with prolonged anticoagulation, up to 4 weeks postoperatively. Currently, there is insufficient evidence to make recommendations for prolonged thromboprophylaxis for routine gynecology patients, except in high-risk situations such as gynecologic cancer surgery (Guyatt, 2012). There is a reduced risk of venous thromboembolism (VTE) with minimally invasive hysterectomy compared with abdominal hysterectomy. Without specific guidelines, the length of time for thromboprophylaxis should be individualized. Prophylaxis will not prevent all DVTs; thus part of daily rounds includes assessments for this complication.

Superficial Thrombophlebitis

Superficial thrombophlebitis is one of the most frequently occurring postoperative complications and is most commonly associated with IV catheters. Superficial thrombophlebitis is a benign disease. However, it is associated with deep vein thrombophlebitis in approximately 5% of cases. Superficial thrombophlebitis is frequently overlooked or disregarded as a cause of postoperative fever. Superficial tenderness and erythema outline the course of the veins. Women with established superficial varicosities in the lower extremities are especially susceptible because of localized stasis or pressure during the operative procedure and inactivity during the first 24 hours after operation. Patients with superficial thrombophlebitis of the legs may also have concomitant deep venous disease. Thus the finding of superficial thrombophlebitis does not eliminate the necessity to consider DVT as well. Some series have documented the association of inherited thrombophilias with superficial phlebitis, increasing the risk by 4- to 13-fold, with the more potent thrombophilias contributing to the higher risk. Recurrent superficial phlebitis, in varying anatomic sites, may be a sign of occult malignant disease. Detailed basic investigations have identified fibrin sheaths surrounding IV catheters in 60% to 100% of patients studied. The exact fate of the several inches of clot and fibrin sheath after the removal of the IV catheter is uncertain. Venography studies have found that these clots and fibrin sheaths do not break up on catheter removal but initially remain in situ. IV catheters are an important source of nosocomial infections. Approximately 30% of all hospital-acquired bacteremias are secondary to IV lines. The most serious complication of IV catheter use is infection of the thrombus, producing suppurative phlebitis or catheter sepsis.

The classic symptom of phlebitis is inflammation of the subcutaneous tissue along the course of a vein or over the area of merging varicosities. The woman develops a painful, tender, erythematous induration (nodule or core). In most severe cases, there is associated fever. The duration of phlebitis is prolonged if the catheter is not immediately removed when the diagnosis of superficial phlebitis is made. It has previously been recommended that the IV catheters be removed and replaced in intervals ranging from 72 to 96 hours, regardless of whether signs or symptoms of superficial phlebitis are present. However, a Cochrane review in 2013 showed no evidence to support routine catheter exchange without evidence of inflammation, infiltration, or blockage (Webster, 2013).

Although routine exchange is not indicated, venous catheters should be removed at the first sign of induration, erythema, or edema. Superficial phlebitis is a common cause of an enigmatic postoperative fever during the first postoperative week. The clinical management of mild superficial thrombophlebitis

includes rest, elevation, and local heat. Moderate to severe superficial thrombophlebitis may be treated with a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen or low-dose heparin. The rare case of proximal progression of the inflammatory process should be treated with therapeutic doses of IV heparin and antibiotics.

Deep Vein Thrombosis

Fifty percent of thromboembolic complications occur within the first 24 hours and 75% occur within 72 hours. Approximately 15% occur after the seventh postoperative day. Diagnosis of deep vein thrombosis by physical examination is insensitive. Thus imaging studies are essential for establishing the correct diagnosis. Venous thrombosis and pulmonary embolism (PE) are the direct causes of approximately 40% of deaths in gynecologic cases. The incidence of fatal PE following gynecologic operations is approximately 0.2%. Because women often die within a few hours of the appearance of initial symptoms, emphasis must be placed on prevention rather than treatment of this complication. PE is not the only major consequence of deep venous thrombosis. Many women develop chronic venous insufficiency or postphlebotic syndrome of the legs as a major sequela following thrombophlebitis. The resulting damage to valves of the deep veins produces shunting of blood to superficial veins, chronic edema, pain on exercise, and skin ulceration.

The reported incidence of DVT with gynecologic operations without prophylaxis varies from 7% to 45%, with an average of approximately 15% (Walsh, 1974). In a review conducted since the institution of universal mechanical prophylaxis, VTE rates as low as 0.6% for open hysterectomies and 0.2% for minimally invasive hysterectomies were documented (Barber, 2015). The incidence of thrombosis is directly dependent on risk factors such as the type and duration of operation, age of the woman, history of thrombophilia, or deep vein thrombosis, peripheral edema, surgical blood loss, restrictions in preoperative ambulation, obesity, immobility, malignancy, sepsis, diabetes, current oral contraceptive or hormone use, and conditions that produce venous stasis, such as ascites and heart failure (Box 25.5) (Kyrle, 2005). Older and obese women have an increased incidence of thrombosis because of dilation of their deep venous system. There is a two- to fourfold increased risk for venous thrombosis in women taking postmenopausal estrogen therapy. The length of the surgical procedure also has an important influence on the development of thrombosis. If the operation is 1 to 2 hours in duration, approximately 15% of women develop the disease; if the surgery is longer than 3 hours, the risk is greater (Table 25.3).

The process of thrombosis usually begins in the deep veins of the calf. It is estimated that 75% of pulmonary emboli originate from a thrombus that began in the leg veins. If one leg is involved, the contralateral leg will have a thrombus in approximately 33% of women. Usually, the thrombus remains localized, it lyses spontaneously, and the local symptoms resolve. In approximately 1 in 20 cases the process extends centrally to the veins of the upper leg and pelvis. Involvement of the femoral vein often results in swelling caused by obstruction of this large vein. Pulmonary emboli from calf veins alone are rare, with only 4% to 10% of pulmonary emboli originating from this area. In contrast, there is a 50% risk of a PE if thrombosis of the femoral vein is not treated.

Box 25.5 Conditions Associated with Increased Risk for Deep Vein Thrombosis

- Active cancer
- Acute medical illness (e.g., acute myocardial infarction, heart failure, respiratory failure, infection)
- Advancing age
- Antiphospholipid syndrome
- Behçet syndrome
- Central venous catheter
- Chronic care facility stay
- Congenital venous malformation
- Dyslipoproteinemia
- Heparin-induced thrombocytopenia
- Hormone replacement therapy
- Immobilization
- Inflammatory bowel disease
- Intravenous drug abuse
- Limb paresis
- Long-distance travel
- Myeloproliferative diseases
- Nephrotic syndrome
- Obesity
- Oral contraceptives
- Other drugs
 - Antipsychotics
- Chemotherapeutic agents
- Tamoxifen
- Thalidomide
- Paroxysmal nocturnal hemoglobinuria
- Pregnancy, puerperium
- Previous venous thromboembolism
- Prolonged bed rest
- Superficial vein thrombosis
- Surgery
- Trauma
- Varicose veins
- Vena cava filter

From Kyrle PA, Eichinger S. Deep vein thrombosis. *Lancet*. 2005;365(9465):1163-1174.

In 1854, Virchow described the three key predisposing or precipitating factors in the production of thrombi: an increase in coagulation factors, damage to the vessel wall, and venous stasis. Subsequent studies have documented that all three events occur with gynecologic operations. Blood flow in the iliac vein decreases by approximately 55% during an operation. During an operation, there are several normal physiologic changes that produce hypercoagulability, including increases in factors VIII, IX, and X, number of platelets, platelet aggregation and adherence, fibrinogen, and, lastly, thromboplastin-like substance from tissue necrosis.

Kakkar has described the cascade of events leading to the development of thrombosis. The initial event in the cascade is stasis. Stasis leads to localized anoxia with subsequent generation of thrombi at the anoxic site. This produces changes in the lining of the vessel, with exposure of the basement membrane, platelet adhesion, and local coagulation. Thus the most important event in thrombosis is the generation of thrombi in the presence of venous stasis. A thrombus may generate in an area of stasis or it may generate wherever a vessel wall is damaged, with resultant exposure of the subendothelial collagen, to which platelets will adhere.

Table 25.3 Risk Categories of Thromboembolism in Gynecologic Operations

Risk Category	Risk Level		
	Low	Medium	High
Age (yr)	40	40	50
Contributing Factors			
Operation	Uncomplicated or minor	Major abdominal or pelvic	Major, extensive
Weight		Moderately obese—75 to 90 kg or >20% above ideal weight	Morbidly obese— >115 kg or >30% above ideal weight
			Previous venous thrombosis
			Varicose veins
			Cardiac disease
			Diabetes (insulin-dependent)
Calf vein thrombosis (%)	2	10-35	30-60
Iliofemoral vein thrombosis (%)	0.4	2-8	5-10
Fatal pulmonary emboli (%)	0.2	0.1-0.5	1
Recommended prophylaxis	Early ambulation	Low-dose heparin or intermittent pneumatic compression	Low-dose heparin or intermittent pneumatic compression

From Mattingly RF, Thompson JD, eds. *Te Linde's Operative Gynecology*. 6th ed. Philadelphia: JB Lippincott; 1985.

Figure 25.5 Stages in development of thrombus in valve pocket of deep veins of leg. **A**, Stasis in valve pocket results in thrombin generation. **B**, Platelet aggregation and fibrin formation. **C**, Propagation of platelet-fibrin nidus. **D**, Blockage of venous flow with resultant retrograde extension. (From Bloom AL, Thomas DP, eds. *Haemostases and Thrombosis*. Edinburgh: Churchill Livingstone; 1981:684.)

The site of initial formation of the thrombus is most often near the base of a valve cusp in the calf of the leg (Fig. 25.5). The thrombus propagates and grows by repetitive layers of platelet aggregation and deposition of fibrin from fibrinogen. The most recently formed portion of the propagating thrombi are free-floating (not attached to the vein) and are most likely to become pulmonary emboli. The body attempts to repair the area of thrombosis through an invasion of fibroblasts from the vein wall to encompass the base of the thrombus. Eventually,

the thrombus is attached to the vein wall, the area is reepithelialized, organization occurs, and symptoms resolve.

The signs and symptoms of deep vein thrombosis depend directly on the severity and extent of the process. Many localized cases of deep vein thrombosis in the calf are asymptomatic and are only recognized by a screening procedure such as duplex ultrasonography. However, even extensive areas of deep vein thrombosis may be asymptomatic; the first sign may be the development of a PE. In a woman who is asymptomatic, the pathophysiologic process may not totally obstruct the individual vein and drainage is obtained via associated competent collateral circulation.

Studies using ¹²⁵I-labeled fibrinogen to screen the legs have documented that approximately one of two women who develop deep vein thrombosis following gynecologic surgery is totally free of symptoms (Walsh, 1974). Among women who develop signs and symptoms, approximately 68% have induration of the calf muscles, 52% have minimal edema, 25% have calf tenderness, and 11% develop a difference of more than 1 cm in diameter of the leg. The Homan sign is present in 10%, and differential pain over the calf with a blood pressure cuff is present in approximately 40%. The clinical diagnosis of iliofemoral thrombosis is much easier—the woman usually develops severe symptoms caused by obstruction of venous return. Usually, there is an acute onset of severe pain and swelling.

The clinician must maintain a high degree of suspicion to begin the diagnostic workup for deep vein thrombosis. The clinical symptoms and signs of DVT are nonspecific. A clinical clue is the persistence of a low-grade fever with unexplained tachycardia. The tachycardia is often more rapid than one would expect with a low-grade fever. The finding of a definite difference in leg circumference is supportive evidence of DVT. Physical examination of the legs produces false-positive findings in approximately 50% of cases. At the time of the initial bedside examination, the physician will develop a level of suspicion for DVT based on physical findings and clinical characteristics. If the likelihood were low, the next step would, in nonsurgical patients, be a D-dimer level; however in the postoperative patient, D-dimer is not as reliable. D-Dimer is a protein from cross-linked fibrin after it has been degraded by plasmin in the fibrinolytic process.

Table 25.4 Options for Initial Anticoagulant Treatment of Deep Vein Thrombosis

Drug	Method of Administration	Dosage*	Reported Risks (No./Total No. [%])	
			Heparin-Induced Thrombocytopenia†	Major Bleeding
Unfractionated heparin	IV	Loading dose, 5000 U or 80 U/kg of body weight with infusion adjusted to maintain aPTT within therapeutic range	9/332 (2.7)	35/1853 (1.9)
LMW heparin			0/333 (0)	20/1821 (1.1)
Dalteparin	Subcutaneous	100 U/kg every 12 hr or 200 U/kg daily; maximum, 18,000 U/day		
Enoxaparin	Subcutaneous	1 mg/kg every 12 hr or 1.5 mg/kg daily; maximum, 180 mg/day		
Tinzaparin	Subcutaneous	175 U/kg daily; maximum, 18,000 U/day		
Nadroparin	Subcutaneous	86 U/kg every 12 hr or 171 U/kg daily; maximum, 17,100 U/day		

From Bates SM, Ginsberg JS. Treatment of deep-vein thrombosis. *N Engl J Med*. 2004;351(3):268-277.

*Doses vary in patients who are obese or who have renal dysfunction. Monitoring of antifactor Xa levels has been suggested for these patients, with dose adjustment to a target range of 0.6 to 1.0 U/mL 4 hr after injection for twice-daily administration or 1.0-2.0 U/mL for once-daily administration. Even though there are few supporting data, most manufacturers recommend capping the dose for obese patients at that for a 90-kg patient.

†The therapeutic range of activated partial thromboplastin time corresponds to heparin levels of 0.3 to 0.7 U/mL, as determined by antifactor Xa assay. High levels of heparin-binding proteins and factor VIII may result in so-called heparin resistance. In patients requiring more than 40,000 U/day to attain a therapeutic aPTT, the dosage can be adjusted on the basis of plasma heparin levels.

Thus D-dimer may be elevated because of trauma, surgery, intravascular hemolysis, pregnancy, and other inflammatory states. If the signs and symptoms are suggestive or the woman is at high risk, the next step should be imaging. Interestingly, the more symptomatic the disease, the more adherent the thrombus. The greater the symptoms, the less likely the development of a PE.

Ascending contrast venography (phlebography) is the most accurate method for detecting deep vein thrombosis with a diagnostic accuracy of more than 95% for peripheral disease and more than 90% for iliofemoral thrombosis. However, it is rarely if ever used. Duplex ultrasound, the combination of Doppler and real-time B-mode ultrasound, and color Doppler are the preferred methods for diagnosing deep vein thrombosis. Duplex ultrasonography has remarkably high sensitivity and specificity in symptomatic women. Real-time ultrasound imaging provides visualization of the larger veins, and sensitive Doppler ultrasound is focused simultaneously on the suspicious vessel. The technology depends on changes in venous flow for a positive diagnosis. The documented sensitivity of duplex ultrasonography in detecting proximal thrombi is 95% (95% CI: 92%-98%) and the specificity is 99% (95% CI: 98%-100%) (Wells, 1995). The advantages of this method are that it is noninvasive, easy to use, highly accurate, objective, simple, and reproducible. Color Doppler ultrasonography may improve the diagnostic accuracy in larger veins. The main disadvantage of duplex ultrasound is its limited accuracy when investigating small vessels in the calf. The inability to compress the deep vein by moderate pressure with the ultrasound probe is the most widely used criterion for the positive diagnosis of DVT.

A prospective study of 220 patients used compressibility of the vein as the sole criterion for diagnosis of DVT (Lensing, 1989). For all patients in their study, including both proximal vein and calf vein thrombosis, the sensitivity was 91% and the specificity was 99%. The objectives of the clinical management of deep vein thrombosis associated with gynecologic surgery are early detection and early therapy. In reality, antithrombotic therapy is preventive medicine, because the therapeutic agent interrupts progression of the disease (thrombus formation) but does not

actively resolve the disease process. Anticoagulation with heparin (unfractionated or LMW) is the initial treatment of choice for the diagnosis of DVT or PE (Table 25.4). LMWH is as effective and is safer than unfractionated heparin. LMWH, although more expensive than unfractionated heparin, has several advantages and has effectively replaced unfractionated heparin as the gold standard for treatment of DVT. LMWH may be given subcutaneously once or twice daily using weight-based dosing, for example enoxaparin: 1.5 mg/kg daily or 1 mg/kg twice daily (Guyatt, 2012). LMWH does not require monitoring in women with normal and stable renal function. It induces significantly less heparin-induced thrombocytopenia and has a lower risk of inducing bleeding. Because blood levels are more reproducible, there is actually a lower incidence of complications noted in some studies in terms of progression from DVT to pulmonary emboli. Additionally, studies comparing LMWH with unfractionated heparin have shown a greater effect with thrombus regression within the veins themselves. Testing of levels of LMWH is based not on the activated partial thromboplastin time (aPTT) but on the antifactor Xa activity level. Levels are calculated specifically for each LMWH. An aPTT of 1.5 times normal corresponds approximately to an antifactor Xa activity level of 0.2. Therapeutic levels are found between 0.4 and 0.8. Bleeding usually occurs when levels of the antifactor Xa activity level rise more than 1.0 to 1.2. If needed in patients with unstable renal status, levels may be checked approximately 4 hours after dosing.

If unfractionated heparin is desired as an IV infusion, weight-adjusted or fixed dose infusions are acceptable. The weight-adjusted dose is 80 IU/kg/hr bolus followed by 18 IU/kg/hr. The fixed dose uses an initial loading dose of 5,000 IU, followed by a continuous infusion of 1000 IU/hr (Guyatt, 2012). The dosage of unfractionated IV heparin should be adjusted to prolong an aPTT to 2.5 times control values. Continuous heparin infusion is preferred over periodic bolus injections because there are fewer hemorrhagic complications (6% versus 14%). The average half-life of heparin is 1 to 2 hours after IV injection. Failure to achieve adequate anticoagulation in the first 24 hours of therapy increases the risk of recurrent venous thromboembolism 15-fold.

For women who are pregnant or have a malignancy, LMWH is the treatment of choice for long-term anticoagulation. Other women can be treated with unfractionated heparin in addition to the initiation of oral warfarin (Coumadin) with a goal international normalized ratio (INR) of 2.5 (range, 2 to 3). A loading dose of warfarin is 5 to 10 mg nightly for two doses followed by INR-guided doses. Heparin should be continued until the INR is greater than 2. The biologic half-life of warfarin is 2 to 3 days. In general, anticoagulation with warfarin should be continued for 3 to 6 months for adequate secondary prophylaxis of a provoked thrombus. The length of treatment should be adjusted based on the clinical scenario with provoked clots from reversible risk factors requiring the shortest duration of treatment. For example, a provoked clot following an abdominal hysterectomy without other risk factors should be managed with 3 months of therapy (Guyatt, 2012). Patients with large DVT, antiphospholipid antibody syndrome, or malignancy may require extended therapy beyond 6 months because of increased risks of recurrence.

The primary risk of chronic anticoagulation therapy is the potential for major bleeding complications. Major bleeding occurs in approximately 4% woman-years of therapy. Thus it is important to follow these women carefully with serial coagulation studies. Approximately 1% of patients on full-dose heparin develop thrombocytopenia (platelet count <100,000/mm³). If thrombocytopenia develops, heparin should be discontinued because of the potential risk of paradoxical thrombosis.

Rarely, patients are not candidates for anticoagulation. In these patients, inferior vena cava filters may be used to protect against pulmonary emboli. Temporary vena cava filters may be placed with fluoroscopic guidance. In some patients with large DVT and other risk factors, such as compound thrombophilias and malignancy, consideration may be given to both anticoagulation and filter placement.

Routine screening for thrombophilia in all patients with VTE is not indicated. The presence of a hereditary thrombophilia does not alter therapeutic or prophylactic management of a patient and has not been associated with improved outcomes. Patients who may benefit from testing include those with recurrent thrombosis, patients with a family history of thrombosis, patients with thrombosis in unusual locations (hepatic vein, portal vein, mesenteric vein, or arterial), and possibly patients younger than 45 years of age. Patients with a provoked thrombosis from cancer, hormonal therapy, and surgery do not require testing for thrombophilias.

There is no evidence that bed rest is helpful for patients with DVT or that immobilization will prevent pulmonary embolism. Patients with confirmed DVT may receive NSAIDs, because coagulation factors will be monitored. Patients should also be prescribed support stockings, which should be worn for several months and for up to 2 years. The use of support stockings decreases the risks of postthrombotic syndrome. In a systematic review, women who used stockings up to 2 years after DVT had up to a 50% reduction in the incidence of postthrombotic syndrome (Segal, 2007).

Pulmonary Embolism

The accurate diagnosis of PE is essential for the prevention of morbidity from lack of treatment or unnecessary anticoagulation therapy. Autopsy studies have documented that

Table 25.5 Symptoms and Signs of Pulmonary Embolism

Symptoms	Patients with Finding (%)
Predisposing factors*	94
Dyspnea	84
Pleuritic chest pain	74
Apprehension	59
Cough	53
Hemoptysis	30
Syncope	14
Signs	
Tachypnea	92
Rales	58
Accentuation of pulmonic valve closure	53
Tachycardia	44
Cyanosis	20

From Blinder RA, Coleman RE. Evaluation of pulmonary embolism. *Radiol Clin North Am.* 1985;23(3):391-405.
*Prolonged immobilization, postoperative state, congestive heart failure, carcinomatosis.

pulmonary emboli are undiagnosed clinically in approximately 50% of women who experience this complication. Approximately 10% of women with a PE die within the first hour. The mortality of women with correctly diagnosed and treated pulmonary emboli is 8%, in contrast to approximately 30% if the disease is not treated. Most pulmonary emboli in gynecologic patients originate from thrombi in the pelvic and femoral veins. Predisposing risk factors are found in most women with PE.

No combination of symptoms or signs is pathognomonic for PE. They are nonspecific and similar to symptoms caused by other forms of cardiorespiratory disease. Many patients with PE will be asymptomatic. Common conditions considered in the differential diagnosis of pulmonary embolism include pneumonia, cardiac failure, atelectasis, aspiration, acute respiratory distress syndrome, and sepsis. Although the differential diagnosis is broad in scope, the symptoms should alert the physician to the possibility of a PE, thus allowing a proper diagnostic workup to establish or rule out the disease. Chest pain, dyspnea, and apprehension are the most common symptoms. The dyspnea is often of abrupt onset. The classic triad of shortness of breath, chest pain, and hemoptysis is seen in less than 20% of women with proved PE. Tachycardia, tachypnea, rales, and an increase in the second heart sound over the pulmonic area are the most frequently found signs of pulmonary emboli (Table 25.5). Approximately 15% of women with pulmonary emboli have an unexplained low-grade fever associated with a PE. A high fever is rarely associated with a PE but may occur. The clinical manifestations of PE are produced primarily by occlusion of the large branches of the pulmonary arteries by embolic material with subsequent associated reflex bronchial constriction and vasoconstriction that intensify the symptomatology. More than 50% of clinically recognized pulmonary emboli are multiple. The most frequent location of pulmonary emboli is in the lower lobes of the right lung. Shock and syncope are associated with massive pulmonary emboli.

Although imaging techniques are the gold standard for establishing the diagnosis of pulmonary emboli, several studies have found that clinical assessment is almost as accurate (Goldhaber,

Figure 25.6 A to D, Helical CT of pulmonary embolism. The letters on the cube help orient the viewer as the three-dimensional image is rotated. A, Anterior; F, foot; H, head; L, left. (Courtesy of Dr. Charles McGlade, Sacred Heart Medical Center, Eugene, OR.)

2003a, 2003b). Laboratory studies that may help in diagnosis and management include electrocardiograms (ECGs), chest radiographs, blood gas analyses, assessment of troponin, d-dimer (not reliable in postoperative patients), and brain natriuretic peptide (BNP). Less than 15% of ECGs demonstrate significant changes of right ventricular strain, with T wave inversion in V_1 to V_4 with a PE. Most women with pulmonary emboli demonstrate hypoxemia on blood gas determinations, but as with other routine tests, these findings do not occur invariably. Diminished pulmonary vascular markings may be a suggestive finding on a chest film, but they are fairly nonspecific. The chest radiograph may be helpful in the differential diagnosis by demonstrating other pulmonary processes. The most common findings on chest film examination with a PE are infiltrate, pleural effusion, atelectasis, and enlargement of the heart or descending pulmonary artery.

In women who are in mild to moderate distress, IV heparin should be started while imaging studies are being ordered. If there is any question of severe distress or hemodynamic

instability, thrombolytic therapy may be indicated for the appropriate patient. In stable patients, a stepwise approach is useful. Many clinicians will order Doppler studies of the lower extremities. If the Doppler studies are positive, the woman will be anticoagulated and no further workup for a thrombotic source is necessary. If the tests are negative, further imaging is still necessary, because in the postoperative patient, pelvic clots may be the origin of the pulmonary embolus, not lower extremity clots. The next two options are a ventilation-perfusion ratio (V/Q) scan or helical CT.

Helical CT has largely replaced V/Q scanning as the most common imaging technique to establish or exclude the diagnosis of PE (Fig. 25.6). Helical CT, also called spiral CT, uses imaging of the pulmonary vessels. Imaging of the pulmonary vessels is facilitated by the use of IV contrast media. The procedure is minimally invasive and provides a volumetric image of the lung by rotating the detector at a constant rate around the woman. A cost-effective analysis from Doyle and colleagues has found that helical CT is the most cost-effective first-line test to

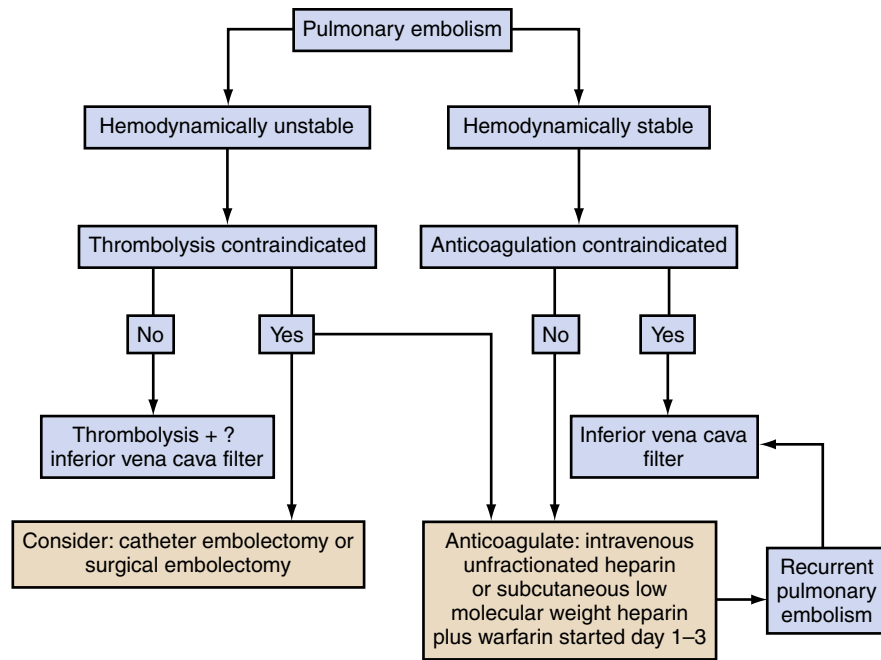

Figure 25.7 Algorithm for treatment of pulmonary embolism. (From Taj MR, Atwal AS, Hamilton G. Modern management of pulmonary embolism. *Br J Surg.* 1999;86[7]:853-868.)

diagnose pulmonary embolus. A limitation of helical CT is a sixfold increase in radiation exposure compared with the \dot{V}/\dot{Q} scan. This leads to a slight increased risk of breast cancer (<1%). Prior to \dot{V}/\dot{Q} scanning, a chest x-ray should be obtained. If the chest x-ray shows other findings, such as atelectasis, the \dot{V}/\dot{Q} scan has a much higher chance of being nondiagnostic and CT should be ordered instead.

The \dot{V}/\dot{Q} scan is a safe and relatively easy-to-perform test. The scan involves the injection of small radiocolloid particles into the circulation. They are trapped in small vessels; their distribution depends on regional pulmonary blood flow. Ventilation scintigraphy uses radionuclides of technetium aerosol or xenon gas. The combination of lack of symmetry and a mismatch in the ventilation scan is the abnormality that leads to the diagnosis. Whereas a normal result effectively rules out the diagnosis of PE, 40% of patients with a suspected PE will have a normal scan. The multicenter Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) found that 4% of patients with normal or near-normal perfusion lung scans subsequently were discovered to have pulmonary emboli. This study emphasized a high sensitivity of 98% but a low specificity of 10% for \dot{V}/\dot{Q} scans in the diagnosis of PE. The authors noted that almost all patients with acute PE had abnormal scans, but so did most patients without emboli. \dot{V}/\dot{Q} scans have a high sensitivity but a variable specificity for the diagnosis of PE. For example, other cardiorespiratory diseases such as asthma may result in regional areas of decreased perfusion. If the scan documents multiple segments or lobar perfusion defects with a ventilation mismatch, the probability of pulmonary emboli is more than 85%. \dot{V}/\dot{Q} scans with less extensive perfusion abnormalities or matching ventilation defects do not reliably exclude the diagnosis of PE.

The management of the majority of pulmonary emboli is with anticoagulation with IV unfractionated heparin or full-dose LMWH, similar to the management of deep vein thrombosis

(Fig. 25.7). Prompt and early therapy with heparin provides anticoagulation and inhibits the release of serotonin from platelets. Potentially, this results in a decrease in the associated bronchoconstriction. Some women are candidates for thrombolytic therapy (streptokinase-urokinase). The time window for effective use of thrombolysis is up to 14 days following the initial symptoms or signs of a PE, although it is rarely used beyond 48 to 72 hours. Thrombolytic therapy works by transforming plasminogen to plasmin. Use of thrombolytic therapy during the early postoperative period is contraindicated because of the increased risk of serious hemorrhage, except for unique circumstances. Recombinant human tissue-type plasminogen activator (TPA) has been shown to be more rapid in onset and safer than urokinase for thrombolytic therapy. Thrombolytic therapy is the method of choice in patients with massive pulmonary emboli (angiographically, >50% obstruction of the pulmonary arterial bed) with associated moderate to severe hemodynamic instability, lobular obstruction, or multiple segmental perfusion defects. Random trials of heparin versus thrombolytic therapy have shown that emboli clear more rapidly with initial thrombolytic therapy.

The Management Strategies and Prognosis of Pulmonary Embolus-3 trial (MAPPET-3) found that in severely affected patients (but not those in shock), thrombolytic therapy was superior to heparin. However, for all patients, particularly those with small emboli, the increased risks of intracranial bleeding may outweigh the benefits (1% to 3% of patients). Trials have evaluated thrombolytic therapy with heparin and found the combination superior to heparin alone. A thrombolytic agent is infused IV for the first 12 to 24 hours and heparin therapy is continued for 7 to 10 days. The clinical assumption is that approximately 7 days are needed for the intravascular venous thrombus to become firmly attached to the vein's sidewall. In patients who have heparin allergies, or develop heparin-induced thrombocytopenia (HIT), thrombin inhibitors are an alternative therapy.

An adjunct for treatment is vena cava filters. The most widely accepted indication for vena cava filters is failure of medical management or a contraindication to heparin therapy. Approximately 35% of vena cava filters are placed for prophylactic indications. A randomized trial reported by Decousos and colleagues compared vena cava filters with LMWH or unfractionated heparin. They concluded that the initial beneficial effect of vena cava filters for the prevention of PE is counterbalanced by an excess of recurrent DVT, without any difference in mortality rates. Treatment of a massive PE in an unstable woman involves a choice of thrombolytic therapy, pulmonary artery embolectomy, transvenous catheter embolectomy, or filter placement in the inferior vena cava.

All patients with pulmonary emboli should have maintenance therapy with warfarin or LMWH for 3 or more months following assessment of the patient's bleeding risk (Guyatt, 2012). New oral medications are emerging, but their role is uncertain at this time, particularly in the oncologic population. The risk of a woman developing a subsequent fatal PE during the 3 months of anticoagulation therapy is approximately 1 in 70 to 100.

URINARY TRACT PROBLEMS

INABILITY TO VOID

Many women experience an inability to void or an incomplete emptying of the bladder during the immediate postoperative period. The cause is complex, but the inability to void is more frequent and lasts longer after an operation that involves the urethra or bladder neck. The major pathophysiologic change is the direct trauma and edema produced by the surgical procedure to the perivesical tissues. Other factors that contribute include the potential of overdistention from excessive hydration and dyssynchronous contractions from the bladder neck. The differential diagnosis includes anxiety, mechanical interference, obstruction by swelling and edema, neurologic imbalance, and drug-associated detrusor hypotonia.

Most voiding dysfunction resolves without medication and with time. If a mechanical obstruction is not suspected, intermittent straight catheterization is indicated to manage postoperative voiding dysfunction. This will result in a lower incidence of urinary tract infections (UTI) and facilitate a more rapid return to normal bladder function. Overdistention of the bladder produces a temporary paralysis of the detrusor activity that may take several days to resolve and should be avoided. Rarely, medications may be given to patients who experience prolonged periods of inability to void. Reflex urethral spasm is common after surgery to repair an enterocele or rectocele. Urethral spasm may be diminished by an α -adrenergic receptor blocking agent such as phenoxybenzamine. However, hypotension may be associated with this drug. Bladder hypotonia may occur as a result of overdistention, prolonged inactivity, or use of medications such as beta-blockers. Bladder hypotonia may be treated with bethanechol, 10 to 50 mg orally every 6-8 hours.

URINARY TRACT INFECTION

The most commonly acquired infection in the hospital and the most frequent cause of gram-negative bacteremia in hospitalized patients is catheter-associated urinary tract infection (UTI).

Approximately 40% of nosocomial infections are UTIs, and 60% of these are directly related to an indwelling urethral catheter. Of patients with infections from bladder catheters, 1% will develop bacteremia. Therefore indwelling catheters should only be used when absolutely necessary and for as short a period of time as possible.

The normal urothelium inhibits adherence of surface bacteria to the walls of the urethra and bladder. A bladder catheter disrupts this property and surface bacteria are able to colonize the lower urinary tract. Additionally, bacteria form a sheet or biofilm of microorganisms and bacterial bioproducts that adheres to the catheter. These biofilms protect bacteria from antibiotics. This characteristic of biofilms explains why antibiotic suppression is ineffective for patients with chronic catheterization and why replacement of a catheter is necessary in the treatment of systemic infection secondary to a colonized urinary tract. The incidence of a positive culture increases dramatically with time. After a Foley catheter has been in place for 36 hours, approximately 20% of women have bacterial colonization and, after 72 hours, more than 75% have positive cultures. If the catheter drains into an open system for longer than 96 hours, 100% develop bacteriuria. Women with an indwelling catheter in place with a closed drainage system develop UTIs at the rate of approximately 5%/24 hours; this increases to 50% after 7 days of continuous catheterization.

Catheter-related UTIs are related to the patient's age. In one study, 30% of women older than 50 years developed an infection, compared with 16% of postoperative women younger than age 50. Diabetes increased the incidence of catheter-related UTIs threefold. The incidence of infection is directly related to how long the catheter is in place. The incidence of a positive urine culture after a single in-and-out catheterization is approximately 1%. Sterile technique used during insertion, strict aseptic catheter care, and maintenance of a closed drainage system are all important steps for reducing the incidence of infection through reduced colonization. Bacteria ascend from the exterior to the bladder via the lumen of the catheter or around the outside of the catheter. A sterile, closed drainage system is another prophylactic measure to reduce the incidence of UTIs. In one study, strict closed drainage reduced the rate of infection from 80% to 23%. Studies have documented a lower risk of infection with a suprapubic, transabdominal urinary catheter. The latter technique also decreases patient discomfort and permits earlier spontaneous voiding. Systemic prophylactic antibiotics exert a short-term effect, decreasing the initial incidence of infection. However, the negative effect of prophylactic antibiotics has been an increased emergence of antibiotic-resistant bacteria. Therefore prophylactic antibiotics should not be used, except in immunocompromised patients. With catheterization for longer than 3 weeks, all patients have bacterial colonization, regardless of the use of prophylactic antibiotics and a closed system.

The symptoms of UTI usually develop 24 to 48 hours after the Foley catheter is removed. Patients with lower UTIs usually do not have fever but experience urinary frequency and mild dysuria, which are difficult to distinguish from normal postoperative discomfort. Older women may manifest mental status changes as the first sign of problems. Women with upper UTIs usually have a high fever, chills, and flank pain. If urinary tract symptoms persist after appropriate antibiotic therapy, one should obtain imaging studies to evaluate the possibility of

obstruction in the urinary tract. Obstruction of the ureter without associated infection may be asymptomatic or produce only mild flank tenderness. No appreciable change may be noted in urinary output or serum creatinine with an isolated unilateral ureteral obstruction.

The diagnosis of UTI is established by urinalysis and urine culture. Women with high-volume urine output may demonstrate minimal findings on urinalysis but have a positive urine culture. In a catheterized specimen, a bacterial concentration of 10^2 organisms/mL is significant. More than 95% of patients with 10^2 colony-forming units (CFU)/mL subsequently developed the standard criterion of infection, which is 100,000 CFU/mL for a midstream culture (Stark, 1984).

A minimum of 3 days of antibiotic therapy for a woman who has developed cystitis after catheter use is the recommended treatment. One-day, single-dose antibiotic treatment is not an effective treatment for UTI.

URETERAL INJURY AND URINARY FISTULA

Vesicovaginal and ureterovaginal fistulas are infrequent yet significant complications of operations for benign gynecologic conditions. In the United States, gynecologic operations are found to be the cause of approximately 75% of urinary tract fistulas. Surprisingly, it is not the difficult cancer operation but rather the simple total abdominal hysterectomy for benign disease, such as myomas or abnormal bleeding that is most frequently associated with this complication. Fistulas following gynecologic surgery are a result of abdominal hysterectomy in 75% of cases and vaginal surgery in the remaining 25%. A Cochrane database review by Aarts and coworkers noticed a higher incidence of urinary tract injuries with minimally invasive surgery (MIS) compared with traditional abdominal hysterectomy (Aarts, 2015). Unfortunately, the numbers for MIS are still too low and the data may still be affected by the learning curve of MIS. The exact incidence of injury to the ureter associated with gynecologic surgery is unknown because many patients do not exhibit symptoms. However, it has been estimated that ureteral injury occurs as frequently as 1/200 abdominal hysterectomies. Ibeanu and associates have performed concomitant cystoscopy on 839 women undergoing hysterectomies for benign disease (few laparoscopic procedures). They noted that 2.9% of patients had bladder injuries and 1.8% had ureteral injuries (Ibeanu, 2009). Other studies have reported similar results. The site of ureteral injury is usually near the uterine artery. Injuries may include transection, sutures that constrict or devascularize the ureter, and thermal injuries from cautery. Stanhope and coworkers have noted a mean increase of only 0.8 mg/dL in the serum creatinine level following unilateral ureteral obstruction secondary to gynecologic surgery (Stanhope, 1991).

The classic clinical symptom of a urinary tract fistula is the painless and almost continuous loss of urine, usually from the vagina. On occasion, the uncontrolled loss of urine may be related to change in position or posture. Urinary incontinence that presents within a few hours of the operative procedure is usually secondary to a direct surgical injury to the bladder or ureter that was not appreciated during the surgery. Most fistulas become symptomatic in 8 to 12 days and occasionally as late as 25 to 30 days after the operation. Damage to the blood supply from clamping, cautery, or figure-of-eight sutures produces

Figure 25.8 Vesicovaginal fistula with the classic “rosette” of inflammatory tissue denoting the opening to the fistulous track. (From Badlani GH, De Ridder D, Mettu JR, et al. Urinary tract fistulae. In: Wein AJ, Kavoussi LR, Partin AW, et al, eds. *Campbell-Walsh Urology*. 11th ed. Philadelphia: Elsevier; 2016.)

avascular necrosis and subsequent sloughing of the urogenital tissue. Pelvic examination often reveals a small erythematous area of granulation tissue at the site of the fistula (Fig. 25.8).

A small fistula may be clinically identified by placing a tampon in the vagina and instilling a dilute solution of methylene blue dye into the urinary bladder. This will also help differentiate between a vesicovaginal fistula and ureterovaginal fistula. If the blue coloring is discovered on the tampon, the defect is most likely in the bladder. If the tampon is not colored, 3 to 5 mL of indigo carmine should be injected IV. The subsequent finding of blue coloring on the tampon is presumptive evidence of an ureterovaginal fistula. Oral phenazopyridine can also be used in lieu of indigo carmine, staining the tampon orange. An IV pyelogram or CT urogram should be obtained in either case to detect obstruction of the ureter and diagnose compound (ureter and bladder) fistulas.

As with most other postoperative complications, preventive medicine is paramount. The woman should have an empty bladder and the physician should obtain adequate exposure of the site. Sharp dissection should be made along tissue planes with proper traction and countertraction. When operating near the bladder or ureter, bleeding vessels should be secured individually. If possible, the ureter should not be completely detached from the overlying peritoneum. With extensive dissection of the periureteral tissue, care should be taken to avoid interference with the longitudinal vascular supply of the ureter, the Waldeyer sheath. In the most difficult cases, in which anatomic landmarks are obscure, opening of the dome of the bladder and palpation with the index finger and thumb may help identify the proper surgical plane. The urinary system, especially the bladder, is very forgiving if given a short period of rest to recover. If trauma to the bladder is suspected, continuous catheter drainage for 3 to 5 days usually results in spontaneous healing. Selective cystoscopy

following complicated or difficult operative procedures can be considered, although universal cystoscopy after all hysterectomies misses less urinary injuries.

When leakage from the urinary tract is first discovered, the bladder should be drained with a large-bore Foley catheter. Ureteral injuries should be evaluated for treatment with retrograde ureteral catheters. Approximately 20% of bladder injuries and 30% of ureteral injuries that are drained and stented will heal spontaneously without further surgery. Ureteral injuries that occur secondary to cauterization or coagulation may present several days to a few weeks after surgery. Symptoms may vary from pain, bloating, ileus, leukocytosis, and urinary ascites. Serum creatinine levels may be normal or elevated with intraabdominal leaking of urine. If levels are elevated in the presence of fever or ileus, imaging studies should be considered. With the increase in laparoscopic and robotic surgery, the incidence of thermal injury to the urinary tract has significantly increased. There is a fourfold increase in urinary tract injury in laparoscopic hysterectomies compared with supracervical cases (Harmanli, 2009). Many injuries go unrecognized at the time of surgery, resulting in readmission. In cases in which the injury is seen at or around the time of surgery, immediate treatment facilitates healing of the defect before epithelialization of the aberrant tract occurs. Spontaneous healing usually occurs within the first 4 weeks. With a ureteral fistula, follow-up imaging should be considered to detect delayed ureteral strictures.

Operative repair of a vesicovaginal fistula is usually accomplished via a multilayered closure performed by the vaginal route. The principles for a successful operation include the following: adequate exposure, dissection, and mobilization of each tissue layer; excision of the fistulous tract; closure of each layer without tension on the suture line; and excellent hemostasis with closure of the dead space. Reliable bladder drainage is provided to avoid tension on the suture line for approximately 10 days. The Latzko operation is the simplest means of repairing a fistula at the vaginal apex. This technique of partial colpocleisis involves denudation of the vaginal mucosa surrounding the fistula and subsequent multilayer closure. The primary disadvantage of the procedure may be postoperative shortening of the vagina.

Many ureteral injuries discovered during the immediate postoperative period will heal when treated by percutaneous nephrostomy and ureteral catheters. Ureterovaginal fistulas that do not heal spontaneously are usually repaired 2 to 3 months after the original operation. Reimplantation of the ureter into the bladder is the preferred repair for an injury involving the lower third of the ureter.

GASTROINTESTINAL COMPLICATIONS

POSTOPERATIVE DIET

Most patients may be given a regular diet as soon as tolerated after elective gynecologic surgery, including patients that undergo bowel resection. This section discusses nausea and postoperative gastrointestinal (GI) complications, as well as glycemic control as it relates to postoperative nutrition. Part of the physiologic stress response to surgery is a drive for gluconeogenesis. This process is enhanced by a hormonally mediated insulin resistance. The

resultant hyperglycemia is advantageous in the teleological sense of the fight-or-flight response, but it is detrimental for wound healing, cardiovascular function, and inflammatory processes. Several studies have correlated clinical outcomes with glucose levels. The American Association of Endocrinology has noted an 18-fold increase in hospital mortality in general medicine and general surgery patients with glucose levels above 200 mg/dL (Garber, 2004).

Glucose control begins preoperatively and is discussed in Chapter 24. Women who are given insulin infusions during surgery should have their infusions continued until they are tolerating regular meals. At this point, they may be given subcutaneous insulin, if necessary. Metformin is often avoided in the perioperative setting because of the potential risks of lactic acidosis. There is no clear consensus, but stopping metformin for 24 hours prior to surgery, with resumption when the patient resumes full oral intake, appears to adequately limit this risk. In women with a history of insulin resistance, women who are morbidly obese, and those older than 60 years, glucose levels should be checked at the bedside every 4 to 6 hours during the first postoperative day. If a woman's glucose rises above 150 mg/dL, she should be treated.

The American Diabetic Association recommendations suggest that critically ill patients have better outcomes with tighter glucose control—fasting levels less than 110 mg/dL and postprandial levels less than 140 mg/dL. Non-critically ill patients should have fasting levels less than 140 mg/dL and postprandial levels less than 180 mg/dL (Umpierrez, 2012). However, a study of 6100 critically ill patients (NICE-SUGAR) has suggested that tight control of 80- to 108-mg/dL fasting levels may actually be associated with worse outcomes because of complications from iatrogenic hypoglycemia (Finfer, 2009). Studies of non-critically ill patients, in contrast, have found that hyperglycemia is associated with more wound infections. Ramos and associates have noted an increased incidence of infection by 30% for every increase in glucose of 40 mg/dL over the recommended 110 mg/dL (Ramos, 2008).

Sliding scale insulin treatments, though less effective than intravenous infusions in the first 24 hours, are easier to manage. Sliding scale regular insulin is most appropriate for women without a previous history of diabetes and without risk factors, and those with short surgeries who will resume normal activity and diet within 24 hours. Infusions are preferable if glucose levels are elevated significantly, early in the postoperative course and for women with longer surgeries who will not resume regular eating and activity for a few days. Insulin infusions are begun with concomitant infusions of D₅ half-normal saline (5% dextrose in half-strength normal saline) with 10 mEq of KCl. The Portland Insulin Protocol allows for control of glucose levels and, with nursing support, can be effective (see Appendix A).

When transitioning off insulin infusions, it is reasonable to use the rule of thumb of 80% of the previous 24-hour total insulin dose. This amount may be divided into split doses of NPH insulin or longer acting glargine. Glargine is associated with less hypoglycemia. Initially, a bolus of fast-acting insulin, lispro, may be added with meals. The bedside glucose level is measured every 4 hours. In patients who go home at 24 hours, oral medications or insulin may be restarted at the time of discharge with the same dose as that which was used before the operative period.

POSTOPERATIVE NAUSEA AND GASTROINTESTINAL FUNCTION

Minor disturbances in GI function are a normal consequence of anesthesia, perioperative medications, and surgical manipulation. Most women experience some nausea for approximately 12 to 24 hours, pass flatus some time during the first 48 hours, and have a spontaneous bowel movement by the third or fourth postoperative day after uncomplicated, benign gynecologic surgery.

Table 25.6 Gastrointestinal Information

Category	Clear Liquid (N = 107)	Regular Diet (N = 138)
Morbidity		
Nausea	21 (19.6)	26 (18.8)
Vomiting	10 (9.3)	19 (13.8)
Abdominal distention	10 (9.3)	18 (13.0)
Nasogastric tube use	1 (0.9)	8 (5.8)
Tolerance		
Diet on first attempt	101 (94.4)	121 (87.7)
Regular diet on first attempt	103 (96.3)	
If intolerant, time to tolerance (days)	5.3 ± 1.5	3.6 ± 1.5
Flatus before discharge	55 (51.4)	69 (50.0)
Intervals (days)		
Bowel sounds	1.2 ± 0.5	1.2 ± 0.5
Flatus	2.8 ± 1.4	2.8 ± 1.0
Regular diet*	2.4 ± 2.5	1.1 ± 0.3
Hospital stay	3.6 ± 3.0	3.4 ± 1.7

From Pearl MI, Frandina M, Mahler L, et al. A randomized controlled trial of a regular diet as the first meal in gynecologic oncology patients undergoing intraabdominal surgery. *Obstet Gynecol.* 2002;100:232.

Data presented as mean ± standard deviation or N (%).

*P < .05; no other significant differences between groups.

The current best practice for women after gynecologic surgery including cancer and bowel resections, regardless of age, is clear liquids within 6 hours of surgery and immediate advancement to a regular diet with cessation of nausea and as tolerated by the patient. Traditionally, patients were to have nothing by mouth until the passage of flatus and then given a gradual resumption of diet from clear liquid to full liquid to soft to regular diet, commonly called *step-up diets*. Several studies have shown that delayed feeding such as this is unnecessary and, in some ways, detrimental. Steed and colleagues, in a study of major gynecologic surgeries, including oncologic cases, compared restricted oral intake with step-up diets to early full diet and found no adverse effects, as well as a shorter length of stay in the early feeding group (Steed, 2002). Similarly, a low-residual diet at 6 hours postoperative followed by a regular diet compared with a traditional delayed feeding and a step-up diet after return of bowel function showed more nausea and emesis in the delayed feeding group, with a shorter length of stay in the early feeding group (Kalogera, 2013) (Table 25.6).

Approximately one third of adult women experience postoperative nausea and vomiting (PONV). Several factors affect the likelihood and severity of PONV, including preoperative anxiety, decreased threshold for nausea and vomiting, previous history of PONV, duration of surgery, drugs used for anesthesia, obesity, and postoperative pain medications. Gan and associates, in the 2014 Consensus Guidelines for the Management of Postoperative Nausea and Vomiting, have recommended certain preventive measures (Gan, 2014). These include avoiding general anesthesia with the use of more regional anesthesia, use of propofol for induction and maintenance, avoidance of nitrous oxide and other volatile anesthetics, adequate hydration, and minimizing the perioperative use of opioids. The list of recommended pharmacologic antiemetics for PONV prophylaxis can be seen in Table 25.7. Serotonin is the

Table 25.7 Antiemetics Used for Postoperative Nausea and Vomiting (PONV)

Drugs	Dose	Evidence	Timing	Evidence
Aprepitant	40 mg per os	A2 ^{113,115}	At induction	A2 ¹¹³
Casopitant	150 mg per os	A3 ^{117,118}	At induction	
Dexamethasone	4-5 mg IV	A1 ¹²¹	At induction	A1 ³²⁶
Dimenhydrinate	1 mg/kg IV	A1 ¹⁵²⁻¹⁵⁴		
Dolasetron	12.5 mg IV	A2 ^{84,85}	End of surgery; timing may not affect efficacy	A2 ⁸⁵
Droperidol*	0.625-1.25 mg IV	A1 ^{138,139}	End of surgery	A1 ¹⁴⁰
Ephedrine	0.5 mg/kg IM	A2 ^{223,224}		
Granisetron	0.35-3 mg IV	A1 ⁹¹⁻⁹³	End of surgery	A1 ¹⁰⁸⁻¹¹⁰
Haloperidol	0.5-2 mg IM/IV	A1 ¹⁴⁶		
Methylprednisolone	40 mg IV	A2 ¹³⁷		
Ondansetron	4 mg IV, 8 mg ODT	A1 ^{74,75}	End of surgery	A1 ¹⁰⁷
Palonosetron	0.075 mg IV	A2 ^{105,106}	At induction	A2 ^{105,106}
Perphenazine	5 mg IV	A1 ¹⁶²		
Promethazine	6.25-12.5 mg IV	A2 ^{222,295}		
Ramosetron	0.3 mg IV	A2 ¹⁰²	End of surgery	A2 ¹⁰²
Rolapitant	70-200 mg per os	A3 ¹¹⁹	At induction	
Scopolamine	Transdermal patch	A1 ^{157,158}	Prior evening or 2 h before surgery	A1 ¹⁵⁷
Tropisetron	2 mg IV	A1 ⁹⁷	End of surgery	Expert opinion

most important neurotransmitter and intestinal hormone affecting nausea. Serotonin affects the GI nerves and also central nervous system (CNS) receptors, specifically through the 5-hydroxytryptamine (5-HT₃) receptors. It should be no surprise that (5-HT₃) receptor antagonists are effective and perhaps the most studied, specifically ondansetron. However, there are other 5-HT₃ receptor antagonist medications, as well as neurokinin-1 (NK-1) receptor antagonists, corticosteroids, butyrophenones, antihistamines, and anticholinergics, that have activity and are currently used in clinical practice.

A randomized clinical trial of 5199 patients by Apfel and colleagues has examined several regimens for the prophylaxis of PONV. This multicenter trial documented several important principles for postoperative management. The antiemetic interventions of dexamethasone, ondansetron, and droperidol were found to be equally effective for treating nausea. Droperidol is associated with a rare but problematic side effect of prolonged QT intervals and has subsequently led to most pharmacies removing this medication from their formularies. Dexamethasone, 2.5 to 5 mg, should be given at the beginning of surgery to be most effective. The repeat use of medications for rescue effects is less efficacious if an agent has been given previously (Apfel, 2004). Previous studies have found that agents such as metoclopramide are ineffective for prophylaxis. Antiemetics in the phenothiazine class, such as promethazine and prochlorperazine, are effective but have some limitations because of side effects of sedation, dry mouth, and extrapyramidal effects, which may be worse for older women. Although ondansetron is the gold standard to which other antiemetics are compared, it is less effective than aprepitant for reducing emesis and Palonosetron on the incidence of PONV.

Apfel and associates' study also looked at risk factors for PONV, and one of the strongest is female gender (RR, 3.13; 95% CI: 2.33-4.20). Thus all women should be considered for prophylactic measures. Other factors include 1.78 RR (95% CI: 1.35-2.95) for patients with hysterectomies, 1.57 RR (95% CI: 1.32-1.07) for nonsmokers, and 2.14 (95% CI: 1.75-2.61) for use of postoperative opioids (Apfel, 2004). With patients going home within 24 hours of surgery, the term *postdischarge nausea and vomiting* (PDNV) is used. Several small randomized controlled trial (RCTs) have demonstrated efficacy in preventing PDNV with orally disintegrating ondansetron tablets, acupoint stimulation of P6, and transdermal scopolamine patches.

ILEUS

Ileus is a delay in the normal return of bowel function caused by an inhibition of the normal propulsive reflexes of the bowel that are regulated by the autonomic nervous system. Adynamic (paralytic) ileus is a misnomer, as it is a normal event defined as delayed bowel function of minor to moderate degree in the absence of a mechanical obstruction. It may be expected to follow any intraperitoneal or pelvic operation. Brief declines in the motility of the GI tract are normal responses after surgery, and the stomach returns to full motility within 24 hours. However, some gastric secretions will continually pass into the duodenum. The stomach secretes 500 to 1000 mL of fluid/day, making the total output from the upper tract approximately 1 to 1.5 L daily. The pancreas secretes an additional liter. The small intestine resumes peristalsis within 6 hours after surgery. The right colon

resumes full motility in about 24 hours, but the left colon may take up to 72 hours. The incidence and duration of adynamic ileus are less following vaginal or laparoscopic hysterectomy than abdominal hysterectomy. If the delay in bowel function persists longer than 5 to 7 days, the patient has an ileus and one should also consider the possibility etiologies: either a mechanical cause such as a bowel obstruction or some other condition leading to an adynamic, or paralytic, ileus such as an infection or retained foreign body.

Ileus, or specifically adynamic ileus, is believed to result from a lack of coordinated motor activity of the intestine, which results in disorganized propulsive activity. Electrical activity is present, but the pathophysiologic problem is continuous activity of the intrinsic inhibitor neurons in the wall of the small intestine. Usually, the process is generalized, but occasionally may be localized, involving only an isolated loop of bowel. The cause of prolonged postoperative ileus is a subject of continued debate. Generally, the mechanisms include an increased neurologic inhibition of intestinal motility caused by sympathetic nerve activity, as well as an inflammation within the intestinal wall. Bauer and Boeckxstaens have described leukocytic infiltration secondary to cytokine production from manipulation of the bowel during surgery. The inflammation inhibits the appropriate neuromuscular reactions, which then decrease motility (Bauer, 2004). Postoperative narcotics also contribute to the problem by stimulating the opioid receptors increasing the dyssynchronous contractions that are the hallmark of an ileus, further decreasing motility and increasing pain.

The classic symptoms of a prolonged ileus include absence of flatus, abdominal distention, and obstipation. Often, these symptoms are associated with nausea and effortless vomiting. Bowel sounds may be hypoactive or absent. This condition may be associated with abdominal tenderness and the abdomen is usually tympanic to percussion. Nausea and vomiting that persist more than 24 hours after surgery are a cause for concern. Diagnostic films of the abdomen (supine, erect, lateral) may help establish the correct diagnosis but are frequently overutilized (Table 25.8). CT scanning has also been found to be a useful test for differentiating adynamic ileus from complete obstruction (Mattei, 2006).

Table 25.8 Differential Radiographic Findings in Ileus and Mechanical Obstruction

Adynamic Ileus	Mechanical Obstruction
Small and large bowel distended in proportion to each other	In small bowel obstruction, there is dilated small bowel proximal to site of obstruction; in colonic obstruction, the colon is distended and small bowel distention is present with an incompetent ileocecal valve
Air-fluid levels in small bowel infrequent; when present, they at the same levels	Air-fluid levels are common and at different levels in the bowel
Quantitative difference in small bowel distention	Greater small bowel distention than with ileus
Small bowel distention in central part of abdomen with colon in periphery	Small bowel distention present in central part of abdomen; no peripheral large bowel distention

From Buchsbaum HJ, Mazer J. The gastrointestinal tract. In: Buchsbaum HJ, Walton LA, eds. *Strategies in Gynecologic Surgery*. New York: Springer-Verlag; 1986.

Table 25.9 Treatment Options for Postoperative Ileus

Treatment	Potential Mechanism	Comments
Nonpharmacologic Options		
Nasogastric tube	Gastric, small bowel decompression	No evidence nasogastric tubes reduce duration of POI May increase pulmonary postoperative complications pulmonary postoperative complications
Early enteral nutrition	Stimulates gastrointestinal motility by eliciting reflex response and stimulating release of several hormonal factors	Appears safe, well tolerated Some, but not all, studies suggest decrease in POI
Sham feeding	Cephalic-vagal reflex	Small clinical trials suggest some benefit
Early mobilization	Possible mechanical stimulation	No significant change in duration of POI but may decrease other postoperative complications
Laparoscopic surgery	Decreased opiate requirements, decreased pain, less abdominal wall trauma	Most studies find decreased duration of POI with laparoscopy
Psychological preoperative preparation	Improves bowel motility through visceral learning	One study found positive benefit in decreasing time to flatus and hospital discharge
Pharmacologic Treatment Options		
Metoclopramide	Dopamine antagonist, cholinergic agent	Possibly effective, withdrawn from U.S. market due to cardiovascular side effects Two RCTs suggest no benefit One RCT shows ADL8-2698 decreases time to flatus, bowel movement, and hospital discharge, but not currently available outside of clinical trials Other agents have not been evaluated in POI movement, and hospital discharge, but not currently available outside of clinical trials Other agents have not been evaluated in POI Several RCTs suggest benefit in decreasing POI, most effective when inserted at thoracic level Probable benefit. COX-2 selective medications need further evaluation No RCTs One nonrandomized, unblinded study suggests possible benefit Little practical benefit in POI drugs often limited by cardiovascular side effects Frequent systemic side effects Neostigmine has possible benefit Possible benefit in reducing POI No RCTs have been reported
Cisapride	Dopamine antagonist, cholinergic agonist, serotonin receptor agonist	
Erythromycin	Motilin agonist	
Opiate antagonists	Block peripheral opiate receptors	
Epidural anesthesia	Inhibits sympathetic reflex at cord level, opioid-sparing analgesia	Several RCTs suggest benefit in decreasing POI, most effective when inserted at thoracic level Probable benefit. COX-2 selective medications need further evaluation No RCTs One nonrandomized, unblinded study suggests possible benefit Little practical benefit in POI drugs often limited by cardiovascular side effects Frequent systemic side effects Neostigmine has possible benefit Possible benefit in reducing POI No RCTs have been reported
NSAIDs	Opiate-sparing analgesia, inhibits COX-mediated prostaglandin synthesis	
Laxatives	Stimulant, prokinetic effects	
Antiadrenergic agents	Blocks sympathetic neural reflex	
Cholinergic agents	Acetylcholine modulation	
Multimodality therapy	Combination therapy may work via multiple mechanisms	

From Behm B, Stollman N. Postoperative ileus: etiologies and interventions. *Clin Gastroenterol Hepatol*. 2003;1(2):71-80.

COX, Cyclooxygenase; NSAIDs, nonsteroidal anti-inflammatory drugs; POI, postoperative ileus; RCTs, randomized controlled trials.

Oral administration of radiocontrast material may be both therapeutic and diagnostic. The osmolality of the radiocontrast material is approximately six times greater than that of normal saline. Thus a large amount of fluid enters the small bowel and acts as a direct stimulant of peristalsis. In one study, after preliminary abdominal films were obtained, a dosage of 120 mL of 66% diatrizoate meglumine, 10% diatrizoate sodium (Gastrografin), was administered orally or via nasogastric tube. Passage of liquid stool occurred within a few hours in patients with adynamic ileus. Gastrografin, unlike barium, is nontoxic if it accidentally contaminates the peritoneal cavity during an operation for bowel obstruction.

Early carbohydrate intake, as well as postoperative gum chewing, has demonstrated some efficacy in decreasing the rates of postoperative ileus and promoting the return of normal bowel function. In addition, a carbohydrate loading drink the night before surgery and allowing fluids up to 4 hours before surgery may assist with postoperative recovery as well (Kalogera, 2013). It is also known that early feeding decreases the incidence of

postoperative ileus, most likely through stimulation of intestinal reflexes. The workup of postoperative ileus should include evaluation of serum electrolyte and magnesium levels, because hypokalemia and abnormal magnesium levels may contribute to the ileus. Narcotics, intraabdominal infection, urinary ascites, and retroperitoneal hematomas may all affect GI motility. The management of a postoperative ileus is controversial, with numerous remedies that are unproved but demonstrate isolated, anecdotal success (Table 25.9).

Severe adynamic ileus is a self-limiting condition that responds to GI rest, IV fluids, and time. During the period of watchful expectancy, adequate fluid and electrolyte replacement is necessary. Patients experience mild cramping and passage of flatus and regain their appetite with the return of normal peristalsis. If adequate bowel sounds are present, a rectal tube, a Fleet enema, or a rectal suppository may facilitate the initial passage of flatus. Some advocate the routine postoperative administration of a "wetting agent," such as simethicone, to reduce surface tension of intestinal mucus and liberate entrapped gas. Opinions

Table 25.10 Average Daily Volume and Electrolyte Concentrations of Gastrointestinal Secretions

Secretion	Volume (mL/day)	ELECTROLYTE CONCENTRATION (mEq/L)		
		Na ⁺	K ⁺	Cl ⁻
Saliva	1000-1500	10-40	10-20	6-30
Gastric juice	2000-2500	60-120	10-20	10-30
Hepatic bile	600-800	130-155	2-12	80-100
Pancreatic juice	700-1000	150-155	5-10	30-50
Duodenal secretions	300-800	90-140	2-10	70-120
Jejunal and ileal secretions	2000-3000	125-140	5-10	100-130
Colonic mucosal secretions	200-500	140-148	5-10	60-90

*Present in solution as lactate but is metabolized to bicarbonate.

are mixed as to whether such an agent reduces the incidence or intensity of adynamic ileus. Randomized trials of the prokinetic agents erythromycin and metoclopramide have shown these agents to be ineffective in relieving ileus. Importantly, prophylactic nasogastric suctioning will not prevent ileus. In many studies, prophylactic nasogastric suctioning is associated with an increased risk of aspiration as well as an increased rate of ileus—the very symptom the treatment is supposed to prevent (Nelson, 2007). However, if a severe ileus does not resolve, nasogastric suctioning is necessary. Nasogastric suction prevents progression of the intestinal distention. During periods when nasogastric suctioning is used, special attention should be given to correct replacement of fluid and electrolytes (Tables 25.10 and 25.11). A rare but worrisome complication of prolonged ileus is massive dilation of the cecum. Massive dilation of the colon related to a pseudo-obstruction produced by severe adynamic ileus in the absence of mechanical obstruction is known as Ogilvie syndrome. This condition may be treated medically by evacuating the air with colonoscopy or rectal tube, and in severe cases, cecostomy may be necessary. An alternative method of treating this condition is IV neostigmine.

INTESTINAL OBSTRUCTION AND ADHESIONS

Adhesions are the most common cause of postoperative intestinal obstruction. During subsequent operations, up to 90% of women are found to have some adhesions following abdominal laparotomy, although most are filmy. In a large retrospective cohort study covering a 10-year period following laparotomy for gynecologic conditions, approximately one in three women had

adhesion-related readmissions to the hospital (Ellis, 1999). Less common causes of intestinal obstruction are hernias, mesenteric defects, intussusception, volvulus, and neoplasm. Large raw areas of the pelvis with hypoxic tissue facilitate the attachment of small intestine following pelvic surgery. Previous gynecologic surgeries are the most common cause of small bowel obstruction in women. The incidence of operation for obstruction of the small intestine after an abdominal hysterectomy is estimated to be approximately 2%. Interestingly, in one series, adhesions involving the pelvic peritoneum were responsible for the intestinal obstruction in 85% of cases, and adhesions to the closure of the anterior abdominal wall accounted for the other 15%. Fortunately, the fibrous adhesions that form during the first 2 to 3 weeks after an operation are soft and filmy. Thus intestinal strangulation during the postoperative period is extremely rare. Dense adhesions may develop several months after surgery. Adhesion formation after surgical procedures appears to be related to irritation of the peritoneum. The reaction of injured peritoneum involves a reepithelialization by peritoneal cells to cover raw intra-abdominal surfaces. The process begins within 24 hours of surgery. Fibrin-rich exudates cover areas of denuded viscera and abdominal wall. Factors that increase adhesion formation include inflammation, infection, and trauma. Thus suturing of peritoneum should be kept to a minimum. The greatest risk, as noted by Dubuisson and colleagues in a series of 1000 consecutive laparoscopies, was in previous midline incisions, with more than 50% having adhesions, compared with less than 3% after a previous laparoscopy (Dubuisson, 2010). The incidence of intestinal obstruction depends on the type of gynecologic surgery performed. Approximately 2/1000 women develop an obstruction

Table 25.12 Differential Diagnosis between Postoperative Ileus and Postoperative Obstruction

Clinical Features	Postoperative Ileus	Postoperative Obstruction
Abdominal pain	Discomfort from distention but not cramping pains	Cramping, progressively severe
Relationship to previous operation	Usually within 48-72 hr of operation	Usually delayed; may be 5-7 days for remote onset
Nausea and vomiting	Present	Present
Distention	Present	Present
Bowel sounds	Absent or hypoactive	Borborygmi with peristaltic rushes and high-pitched tinkles
Fever	Only if related to associated peritonitis	Rarely present unless bowel becomes gangrenous
Abdominal radiograph	Distended loops of small and large bowels; gas usually present in colon	Single or multiple loops of distended bowel, usually small bowel with air-fluid levels
Treatment	Conservative with nasogastric suction, enemas, cholinergic stimulation	Partial—conservative with nasogastric decompression, or Complete—surgical

after a benign gynecologic operation, whereas approximately 8% develop intestinal obstruction after radical cancer surgery. Intestinal obstruction occurs in the small intestine in approximately 80% of cases and in the colon in the remaining 20%. As noted, differentiating between bowel obstruction and ileus can be difficult in the postoperative period (Table 25.12).

The acute symptoms of intestinal obstruction usually present between the fifth and seventh postoperative days. Most patients have a short period of normal intestinal function before the onset of symptoms. Women with bowel obstruction appear to have more acute distress than women with an ileus. The abdominal pain is intermittent, colicky, and may be sharp in nature. Episodes of colicky pain usually last from 1 to 3 min. Associated symptoms include vomiting, abdominal distention, and constipation. Bowel sounds are loud, high pitched, and rushing. Nasogastric drainage is usually more profuse than in patients with severe adynamic ileus.

Abdominal radiographs demonstrate a stepladder appearance—multiple air-fluid levels throughout the small intestine, with a paucity of gas in the colon and rectum. Pneumoperitoneum from an exploratory celiotomy usually persists for up to 7 days. Thus in the early postoperative period, free air under the diaphragm is not diagnostic of perforation of a hollow viscus. Obstruction of the colon may be diagnosed by retrograde infusion of contrast material or by flexible endoscopy.

The foundation of early treatment of postoperative intestinal obstruction is decompression of the small intestine and adequate replacement of fluids and electrolytes. Decompression may be accomplished by means of a nasogastric tube. Serial monitoring of white blood cell counts with differentials should be performed. Repeat physical examinations and abdominal radiographic examinations are used to assess the degree of intestinal distention. Expectant management is successful in the majority of patients. Historically, less than 40% of patients with small bowel obstruction caused by adhesions will require surgery. Some advocate for immediate administration of Gastrografin upon presentation for adhesive obstruction with conservative management of patients in whom Gastrografin dose not reach the colon in 24 hours. Patients in whom contrast reached the colon in 5 hours or less had a 90% success rate of conservative management (Gowen, 2003).

The major cause of morbidity and death with bowel obstruction is delay in diagnosis, with resultant strangulation, perforation and secondary sepsis. Women who develop strangulation experience a dramatic increase in the intensity of abdominal pain, and

the pain becomes continuous. Strangulation of the small bowel is associated with localized peritoneal irritation, increase in temperature, and marked leukocytosis. Bowel obstruction may also lead to translocation of intestinal bacteria across the bowel wall, promoting sepsis. It has been shown that the more distal the obstruction, the greater the incidence of anaerobic septicemia.

Fecal impaction is most often seen in older patients. It results from loss of peristalsis in the colon, with an impaired perception of rectal fullness. This may result in diarrhea as intestinal contents pass around the impaction or obstipation. Treatment involves obtaining partial analgesia with lidocaine jelly and, subsequently, manually fragmenting and extracting the fecal mass.

RECTOVAGINAL FISTULA

Rectovaginal fistulas and fecal incontinence secondary to perineal tears are usually obstetric complications and are only rarely associated with gynecologic surgery. In general, rectovaginal fistulas following hysterectomy or repair of an enterocele are usually located in the upper third of the vagina, whereas those secondary to a posterior colporrhaphy are in the lower third of the vagina. Other causes of rectovaginal fistula are carcinoma, radiation therapy, perirectal abscess, inflammatory bowel disease, lymphogranuloma venereum, and trauma.

The initial signs and symptoms associated with potential fistulous tracts between the rectum and vagina usually present 7 to 14 days after an operation. The first warning may be the rectal passage of several blood clots, indicating that a hematoma has ruptured into the rectum. Distressing symptoms include passage of gas from the vagina and, depending on the size of the opening, the passage of fecal material from the vagina. Associated with these classic symptoms and signs are a chronic, foul-smelling vaginal discharge and subsequent dyspareunia. Aside from the physical symptoms of the anatomic defect, fistulas cause severe emotional distress because they affect almost every aspect of the woman's daily life.

The diagnosis is not difficult to establish, and only very small openings present a diagnostic problem. What appears to be granulation tissue in the posterior aspect of the vagina is the dark red rectal mucosa, which stands out in contrast to the lighter vaginal mucosa. Usually, the defect may be successfully defined with a small, malleable metal probe. If this is not successful, a Foley catheter should be placed in the rectum. Methylene blue dye or milk may then be instilled into the rectum with a tampon in the vagina, similar to the procedure for establishing the diagnosis of

Table 25.13 Differences between Antibiotic-Associated Diarrhea from *Clostridium difficile* and Diarrhea from Other Causes

Characteristic	CAUSE	
	<i>C. difficile</i> Infection	Other Causes
Most commonly implicated antibiotics	Clindamycin, cephalosporins, penicillins	Clindamycin, cephalosporins, or amoxicillin-clavulanate
History	Usually no relevant history of antibiotic intolerance	History of diarrhea with antibiotic therapy common
Clinical Features		
Diarrhea	May be florid; evidence of colitis with cramps, fever, and fecal leukocytes common	Usually moderate in severity (i.e., nuisance diarrhea) without evidence of colitis
Findings on CT or endoscopy	Evidence of colitis (not enteritis) common	Usually normal
Complications	Hypoalbuminemia, anasarca, toxic megacolon, relapses with treatment with metronidazole or vancomycin	Usually none except occasional cases of dehydration
Results of assay for <i>C. difficile</i> toxin	Positive	Negative
Epidemiologic pattern	May be epidemic for endemic in hospitals or long-term care facilities	Sporadic
Treatment		
Withdrawal of implicated antibiotic	May resolve but often persists or progresses	Usually resolves
Antiperistaltic agents	Contraindicated	Often useful
Oral metronidazole or vancomycin	Prompt response	Not indicated

From Bartlett JG. Antibiotic-associated diarrhea. *N Engl J Med*. 2002;346(5):334-339. CT, Computed tomography.

a vesicovaginal fistula. Contrast enemas and colonoscopy may also be used in cases where there is a high degree of suspicion and the fistula cannot be identified by other means.

For initial treatment the woman should be obstipated with a low-residue diet and diphenoxylate hydrochloride (Lomotil). Approximately one in four anatomic defects heal spontaneously before epithelialization of the tract. A low-residue diet or hyperalimentation may be helpful in facilitating spontaneous closure of some anatomic defects. Timing of the operative repair is important. The gynecologist should inspect the area surrounding the fistula to ensure that the tissues are free of edema, induration, and infection. Preoperative evaluation includes visualization of the entire vagina and sigmoidoscopy of the rectal mucosa in an attempt to discover more than one opening. Imaging studies and endoscopy are important diagnostic tools if there is any suspicion of coexistence of Crohn disease.

The operative technique used depends on the size and location of the fistula. Standard operative principles include removal of the entire fistulous tract and closure of tissue layers without tension on the suture line. In the repair of large rectovaginal fistulas in the lower part of the vagina, it is usually easier to convert the rectovaginal fistula into a fourth-degree laceration. Diverting colostomy should be used for all radiation-induced fistulas, most fistulas associated with inflammatory bowel disease, and some large postoperative fistulas at the apex of the vagina. The stool should be kept soft with low-residue diets and stool softeners such as mineral oil for the first 2 weeks after the operative repair.

ANTIBIOTIC-ASSOCIATED DIARRHEA

Patients may develop diarrhea in the postoperative period after exposure to antibiotics. Oral and parenteral antibiotics produce similar rates of diarrhea, with some studies noting that up to one third of patients receiving antibiotics will develop diarrhea. Antibiotic therapy, for prophylaxis or treatment, can disrupt the normal intestinal flora. The result is a disturbed breakdown of bile acids and carbohydrates that induce loose stools. Diarrhea

may develop secondary to medications other than antibiotics, including oral contrast media, diabetic foods that contain artificial sweeteners, and many cardiac medications. If the woman is afebrile, the diarrhea is mild, and the abdominal examination is unremarkable, stopping or changing antibiotics and providing supportive care are all that is necessary. If the woman has a temperature higher than 38° C, a leukocytosis, abdominal tenderness, severe abdominal distention, bloody diarrhea, or persistent diarrhea, evaluation for *Clostridium difficile* infection is indicated (Table 25.13).

C. difficile is a species of spore-forming, gram-positive anaerobic bacteria found normally in 5% of healthy adults. However, after antibiotic treatment and disruption of normal enteric flora, up to 25% of hospitalized adults will become colonized with *C. difficile*. The organism is spread by nosocomial oral-fecal contamination. Persistence of the spores of *C. difficile* and contamination of the environment are primary factors in cross infection. After colonizing the intestine, the organism may secrete toxins, which produce a spectrum of clinical disease. Symptoms from the infection are varied and range from a mild diarrhea to colitis to a pseudomembranous colitis that in rare cases may be fatal (Bartlett, 2002). Almost any antibiotic has been associated with the development of *C. difficile* diarrhea, but second- and third-generation cephalosporins are the antibiotics associated with the highest risk of developing *C. difficile* diarrhea. Symptoms usually appear 5 to 10 days after the initiation of antibiotic therapy; however, they may appear from a few days to a few weeks after antibiotic exposure. Enzyme-linked immunosorbent assay (ELISA) testing for *C. difficile* cell cytotoxin B in the stool is the gold standard for diagnosis because it is the most sensitive and specific and is also relatively inexpensive. The results are usually available within 24 hours.

Use of drugs that slow intestinal transit time, such as diphenoxylate atropine (Lomotil) or narcotics, are definitely contraindicated because the toxins of *C. difficile* remain in the GI tract for a longer period. Therapy for the infection is metronidazole 500 mg PO three times daily or 250 mg PO four times

daily. Alternatively, vancomycin PO 125 mg four times daily can be used. Metronidazole therapy has a lower cost and 90% clinical cure rate, so is often preferred as first-line treatment. Vancomycin has a higher cure rate, 98%, and should be used in cases not responsive to metronidazole. Gastrointestinal symptoms usually improve within the first 72 hours of therapy and complete resolution of symptoms occurs within 10 days. Host factors are involved in the pathogenesis of the disease; older and more chronically ill patients usually develop more severe symptoms. Up to 25% of women may develop a recurrence or relapse. Studies have confirmed that more than 50% of recurrences of symptoms after initial response to treatment are caused by reinfection rather by a relapse. Recurrences usually can be successfully treated with oral antibiotics using longer courses (Bartlett, 2002).

WOUND COMPLICATIONS

INFECTION

A major wound infection prolongs the hospital stay by approximately 2 to 6 days. In a historic review of 23,649 operations, the incidence of abdominal wound infection after abdominal hysterectomy was approximately 5%. Contemporary studies show rates of surgical site infection after hysterectomy of 3.9% for abdominal surgery and 1.8% for minimally invasive approaches ($P < .001$), with an odds ratio of 0.44 (CI 0.37-0.53) (Gandaglia, 2014). Hysterectomy is classified as a clean-contaminated operative procedure because the bacterial flora of the vagina is in continuity with the operative site during the surgery. The Centers for Disease Control and Prevention have revised their nomenclature describing incisional infection. They subdivide incisional infections into superficial infections that involve only the skin and subcutaneous tissue and deep infections that involve the deep soft tissues, including fascia and muscles. Although some infections are generally associated with specific organisms such as streptococcus or clostridia, most gynecologic infections are polymicrobial. Thus antibiotic treatments are aimed at providing broad-spectrum coverage for aerobic, anaerobic, and gram-negative organisms. A list of common antibiotics is found in Appendix B.

The pathophysiology of wound infection depends on an interaction between the number and virulence of bacterial contamination and the resistance of the woman. Inoculation of bacteria into the wound occurs in the operating room during the surgical procedure. A wide spectrum of common endogenous bacteria produce wound infections, including most gram-positive cocci and aerobic and anaerobic rods. Small numbers of bacteria are present in all surgical wounds; however, bacterial growth is facilitated by decreased tissue oxygen and excessive amounts of necrotic tissue. It takes from 100,000 to 1,000,000 bacteria/g of tissue to produce infection in a surgical wound of the skin and subcutaneous tissue. The incidence of superficial skin infection is directly related to the length of the operative procedure. Each additional hour of surgery results in a doubling of the incidence of superficial skin infections. The primary source of bacterial contamination of an abdominal wound may be exogenous to the woman (e.g., a break in sterile technique) or endogenous (e.g., purulent material from a pelvic abscess).

Local and systemic factors contribute to the level of host resistance and thus to the incidence of wound infections. Local

Box 25.6 Factors Associated with Wound Infections

- Preexisting skin and operative site infection
- Tissue with poor oxygenation
- Hematoma
- Necrotic tissue
- Foreign bodies
- Cauterized tissue
- Poor circulation from vascular disease
- Dead space within the wound
- Anemia
- Decreased perfusion from tension
- Obesity
- Long preoperative hospitalization
- Poor nutrition
 - Vitamin deficiencies
 - Mineral deficiencies (e.g., zinc)
- Glucocorticoids, other immunosuppressive medications
- Diabetes
- Liver disease
- Ionizing radiation
- Advanced age

factors are more significant and include the presence of hematoma, necrotic tissue, foreign bodies, dead space, use of cautery, and decreased local tissue perfusion. Systemic factors include obesity, diabetes, liver disease, malnutrition, immunosuppression, defects in the reticuloendothelial system, age, and duration of preoperative hospitalization (Box 25.6). The incidence of postoperative wound infection is increased eightfold when the woman's preoperative weight exceeds 200 pounds. In a series of women undergoing abdominal hysterectomy, the thickness of subcutaneous tissue was the greatest risk factor for wound infection (Soper, 1995). If an abdominal incision is more than 4 cm in depth, the risk of a superficial skin infection is increased approximately threefold. Multiple regimens and protocols have been studied to decrease rates of wound infection. Skin warming to improve circulation, supplemental oxygen, and antibiotics given before incision time have all been emphasized as techniques for infection prevention.

The first symptom of most wound infections usually appears between the fifth and tenth postoperative days. Wound infection may occur as late as several months following surgery, but more than 90% of cases present within the first 2 weeks of the postoperative period. The first sign is usually fever, followed by tachycardia and varying degrees of increased incisional erythema, induration, tenderness, and pain. As the infection progresses, many wounds develop areas that are fluctuant or firm, and some develop crepitus. There may be associated spontaneous purulent drainage from the wound later in the course of the infection.

Fever during the first 24 to 48 hours is usually secondary to atelectasis. However, two rare types of wound infections are so virulent that they produce toxicity within the first 48 hours. Typically, these early infections are those produced by *Clostridium* spp. and acute β -hemolytic streptococcal infection. Clinically, wound infections secondary to β -hemolytic streptococci appear swollen and red and have an odorless discharge. In contrast, infections secondary to *Clostridium* are boggy and edematous and the discharge has a sweet odor.

Initial treatment of any wound infection consists of opening and draining the wound. Purulent material exhibits a wide

range of consistency from the thin watery discharge typical of a streptococcal infection to the thick purulence associated with staphylococcal subcutaneous infections. Gram staining with aerobic and anaerobic cultures of the wound should be performed. These cultures are valuable in guiding treatment if the woman does not respond to initial management. In such cases, the differential diagnosis would be between infections involving deeper tissue planes and infection for which host resistance has failed, even after drainage of the wound. Once a wound infection has been opened and drained, care is directed toward initial packing of the wound with gauze to effect débridement and periodic irrigation. If necrotic tissue is seen, the tissue should be resected back to the point where vital tissue can be identified. If there is a distinct zone of diffuse erythema surrounding a wound infection, the most likely organism is a streptococcal infection, and IV antibiotics are indicated. If methicillin-resistant *Staphylococcus aureus* (MRSA) is cultured, the great majority of women will respond solely to débridement. If the woman does not respond or responds slowly, antibiotics specific for MRSA should be used, such as clindamycin or sulfamethoxazole-trimethoprim. Systemic antibiotics are always indicated for women with immunosuppression or concomitant disease with impaired defense mechanisms.

Most women with a wound infection will become afebrile within 48 to 72 hours after the wound has been opened and débrided. When the woman becomes afebrile and granulation tissue begins to form, consideration may be given to delayed secondary closure. If the incision is large and débridement has been extensive, closure may be facilitated with the use of vacuum-assisted devices. The vacuum promotes granulation, reduces edema in the subcutaneous tissue, and greatly speeds healing. The vacuum should be changed every 48 to 72 hours for wound evaluation. It may be used on an outpatient basis (Fig. 25.9).

Prevention is the foundation of any approach to the treatment of wound infections. Prevention involves consideration of local and systemic factors, which, if unattended, predispose to infection. Prophylactic antibiotics decrease the incidence of wound infection. These antibiotics are discussed in Chapter 24. If the wound is grossly contaminated, it should be left open after surgery. Delayed primary closure on the third or fourth postoperative day may be appropriate. Women who should be considered as candidates for delayed primary closure include those who are immunosuppressed or malnourished, have advanced malignancies, have a contaminated wound, or are morbidly obese. Delayed primary closure reduces the incidence of wound infection from 23% in a control group to 2%. When delayed primary closure is planned, sutures may be placed at the time of surgery and secured, but not tied. The incision should be packed loosely with gauze. If the wound is dry and without evidence of infection on postoperative day 3, the edges may be approximated with the preplaced sutures.

Delayed secondary closure may be accomplished in previously infected wounds after several days of drainage and débridement, and once the wound exhibits nice healthy granulation tissue. Delayed secondary closure markedly reduces the time necessary for eventual closure of the skin defect by secondary intention. The woman's satisfaction is dramatically increased with delayed secondary closure. If delayed closure does not appear to be a

Figure 25.9 Wound-Vac device on an abdominal wound. The black area is the sponge within the incision. (From Heridge RT, Leong M, Phillips L: Wound healing. In: Townsend CM, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Saunders; 2008:191-216.)

likely option, such as in women who have more than 3 cm of subcutaneous tissue, application of a closed vacuum system can be initiated.

A virulent, rapidly progressing form of soft tissue wound infection is necrotizing fasciitis. Often, the diagnosis is not suspected during the early part of the infection because of the relative minor changes in the skin overlying the deeper infection. The early symptoms are local pain with systemic symptoms of tachycardia and fever, which are higher than would be expected with an uncomplicated wound infection. The woman may experience marked tenderness when the infected area is palpated. Conversely, necrotic tissue may become hypoesthetic, or completely numb. An appearance of an area that appears infected but is anesthetic should heighten the suspicion for the diagnosis of necrotizing fasciitis. As the disease progresses, the wound edges usually darken, with crepitation and bullae formation and anesthetic areas developing. Necrotizing fasciitis involves the subcutaneous tissue and superficial fascia. The infection rapidly expands in the subcutaneous spaces and often tracks far beyond the superficial margins of the involved skin.

This condition is a life-threatening surgical emergency and patients should have débridement as soon as possible. It is important for the gynecologist to have a high degree of suspicion for this condition because even with adequate surgical débridement, the mortality rate is 30% to 50%. Only 35% of patients with necrotizing fasciitis will display radiographic evidence of subcutaneous gas. If the diagnosis is questionable, a full-thickness core biopsy and frozen section of the tissue should be performed. This rare but potentially fatal condition necessitates wide débridement of all necrotic tissue, high levels of broad-spectrum antibiotics, and sometimes hyperbaric oxygen. Débridement to freely bleeding tissue helps determine the surgical margin. It is not unusual for the woman to need repetitive débridement. Women with diabetes, malnutrition, immunosuppression, malignancy, obesity, and poor tissue perfusion are most susceptible to this complication.

DEHISCENCE AND EVISCERATION

Dehiscence is a failure of normal healing and refers to a disruption of any of the layers of a surgical incision. The physiologic, biochemical, and structural changes that characterize normal wound healing are complex and, at best, imperfectly understood. However, the most important fact for the clinician is that the strength of the wound increases over time (Fig. 25.10). The strength of a skin incision increases at a rapid and almost constant rate for the first 4 months and at a much slower rate for the first year. Clinically, a wound dehiscence refers to the separation of the skin, subcutaneous tissue, and fascia, but not peritoneum. This complication usually occurs during the first several days following an operation. Wound evisceration is a complete breakdown of the healing process through all levels of the abdominal incision, with omentum or bowel presenting through the fascia.

The incidence of wound dehiscence is approximately 1 in 200 gynecologic operations. The major short-term result of wound dehiscence is the prolongation of hospital stay. Over the long term, dehiscence predisposes to incisional hernias. Wound

infection is present in approximately 50% of women with wound disruption. As with wound infections, preventive management is the most important therapeutic consideration. The incidence of dehiscence has decreased with the use of longer lasting and stronger sutures. Many clinicians prefer to use polydioxanone suture (PDS), a treated Vicryl, or a permanent suture such as polypropylene (Prolene) for greater strength and prolonged presence in the tissue. The rule of thumb is that the suture should remain strong in the tissue until the tissue can resume its original strength. In patients with a propensity for poor or prolonged healing, such as women with malignancy, diabetes, or immune suppression, the use of a permanent suture should be strongly considered. When infection is present, a monofilament suture is preferable to a braided or polyfilament suture (Tables 25.14 and 25.15).

The consensus regarding fascial disruption is that local factors are much more important in the pathophysiology of wound disruption than systemic factors, although both should be considered. Important mechanical factors predisposing to disruption are conditions that increase the tension on the incision line, such as abdominal distention and chronic lung disease, or a technically inadequate closure of the wound. Other factors include obesity, advanced age, malignancy, uremia, liver failure, diabetes, hypoproteinemia, hematoma formation, sepsis, corticosteroids or chemotherapy, prior radiation therapy, and whether the incision is made through an area of a previous incision. Whether an incision is horizontal or vertical has little effect on the incidence of wound disruption. The pathophysiology of fascial dehiscence involves exaggerated collagen lysis in the wound. Clinically, the sutures tear through the fascia rather than dissolving or becoming untied. For example, approximating and tying sutures too vigorously, especially with a figure-of-eight suture, may lead to strangulation and necrosis of the tissue and subsequent wound dehiscence. Primary mass closure with a continuous monofilament, delayed absorbable suture, helps avoid this problem in high-risk patients.

The classic symptom and sign of wound disruption is the spontaneous passage of copious serosanguineous fluid from the abdominal incision. This usually occurs between the fifth and eighth postoperative days. Patients with uninfected wounds generally have been asymptomatic, but often report a “pop” after

Figure 25.10 Wound healing over time. (From Heridge RT, Leong M, Phillips L. Wound healing. In: Townsend CM, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Saunders; 2008:191-216.)

Table 25.14 Comparison of Absorbable Sutures

Suture Reaction	Types	Raw Material	Tensile Strength Retention in Vivo	Tissue
Surgical gut suture	Chronic	Collagen derived from healthy beef and sheep	Individual patient characteristics can affect rate of tensile strength loss.	Moderate reaction
Monocryl suture (poligle-caprone 25)	Monofilament	Copolymer of glycolide and epsilon-caprolactone	~50%-60% (violet, 60%-70%) remains at 1 wk; ~20%-30% (violet, 30%-40%) remains at 2 wk; lost within 3 wk (violet, 4 wk)	Minimal acute inflammatory reaction
Coated vicryl (polyglactin 910)	Braided	Copolymer of lactide and glycolide coated with 370 and calcium stearate	~75% remains at 2 wk	Minimal acute inflammatory reaction
Suture PDS II suture (polydioxanone)	Monofilament	Polyester polymer	~50% remains at 3 wk, 25% at 4 wk	Slight
	Monofilament		~70% remains at 2 wk; ~ 50% remains at 4 wk; ~ 25% remains at 6 wk	

Modified from Neumayer L, Vargo D. Principles of perioperative and operative surgery. In: Townsend CM, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Saunders; 2008:251-279.

an episode of coughing or emesis. Patients who develop wound defects often lack the normal healing ridge of tissue that can be palpated in normal healing wounds.

Imperative for prevention of wound dehiscence is proper closure of the incision in a woman at high risk for less than optimum healing. Although there are many regional preferences for the choice of suture and method of closure, the most popular technique is some modification of the Smead-Jones closure with permanent suture (Fig. 25.11). Closure with the Smead-Jones technique results in a dehiscence rate of approximately 1 in 1000 operations. With this technique, it is important to place individual sutures at least 1 to 1.5 cm away from the adjacent sutures and include at least 2 cm of fascia on either side of the incision. The alternative technique is the more common, running mass closure using a monofilament permanent suture material such as nylon or Prolene.

Rarely, the vaginal cuff may separate, producing a dehiscence and possibly vaginal evisceration of abdominal contents. This complication often presents with sudden vaginal drainage, bleeding, and pain. The incidence of vaginal cuff dehiscence varies by mode of surgery and is lowest in vaginal hysterectomy (0.11%), followed by abdominal hysterectomy (0.38%), and highest in laparoscopic hysterectomy (range 0.75 to 4.93%) (Hurr, 2011). Risk factors for vaginal cuff dehiscence are summarized in Table 25.16. If there is no evidence of infection at the time of repair, the vaginal cuff may be closed primarily without opening the abdomen. If there is any concern about an intraabdominal complication, an abdominal approach allows for a better intraabdominal evaluation, although reports of laparoscopic evaluation of the abdomen, even in the setting of evisceration with vaginal closure of the cuff, have been successful. Most would also consider antibiotic treatment with broad-spectrum coverage because of the association of vaginal dehiscence with vaginal cuff cellulitis. Vaginal evisceration is uncommon but, when it occurs, it is

usually several weeks after surgery and may follow intercourse. Reports have noted an increase in vaginal cuff disruption and evisceration with robotic surgery. This is postulated to be secondary to increased use of cauterization, leading to poor wound healing (Hurr, 2011). This complication may present up to 8 weeks or more after surgery. As a result, many gynecologists ask patients to refrain from intercourse for up to 12 weeks after surgery to allow time for the sutures to dissolve completely and for the tissue to heal.

The treatment of vaginal dehiscence is prompt reclosure in the operating room. Once the diagnosis is recognized, the wound and viscera should be covered with moist gauze and transported to the operating room supine and possibly in slight Trendelenburg position to help keep abdominal contents from eviscerating. Broad-spectrum antibiotics are usually begun, although there is no proof of their efficacy in this circumstance. Once the woman is anesthetized, the wound should be evaluated so that the full extent of the problem can be evaluated. The wound edges may have to be débrided and the wound closed with a wide mass closure, making sure not to incorporate the bladder or rectum in the closure.

WOUND CARE FOR OBESE PATIENTS

Obesity is one of the most significant risk factors for wound infection and disruption. As noted, hyperglycemia is an associated risk factor in this population of patients. Optimal healing, collagen synthesis, and reepithelialization require good oxygenation. Adipose tissue is poorly vascularized and thus has suboptimal oxygenation. Poor ventilation after surgery in the obese woman further exacerbates this problem. Techniques to improve wound healing in obese patients have been summarized by Walsh and associates; these include maintaining normothermia in the operating suite, which decreases vasoconstriction, supplemental

Table 25.15 Comparison of Nonabsorbable Sutures

Suture	Types	Raw Material	Tensile Strength Retention in Vivo	Tissue Reaction
Perma-Hand—silk suture	Braided	Organic protein called <i>fibroin</i>	Progressive degradation of fiber may result in gradual loss of tensile strength over time	Acute inflammatory reaction
Ethilon—nylon suture	Monofilament	Long-chain aliphatic polymers nylon 6 or nylon 6,6	Progressive hydrolysis may result in gradual loss of tensile strength over time	Minimal acute inflammatory reaction
Nurolon—nylon suture	Braided	Long-chain aliphatic polymers nylon 6 or nylon 6,6	Progressive hydrolysis may result in gradual loss of tensile strength over time	Minimal acute inflammatory reaction
Mersilene—polyester fiber suture	Braided Monofilament	Polyethylene terephthalate	No significant change known to occur in vivo	Minimal acute inflammatory reaction
Ethibond <i>Excel</i> —polyester fiber suture	Braided	Polyethylene terephthalate coated with polybutylate	No significant change known to occur in vivo	Minimal acute inflammatory reaction
Prolene—polypropylene suture	Monofilament	Isotactic crystalline stereoisomer of polypropylene	Not subject to degradation or weakening by action of tissue enzymes	Minimal acute inflammatory reaction
Pronova—poly(vinylidene fluoride) suture	Monofilament	Polymer blend of poly(vinylidene fluoride) and poly(vinylidene fluoride-cohexafluoropropylene)	Not subject to degradation or weakening by action of tissue enzymes	Minimal acute inflammatory reaction

Modified from Neumayer L, Vargo D. Principles of perioperative and operative surgery. In: Townsend CM, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Saunders; 2008:251-279.

Figure 25.11 Types of abdominal incision closures. **A**, Layered. **B**, Smead-Jones. **C**, Through and through. **D**, Far near. (From Braun TE. Wound dehiscence. In: Schaefer G, Graber EA, eds. *Complications in Obstetric and Gynecological Surgery*. Hagerstown, MD: Harper & Row; 1981.)

oxygen, and closure of the subcutaneous space if it is larger than 2 cm (Walsh, 2009). Subcutaneous drains do not decrease the infection or wound disruption rate. When patients weigh greater than 120 kg, prophylactic antibiotic dose should be increased (e.g., from 2 g of cefazolin to 3 g). However, extending the dosing beyond surgery is not helpful. Maintaining euglycemia is essential as previously discussed. See Box 25.7.

Table 25.16 Predisposing Factors to Evisceration*

Predisposition	Clinical No./No. with Data Reported (%)
Postmenopausal (age >51 yr)	9/12 (75)
Prior pelvic surgery	10/12 (83)
Postmenopausal with surgery	9/12 (75)
Enterocoele and vaginal vault	10/12 (83)
Posterior enterocoele	6/12 (50)
Vaginal cuff defect	4/12 (33)
Coital trauma	1/12 (8)
Spontaneous	7/12 (58)
Trauma	1/12 (8)

From Croak AJ, Gelshart JB, Kingele CJ, et al. Characteristics of patients with vaginal vault rupture and evisceration. *Obstet Gynecol.* 2004;103:573.

*Total numbers reported for each predisposition were limited by availability of data. Some patients had more than one predisposition.

Box 25.7 Techniques to Decrease Wound Disruption and Infection in Obese Surgical Patients

1. Chlorhexidine bath or shower the night before surgery
2. Women with BMI >35—double the dosage of prophylactic antibiotics
3. Maintain core normothermia during the operation
4. Close subcutaneous tissue if >2 cm in depth
5. Sterile dressing for 24-48 hours
6. Maintain euglycemia
7. Subcutaneous drains do not improve outcomes

OPERATIVE SITE COMPLICATIONS

PELVIC CELLULITIS AND ABSCESS

Infections of the contiguous retroperitoneal space immediately above the vaginal apex are common complications following abdominal or vaginal hysterectomy. However, the frequency of this postoperative complication has dramatically decreased in direct relation to the use of prophylactic antibiotics and MIS. These soft tissue infections range in severity from localized minor cellulitis to large pelvic abscesses and have many names, from cuff cellulitis to infected hematoma. Nevertheless, they are similar to soft tissue infections in other parts of the body. These infections prolong hospital stay and increase the cost of patient care. The bacterial spectrum that produces these infections includes aerobic and anaerobic bacteria from exogenous and endogenous sources. Most postoperative pelvic infections are polymicrobial, usually from endogenous vaginal flora, and approximately 60% to 80% involve anaerobic organisms.

The pathophysiology of the development of retroperitoneal infection is straightforward. The classic “clamp, crush, cut, and tie technique” used in pelvic surgery produces an abundance of hypoxic and anoxic tissue that helps establish an optimal environment for infection. In addition to this anoxic tissue, the retroperitoneal tissue produces an average of 40 mL of serosanguineous fluid daily during the first 72 postoperative hours. When the endogenous flora of the upper vagina colonize and multiply in this retroperitoneal serosanguineous fluid or pelvic hematoma, a pelvic cellulitis and possibly a pelvic abscess can form.

The major symptoms of an operative site infection are fever associated with lower quadrant abdominal and pelvic pain. The fever usually becomes prominent between the third and fifth postoperative days. As the infection becomes more severe, the fever becomes spiking in character, the pain intensifies, and the patient develops moderate leukocytosis.

The diagnosis of cuff cellulitis is confirmed by pelvic examination. Pelvic tenderness and induration are prominent during the bimanual examination. A subtle difference exists between normal postoperative pelvic tenderness and induration and the tenderness and induration produced by an infection. Postoperative infection is accompanied by an increase in suprapubic pain and lateral parametrial tenderness. Cuff cellulitis sometimes responds to drainage by opening the vaginal cuff. Persistent cellulitis, one encompassing a large area, or a pelvic abscess necessitates parenteral antibiotic therapy. Large or complex fluid collections may be present without adverse clinical consequences. CT-directed drainage and culture may aid in diagnosis.

Because of their polymicrobial origin, infections are usually treated with an aminoglycoside (gentamicin) and an antibiotic specific for anaerobic infection (clindamycin). Metronidazole (Flagyl) may be substituted for clindamycin. An alternative therapy is substitution of a third-generation cephalosporin or the monobactam agent aztreonam (Azactam) for the aminoglycoside. IV antibiotics should be continued until the patient is afebrile for 24 hours. Once afebrile, the patient can be transitioned to a 10- to 14-day course of oral antibiotics, although some authors question the utility of this practice. Alternatives to the aminoglycoside-clindamycin regimen include broad-spectrum antibiotics combined with β -lactamase inhibitors such as ampicillin-sulbactam, amoxicillin-clavulanate, piperacillin-tazobactam, or ticarcillin-clavulanate. These drugs have better coverage of *Enterobacteriaceae* spp. and *Enterococcus*. Ertapenem can also be used in this patient population.

Drainage of an abscess through surgical intervention or interventional radiology is a key component of treatment. The success rates seen with antibiotic therapy alone (without drainage) range from 34% to 87%, depending on the abscess size and location (Jaiyeoba, 2012). Abscesses over 5 cm would likely benefit from immediate drainage. Appropriate cultures should be obtained from the center of an abscess cavity when the abscess is operatively incised. If a woman does not become afebrile within 48 hours of adequate drainage of a retroperitoneal abscess, a concomitant complication of pelvic thrombophlebitis should be suspected. If pelvic thrombophlebitis is suspected, a 72-hour trial of IV heparin therapy with concurrent antibiotics should be instituted.

GRANULATION TISSUE

Granulation tissue at the apex of the vaginal vault is a frequent complication following hysterectomy. Small areas of friable, red granulation tissue are seen at the 6-week postoperative pelvic examination in more than 50% of women. Granulation tissue is more common following abdominal than vaginal hysterectomy. In women undergoing total abdominal hysterectomy, polyglactin (Vicryl) has a reduced risk of developing granulation tissue compared with chromic catgut for closure of the cuff, 32% versus 68%.

Excessive granulation tissue is the result of an exaggerated healing response of the vascular-rich pelvic tissues. One of the causes is believed to be inversion of the vaginal epithelium

between the margins of the edges of the incision at the apex of the vaginal vault. Some patients are asymptomatic, but many women experience spotting or a bloody discharge after intercourse. On speculum examination, the granulation tissue appears as a polypoid projection hanging from the vaginal suture line. The differential diagnosis includes a prolapsed fallopian tube and recurrent carcinoma in a woman with a pelvic malignancy. The polypoid mass is easily avulsed from the vaginal apex. The remaining area of granulation tissue should be treated with a chemical cautery (e.g., silver nitrate, Monsel solution) in the office or by cryocauterization or electrocauterization, if proper anesthesia is available.

INCISIONAL HERNIA

Vertical midline incisions produce the highest rate of abdominal wall hernias, 10% to 15%. Most will present within 1 year of surgery. Diabetes, poor nutrition, and obesity are all predisposing factors for postoperative hernia. Transverse and Pfannenstiel incisions have a low rate, followed by laparoscopic incisions, with the lowest rate of hernia formation. In obese and diabetic patients, it is prudent to close the fascia if the laparoscopic incision extends beyond 1 cm. Studies have noted a 2% to 3% hernia rate in laparoscopic sites of 12 mm or larger. Studies performed since the institution of modern trocars have noted even lower rates of (1%) of trocar site hernias.

PROLAPSED FALLOPIAN TUBE

Prolapse of the distal end of the fallopian tube is a rare complication of abdominal or vaginal hysterectomy. It is usually discovered during a routine visit during the first few months (up to 6 months) following surgery. Factors that may predispose a woman to develop prolapse of the fallopian tube include hematoma formation and postoperative pelvic infection.

Many women with this complication are free of symptoms, but others experience a watery discharge, postcoital spotting and pain, or moderate lower abdominal and pelvic pain. Differing from granulation tissue, the fallopian tube is not friable and is firmly attached. Grasping the fallopian tube with an instrument and applying traction produces much more pain than traction on granulation tissue. Treatment is the destruction of the segment of the fallopian tube protruding through the vaginal vault with cryocauterization or laser. Because the fallopian tube is well innervated, any destructive procedure must be performed with anesthesia. The fallopian tube may be removed during a subsequent outpatient procedure with adequate anesthesia. Most clinicians opt for a vaginal approach, with ligation of the fallopian tube as high as possible. The stump of the tube is buried retroperitoneally and the vaginal epithelium is closed. Some difficult cases can also be performed using MIS. An alternative treatment is coagulation of the segment of fallopian tube protruding through the vaginal apex with cryocauterization. Often, the vaginal wall reepithelializes over the area, thereby excluding the tube from any connection with the vaginal cavity.

LYMPHOCYST

A lymphocyst is a local collection of lymphatic fluid within the retroperitoneal spaces of the pelvis resulting from retrograde

drainage of lymph. It is a rare complication, discovered most frequently after pelvic node dissections. In the past, this complication occurred in approximately 20% of patients having undergone radical surgery. However, with meticulous attention to ligation of distal lymphatic channels and abandonment of the practice of reperitonealization, this complication is reported in less than 5% of these cases. A peritoneal opening, or peritoneal window, allows flow of the lymphatic fluid into the peritoneal cavity, with subsequent peritoneal resorption. The incidence is lower in series in which palpation alone is used to identify the cysts. If ultrasound examination is used postoperatively to screen for lymphocysts, the incidence is 10-fold greater. Conditions that predispose the woman to formation of a lymphocyst are previous radiation and anticoagulation.

Lymphocysts usually present during the first 6 postoperative weeks. They vary greatly in size and seldom become infected. The cyst usually begins anteriorly and medially to the iliac vessels. As it expands, it may produce pelvic pain, leg pain, fever, obstruction or angulation of the ureter, pressure symptoms on the bladder, or partial venous obstruction. Small lymphocysts (<4 cm in diameter) are usually asymptomatic and regress spontaneously within 8 weeks. Larger cysts may necessitate treatment by intermittent aspiration or marsupialization performed laparoscopically, or placement of an omental flap.

POSTOPERATIVE NEUROPATHY

Postoperative neuropathy is an uncommon but significant and sometimes debilitating problem. The three most common causes of neuropathy in gynecologic surgery are self-retaining retractors, overly flexed thighs in the dorsal lithotomy position, and surgical resection.

The femoral nerve is the largest branch of the lumbar plexus and arises from the primary dorsal rami of L2, L3, and L4. It provides motor function to several leg muscles, including the quadriceps, and sensory fibers that innervate the anterior and medial surfaces of the thigh and leg. The vascular supply to the femoral nerve may be compromised during an abdominal or vaginal hysterectomy. The cause of this complication is usually related to continuous pressure, usually by a self-retaining retractor producing ischemic necrosis of the nerve. The vascular circulation of the nerve itself is compromised by diminished blood flow in the vasa nervorum. The most common site of nerve compression is 4 to 6 cm above the inguinal ligament where the nerve pierces the psoas muscle.

Factors that contribute to the development of this complication are thinness of the woman, long retractor blades, prolonged operative times, and systemic diseases such as diabetes mellitus, gout, alcoholism, and malnutrition. The classic woman who develops this complication is a short, thin, athletic woman who has a transverse incision in which a self-retaining retractor is used. A similar problem may develop after vaginal operations or laparoscopy in thin women who are placed into exaggerated hip flexion or abduction in the dorsal lithotomy position. Femoral neuropathy following vaginal surgery is believed to be secondary to compromise of the nerve by severe angulation of the woman, not secondary to pressure injury from retractors. Bohrer and associates found peripheral nerve injury in 1.8% of 616 patients with elective gynecologic procedures, with almost all related to positioning. Most of these could be related to exaggerated flexion

Figure 25.12 Ilioinguinal nerve entrapment during needle suspension for stress incontinence. (From Miyazaki F, Shook G. Ilioinguinal nerve entrapment during needle suspension for stress incontinence. *Obstet Gynecol.* 1992;80[2]:246-248.)

for laparoscopic and vaginal surgeries. Two patients had motor and sensory losses. In this series, all but one woman had resolution of neuropathy with medical treatment (Bohrer, 2009).

Patients with this complication may experience numbness, paresthesias, and difficulty with their gait. Patients may have difficulty lifting the affected knee because of the involvement of the quadriceps. Symptoms may present with a spectrum of severity. Usually, the neurologic symptoms develop within the first 24 to 72 hours following surgery. Because of the inability to lift the leg, climbing stairs is a particular problem. Muscle and sensory function recover spontaneously over several weeks to several months. The woman should be seen by a physical therapist to facilitate ambulation and prevent muscle atrophy.

To prevent this complication, it is important to palpate the lateral pelvic wall after placement of a self-retaining retractor. In a thin woman, placing folded towels between the skin surface and self-retaining retractor helps prevent this complication by decreasing the depth of penetration of the lateral retractor blades. The ilioinguinal and iliohypogastric nerves pass in a transverse and diagonal course through the anterior lower abdominal musculature medial to the inguinal ligament and through the inguinal canal. The nerves supply sensory fibers to the labia, mons pubis, and medial thigh. The nerves may become injured during surgery with a Pfannenstiel incision or during a urinary incontinence procedure (Fig. 25.12). Pathophysiologically, the nerve may be transected or entrapped by suture or scar formation. Sharp or burning pain may develop immediately postoperatively or usually within a few days. The pain may radiate to the groin or vulva. Most symptoms will resolve spontaneously. Severe pain may necessitate nerve block, suture removal, or segmented removal of the involved nerve.

Several specific postoperative neuropathies are related to specific procedures. Uterosacral ligament suspension may affect the sacral plexus (S2 to S4) and produce pain and numbness in the posterior thigh and buttocks. Genitofemoral neuropathy and injury to the obturator nerve can be seen following pelvic lymphadenectomy. If the nerve was not cut, most will resolve in

Figure 25.13 Schematic drawing of the pathways for transmission of painful stimuli. (From Sherwood E, Williams CG, Prough DS. Anaesthesiology principles, pain management, and conscious sedation. In: Townsend CM, Beauchamp RD, Evers BM, et al, eds. *Sabiston Textbook of Surgery*. 17th ed. Philadelphia: Saunders; 2004.)

time, although physical therapy is very helpful. Pudendal neuropathy has been reported with cystocele repairs and graft placement producing pain and numbness in the vulva and perineum. If symptoms are not relieved with analgesics and other medications, such as gabapentin, surgical removal of the sutures may be necessary.

PSYCHOLOGICAL SEQUELAE

PAIN RELIEF

The proper management of pain during the postoperative period should be an essential task and goal of all gynecologists. Most women experience moderate to severe pain during the first 36 to 48 hours following a gynecologic operation. Pain is initiated at the local level through the trauma of the surgery. Systemic and neurologic pathways are then activated (Fig. 25.13). The most effective pain management strategies involve inhibiting the initiation and activation of these broader pain reflexes. Such inhibition is also associated with the fewest side effects. Factors that predict postoperative pain and the use of pain medications include preoperative pain, mental state, and type of surgery. Age is inversely correlated with pain and pain medication usage (Vivian, 2009). Studies comparing types of hysterectomy, abdominal, vaginal, and laparoscopic have found a descending order of postoperative pain, as may be anticipated.

The current literature documents that pain relief is often treated inadequately in postoperative patients. Inadequate pain relief prolongs hospital stay and has adverse psychological consequences. Also, several investigators have noted that inadequately treated pain increases secondary morbidities, including atelectasis from decreased mobility, increased inflammatory response, and elevated glucose levels, with higher catecholamine levels. Studies have shown that epidural anesthesia has a significantly diminished effect on the immune response in patients undergoing laparotomy. Syndromes of chronic pain are presumed to begin with inadequate pain relief in the postoperative period.

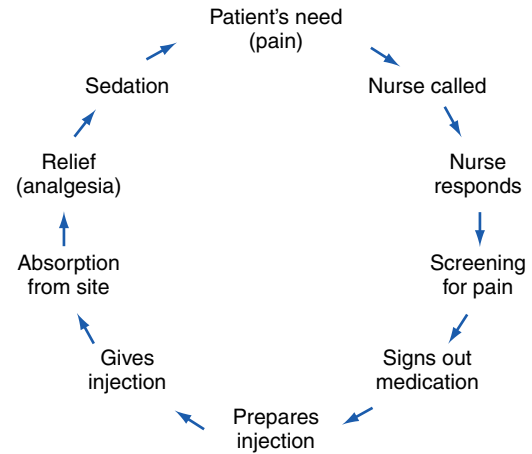

Figure 25.14 Pain cycle. (From White PF. Pain management [special report]. *Postgrad Med*. 1986;80:8.)

A schematic representation of the pain cycle and the potential delays in pain relief with traditional as-needed analgesic regimens is shown in Fig. 25.14. Many studies have confirmed that regular-interval preventive pain relief is superior to conventional on demand analgesic medication during the first 36 to 48 hours after surgery. However, there is great variability in absorption. In addition, the therapeutic window—the range of effective blood concentration before undesired side effects occur—is narrow. Peak concentrations can vary as much as fivefold among different individuals, and the time to reach peak blood level can vary as much as sevenfold. Thus patient-controlled analgesia (PCA) systems became popular because they dramatically decrease patients' anxiety over pain control as the patient is in control, rather than the hospital staff (Fig. 25.15). PCA systems are safe and effective as long as there is a lockout period, and they help minimize individual differences in pharmacokinetics. Unfortunately, they also lead to a great deal of postoperative bowel dysfunction and, as a result, are frequently “de-emphasized” in most postoperative enhanced recovery after surgery (ERAS) protocols as discussed in Chapter 24. The current recommendations for postoperative pain relief is for multimodality therapy with NSAIDs, acetaminophen, and regional blocks with injection of long-acting local anesthetics such as bupivacaine and oral narcotics. In general, patients use PCA much less frequently in this setting. If a PCA is used, the patient should be given instructions about use of a PCA. Additionally, families need instruction in not pushing the medication for the patient to help alleviate pain. Sample dosing for PCA is listed in Appendix C.

Some patients can also benefit from the use of continuous postoperative thoracic epidural anesthesia, especially patients who are planning larger open cases with a more prolonged recovery. Perioperative intrathecal or epidural injections of opioids effectively relieve postoperative pelvic pain in most situations. Side effects are primarily itching and a small risk of hypotension. Continuous PCA epidurals may also be used. The advantages and disadvantages of PCA and epidural anesthesia are presented in Table 25.17.

In addition to narcotics, NSAIDs are valuable as adjunctive agents. NSAIDs are most effective when given as scheduled medications and as early as possible in the postoperative period. Their mechanism of action is the inhibition of prostaglandin

Figure 25.15 Theoretic relationships among dosing interval, analgesic drug concentration, and clinical effects when comparing patient-controlled analgesia (PCA) system (solid lines) with conventional intramuscular therapy (dashed lines). (Modified from White PF. Patient-controlled analgesia: a new approach to the management of postoperative pain. *Semin Anesth.* 1985;4:255-266.)

Table 25.17 Advantages and Disadvantages of Epidural Analgesia and Patient-Controlled Analgesia

Epidural Analgesia	Patient-Controlled Analgesia	Comments
Advantages	Immediate pain relief	Requires no special nursing or anesthesia support postoperatively
	May improve colon motility	Gives the patient personal control over administration of pain medication
	May improve postoperative pulmonary function after lower abdominal and pelvic surgery	
Disadvantages	Less sedating than patient-controlled analgesia	
	Requires a skilled anesthesiologist for correct placement	Patient may experience pain in the recovery room until an adequate serum level of medication is achieved
	May interfere with ambulation	
	May delay removal of Foley catheter	

From Baker VV. Principles of postoperative care. In: Baker VV, Deppe G, eds. *Management of Perioperative Complications in Gynecology*. Philadelphia: WB Saunders; 1997.

production. Through inhibition of prostaglandins, pain is prevented rather than blocked centrally. NSAIDs have three potential side effects. The first is increased gastric acid, best treated by H2 blockers or proton pump inhibitors. The second is renal toxicity, which may be prevented by using set doses and prescribing only for women with normal renal function and adequate intravascular volume. The third is inhibition of platelet function with higher doses of NSAIDs. Some clinicians will wait 1 to 2 hours after surgery before giving these agents to avoid excessive bleeding, but there are no data to support this practice. Advantages of prostaglandin synthetase inhibitors are a lack of effect on gastrointestinal motility and a much smaller effect on sensorium than narcotic agents. Commonly used NSAIDs for postoperative pain include ibuprofen, naproxen, and ketorolac (Toradol). Ketorolac should not be used for more than 4 consecutive days because of GI side effects. In older adults, changes in GI function may limit the usefulness of these agents. Stomach colonization with *Helicobacter pylori* increases with increasing age. Of

women older than 80 years, 80% are colonized. These bacteria increase sensitivity to GI irritation. Prophylactic H2 blockers or proton pump inhibitors should be considered when administering NSAID to older patients. Further NSAID use should be limited in patients with prior gastric bypass surgery due to risk of marginal ulcer development.

Many surgeons and anesthesiologists believe that giving preemptive analgesics in the perioperative period prior to the patient's sensation of pain leads to better pain control. Many studies have noted that the beneficial effects are significant when infiltration is given prior to the surgical incision. Because much pain arises from peritoneal irritation and fascial trauma, incisional infiltration is most effective with minimally invasive procedures such as laparoscopy. Infiltration is most commonly used with a local anesthetic, lidocaine 1%, or bupivacaine, 0.25%. Temporary indwelling infusion catheters that use local anesthetics have been shown in multiple studies and systematic reviews to benefit patients through decreased opioid use, earlier

ambulation, and decreased PONV. Catheters are placed above and below the fascia and removed on day 3. In patients who are expected to require large amounts of opioid, such as those already on chronic narcotics for pain, the addition of gabapentin decreases narcotic use, perceived pain levels, and PONV. A meta-analysis has found a 35% reduction in pain (95% CI: 0.59-0.72). Most studies used 1200 mg/day.

Patients with persistent incisional pain, longer than 4 to 6 months, should be evaluated for incisional neuromas. Neuromas are thought to arise from damaged and transected peripheral nerves that develop a fibrous capsule. If a superficial small trigger area can be identified, an injection of 1% hydrocortisone with 2 to 3 mL of 0.25% bupivacaine may be attempted and is diagnostic if it helps. If this is unsuccessful, referral to a surgeon with expertise in peripheral nerves and chronic pain should be considered.

POSTOPERATIVE CONCERNS IN OLDER SURGICAL PATIENTS

Patients older than 70 years, particularly those older than 80 years need special consideration in the perioperative period. Studies of older women undergoing gynecologic surgery have found that for elective procedures, the complication rates are no different from those of younger women after adjusting for comorbidities. [Box 25.8](#) summarizes physical changes that should be kept in mind when caring for older surgical patients. The cardiovascular system is affected with increased systemic vascular resistance and a poorer response to systemic catecholamines. Many anesthetic agents decrease cardiac contractility. Atrial fibrillation and cardiac failure are the two most common cardiac complications, and attention to intravascular volume is important to maintain cardiac output. Many older women have decreased appetites and poor nutrition; this should be addressed prior to elective surgery. The nursing staff often is hesitant to give enough pain medications for fear of oversedation. However, inadequate pain relief can lead to worse sequelae. Epidural PCA is a desirable postoperative tool for pain relief in this patient population.

Postoperative delirium and postoperative cognitive dysfunction (POCD) are examples of altered levels of mental function occurring after surgery. These conditions are more common in older adults. Prolonged and delayed mental status changes may be caused by decreased oxygen, decreased cardiac output, medications, and drug-drug interactions. In general, postoperative delirium occurs 24 to 72 hours after surgery. Disorientation, sleep deprivation, polypharmacy, and pain may all be contributing factors. The condition occurs in 5% to 15% of older patients and increases the risk of patient falls. Postoperative cognitive dysfunction may occur for a few months after surgery and has been noted to some degree in up to 5% of older surgical patients.

Postoperative disorientation and agitation are associated with higher risk of patient falls, as patients attempt to get out of bed without assistance.

PSYCHOSEXUAL PROBLEMS AND DEPRESSION

The time immediately before and after a surgical procedure is a stressful period for all women and their families. Anxiety and fear are normal responses and should be anticipated by health care providers. Any surgery on the female reproductive organs

Box 25.8 Physiologic Changes in Older Adults That May Affect Surgery

Cardiovascular

- Approximate 1% decrease in cardiac output/yr after age 30 yr
- Decreased vascular compliance and increased systemic vascular resistance (SVR)
- Increased cardiovascular disease
- Decreased cardiac output in response to stress
- Increased susceptibility to conduction abnormalities

Pulmonary

- Decreased pulmonary reserve
- Decreased mucus-producing cells, with increased susceptibility to infection
- Decreased elasticity in the lungs
- Decreased forced expiratory volume in 1 second (FEV₁)
- Decreased functional residual capacity (FRC), exacerbated with postoperative pain and atelectasis

Renal

- Decreased glomerular filtration rate (GFR), \approx 1% decrease/yr after age 20
- Serum creatinine level not effective measure of renal function in this situation

Skeletal

- Increased osteoporosis, with increase in injury from falls
- Decreased rib expansion, so poorer response to need for postoperative lung expansion

Nutritional

- Poorer nutrition
- Greater incidence of vitamin deficiencies, including vitamin B₁₂

stimulates questions and conflicts concerning body image, feminine identity, sexuality, and possibly future childbearing. The period after a gynecologic operation is one of transition and is a unique psychological challenge to the woman. The reader should review [Chapter 9](#) for a more detailed discussion of the problems of loss and grief. After gynecologic surgery, every woman needs support to deal with this challenge, and it is important to emphasize that it may take many months to complete the process.

Personal issues that relate to a woman's body image and sexuality are particularly affected by hysterectomy. Open discussions with the woman that allow her to discuss issues regarding sexuality are important during preoperative and postoperative visits. Psychological studies have confirmed that sexual function after a hysterectomy is related to a number of factors. Poor knowledge of reproductive anatomy, a negative expectation of sexual recovery after the operation, preoperative psychiatric morbidity, and a history of unsatisfactory sexual relationships are all associated with a poor outcome. The effect of hysterectomy on sexual function is an exceedingly complex topic, with both physical and psychological factors known to have varying and almost unquantifiable influences.

MENTAL STATUS CHANGES

Anxiety and mental status changes are not uncommon in the postoperative period. Medications, hemodynamic changes, fever, and altered sleep patterns contribute to changes in sensorium. These changes are most pronounced in older adults. Multivariate analyses have correlated pain levels, hematocrit under 30%, smoking,

Box 25.9 Causes of Acute Delirium

Drug intoxication (alcohol, antihistamines, sedatives)
 Drug withdrawal (alcohol, narcotics, anxiolytics)
 Acute cerebral disorders (edema, transient ischemic attack stroke, neoplasm)
 Metabolic disturbances (electrolyte, imbalance, hypoglycemia)
 Hemodynamic disturbances (hypovolemia, myocardial infarction, congestive heart failure)
 Infections (septicemia, urinary tract infection, pneumonia)
 Respiratory disorders (respiratory failure, pulmonary embolism)
 Trauma (head injury, burns)

From Dayton MT. Surgical complications. In: Townsend CM, Beauchamp RD, Evers BM, et al, eds. *Sabiston Textbook of Surgery*. 17th ed. Philadelphia: Saunders; 2004.

and a history of psychiatric disorders with postoperative mental status changes. Other than hematocrit levels, these factors are difficult to control. Mental status change does require evaluation (Box 25.9). Changes in oxygenation, electrolyte imbalance, sepsis, medication interactions, and acute anemia need to be excluded.

A syndrome of nausea, sweating, tachycardia, tremors, delirium, and even grand mal seizures postoperatively is often misdiagnosed as a drug or anesthetic reaction. This constellation of signs and symptoms is usually caused by alcohol withdrawal. The presence of a tremor should alert health care providers to the correct diagnosis. In the treatment of post-alcohol withdrawal symptoms, benzodiazepines are the drug of choice. In older women, especially after emergency surgery, postoperative confusion, anxiety, changes in personality, and memory impairment are frequent findings, and a large differential diagnosis must be considered.

DISCHARGE INSTRUCTIONS AND POSTOPERATIVE VISITS

Simple but complete discharge instructions are an important component of postoperative care. The physician should anticipate the most common questions and give the woman explicit instructions. Particular attention should be given to limitations in physical activity, such as heavy lifting and resumption of sexual relations. Information should be given about vaginal spotting as sutures dissolve. Appropriate contact information

should be provided in case of unanticipated complications and to schedule return appointments. Discharge instructions should not be given on the morning of discharge. Rather, patients should receive these instructions the day before discharge; this ensures that on the morning of discharge instructions can be reviewed and questions answered to ensure the patient understands. Instructions should be given in verbal and written format. Because an increasing number of procedures are performed as outpatient surgery or short stays, the physician must modify instructions to accommodate the gradual resumption of activity. The 24- to 48-hour postdischarge phone call to the recovering woman provides an excellent forum for answering questions and providing reassurance. Studies of outpatient surgeries have found this contact to be most important. Additionally, it is difficult for the woman and her significant others to remember instructions received during the first 24 hours after surgery. Written guidelines are extremely valuable for outpatient procedures. Careful training of nursing and triage staff in regard to postoperative questions cannot be overemphasized. Patients will usually be home when the first signs of complications occur. These signs and symptoms may in themselves be minor, but they may presage a more serious complication that could evolve. Thus a much higher index of suspicion should be used with these patients.

Most clinicians will see patients one or more times in the postoperative period as patients are transitioning back to routine activities. Questions about appropriate levels of activity can be answered in person or via a postdischarge phone call. Discussions of reestablishing sexual relations and physical activity are important to review at several time points. Unless there is a problem or a specific issue, a pelvic examination may be deferred until 5 to 6 weeks after the procedure. The discussion of surgical findings occurs at several points during the postoperative period. Initially, patients are drowsy after waking up from anesthesia or IV analgesics. Families may want to know the results prior to the patient hearing them. Preoperatively, it is important to clarify with the woman who in the family can know what information. During the early postoperative period, the gynecologist must judge how much information to provide. This should be tailored to what the patient can understand, depending on her level of wakefulness. By the end of the first few days, the discussion may move to details of surgical findings as well as treatment options, sequelae, and prognosis if a long-term problem has been found.

KEY POINTS

- Postoperative febrile morbidity is related to infection in approximately 20% of cases and noninfectious causes in 80% of cases.
- Infection in older adults will not always present with classic findings. The amount of temperature elevation may not reflect the severity of the infection. Not uncommonly, the first signs of infection in older adults will be mental status changes. Also, the degree of leukocytosis may not reflect infection, being blunted or absent.
- Minimum urine output should be 0.5 mL/kg/hr. The use of a 20-mL/hr benchmark for all women is only an approximation and should be adjusted for the patient's weight.
- Because of the shifts in water balance, the postoperative hemoglobin at 72 hours is a more accurate measurement of operative and postoperative blood loss than a hemoglobin at 24 hours.
- After subtracting the effects of the operative blood loss from the preoperative hemoglobin, a further reduction in hemoglobin of 1 to 2 points reflects a postoperative hemorrhage of approximately 500 mL.
- Women should be transfused when their hemoglobin falls below 7, or sooner if they are symptomatic or have significant cardiac or pulmonary comorbidities.
- Microatelectasis is a common occurrence developing during almost all pelvic surgeries and is persistent 24 hours

KEY POINTS—cont'd

- postoperatively in approximately 50% of women. Current studies have demonstrated that there is no association between fever and the amount of atelectasis diagnosed radiologically.
- Radiographic diagnoses are approximately 60% accurate for bacterial or viral pneumonia in women with laboratory-proved pneumonia.
 - Rapid loss of 20% of a woman's blood volume produces mild shock, whereas a loss of greater than 40% of blood volume results in severe shock.
 - From 15% to 45% of surgical blood loss is absorbed onto drapes, pads, and other areas. Thus blood levels in the suction bottle are inaccurate markers of total operative blood loss.
 - Massive blood loss has been defined as hemorrhage that results in replacement of 50% of circulating blood volume in less than 3 hours.
 - Returning a patient to the operating room to control hemorrhage is often a difficult decision. However, when indicated this decision should not be postponed, and the patient should have an exploratory operation as soon as possible after volume replacement.
 - The extent of wound or pelvic hematomas is determined by the potential size of the compartment into which the bleeding occurs. Retroperitoneal or broad ligament hematomas may contain several units of blood.
 - Superficial phlebitis is the leading cause of an enigmatic postoperative fever during the third, fourth, or fifth postoperative day.
 - The clinical management of mild superficial thrombophlebitis includes rest, elevation, and local heat. Moderate to severe superficial thrombophlebitis may be treated with nonsteroidal antiinflammatory agents.
 - Venous thrombosis and PE are the direct causes of approximately 40% of deaths in gynecologic cases once the diagnosis is confirmed.
 - Signs and symptoms of pulmonary emboli are nonspecific; however, the most common symptoms are chest pain, dyspnea, apprehension, tachypnea, rales, and an increase in the second heart sound over the pulmonic area.
 - Intermittent in-and-out catheterization is preferable to continuous drainage with a Foley catheter for women with intermediate-term voiding dysfunction.
 - Although symptoms of urinary incontinence may present within a few hours of the operative procedure, most fistulas usually present 8 to 12 days after operation, and occasionally as late as 25 to 30 days after the operation.
 - If there is a suspicion that trauma to the bladder has occurred during an operative procedure, continuous catheter drainage for 3 to 5 days usually results in spontaneous healing.
 - Approximately 25% of adult women experience postoperative nausea and vomiting.
 - Normal return of bowel function after abdominal surgery can take 3 to 7 days. The left colon takes the longest to resume function, approximately 72 hours after surgery. If an ileus lasts for longer than 5 to 7 days, a diagnosis of mechanical bowel obstruction or another cause for the ileus should be considered.
 - Postoperative oral feeding is safe and efficacious. This practice is preferred as it facilitates recovery and shortens hospital stay.
 - The difference between small bowel obstruction and adynamic ileus is subtle, because adynamic ileus can be associated with partial obstruction of the small intestine. The use of Gastrografin contrast can be both diagnostic and therapeutic.
 - Second- and third-generation cephalosporins are the antibiotics associated with the highest risk of developing *C. difficile* diarrhea.
 - The incidence of postoperative wound infection is increased eightfold when the woman's preoperative weight exceeds 200 pounds. The thickness of subcutaneous tissue is the greatest risk factor for wound infection in women undergoing abdominal hysterectomy.
 - Necrotizing fasciitis involves the subcutaneous tissue and superficial fascia. It rapidly expands in the subcutaneous spaces. This condition is a surgical emergency and patients should have operative débridement as soon as possible.
 - The incidence of wound dehiscence is approximately 1 in 200 gynecologic operations. Wound infection is found in approximately 50% of women with wound disruption.
 - The classic feature of an impending wound disruption is the spontaneous passage of copious serosanguineous fluid from the abdominal incision.
 - Most postoperative pelvic infections are polymicrobial, usually from endogenous vaginal flora, and approximately 60% to 80% involve anaerobic organisms.
 - Common causes of femoral neuropathy are continuous pressure from self-retaining retractors or exaggerated hip flexion or abduction in the dorsal lithotomy position in thin women.
 - Discharge instructions should be given in verbal and written forms, and the gynecologist should anticipate the most common questions.

APPENDIX A

PORTLAND CONTINUOUS INTRAVENOUS INSULIN PROTOCOL (VERSION 2001): TARGET BLOOD GLUCOSE LEVEL, 100 TO 150 mg/dL

- 1. Start Portland Protocol during surgical procedure and continue through 7 AM of the third postoperative day (POD). Patients who are not taking enteral nutrition on POD 3 should remain on this protocol until taking at least 50% of a full liquid or soft American Diabetes Association (ADA) diet.
- 2. For patients with no previous diagnosis of diabetes mellitus (DM) who present with hyperglycemia: Start protocol if blood glucose (BG) level >200 mg/dL. Consult endocrinologist on POD 2 for DM workup and follow-up orders.
- 3. Start insulin infusion through pump piggybacked to maintenance IV line, as follows:

Blood Glucose (mg/dL)	IV Insulin Bolus (U)	INITIAL PREOPERATIVE INSULIN RATE (U/hr)	
		(CIRCLE ONE)	
		Type 2 DM	Type 1 DM
80-119	0	0.5	1.0
120-179	0	1.0	2.0
180-239	0	2.0	3.5
240-299	4	3.5	5.0
300-359	8	5.0	6.5
≥360	12	6.5	8.0

- 4. Test blood glucose (BG) level by fingerstick method or arterial line drop sample. The frequency of BG testing should be as follows:
 - a. If BG ≥200 mg/dL, check BG every 30 min.
 - b. If BG <200 mg/dL, check BG every hr.
 - c. When titrating vasopressors (such as epinephrine), check BG every 30 min.
 - d. If BG is 100 to 150 mg/dL with <15-mg/dL change and insulin rate has remained unchanged for 4 hr (stable infusion rate), may test BG every 2 hr.
 - e. May stop every 2-hr testing on POD 3 (see items 5 and 8 below).
 - f. At night on telemetry unit:
 - If BG is 150 to 200 mg/dL, test every 2 hr.
 - If BG <150 mg/dL and stable insulin infusion rate exists, test every 4 hr.

5. Insulin titration guidelines:

Blood Glucose (mg/dL)	Action
<50	Stop insulin; give 25 mL of 50% dextrose; recheck BG in 30 min. When BG >75 mg/dL, restart with rate 50% of previous rate.
50-75	Stop insulin; if previous BG >100 mg/dL, then give 25 mL of 50% dextrose; recheck BG in 30 min. When BG >75 mg/dL, restart with rate 50% of previous rate.
76-100	If <10 mg/dL lower than last test, decrease rate by 0.5 U/hr. If >10 mg/dL lower than last test, decrease rate by 50%. If ≥last test result, maintain same rate.
101-150	Use same rate.
151-200	If 20 mg/dL lower than last test, use same rate. Otherwise, increase rate by 0.5 U/hr.
>200	If ≥30 mg/dL lower than last test, use same rate. If <30 mg/dL lower than last test (or if higher than last test), increase rate by 1 U/hr. and If >240 mg/dL, give IV bolus of regular insulin per IV insulin bolus dosage scale (see item 3 above). Recheck BG in 30 min. If BG >200 mg/dL and has not decreased after three consecutive increases in insulin, give IV bolus per item 3 and double the insulin rate. If BG >300 mg/dL for four consecutive readings, call physician for additional IV bolus orders.

From American Association of Clinical Endocrinology: *Endocr Pract.* 2004;10(Suppl 2):32-33.

- 6. Begin use of 1800-calorie ADA diabetic diet with any oral intake.
- 7. Postmeal subcutaneous insulin lispro (Humalog) supplement in addition to insulin infusion when oral intake advances beyond clear liquids:
 - a. If patient eats 50% or less of servings on breakfast, lunch, or supper tray, then give 3 U insulin lispro subcutaneously immediately after that meal.
 - b. If patient eats more than 50% of serving on breakfast, lunch, or supper tray, then give 6 U of insulin lispro subcutaneously immediately after the meal.
- 8. On POD 3: Restart preadmission glycemic control medication, unless patient is not tolerating enteral nutrition; then maintain insulin drip per protocol.

APPENDIX B

COMMON ANTIBIOTICS FOR POSTOPERATIVE INFECTIONS

Drug Class and Name	Mechanism of Action	Comment	Half-Life	Toxicity	Antibacterial Spectrum
Penicillins					
Penicillin G	β -Lactam mechanism: Inhibits bacterial cell wall by binding to penicillin-binding proteins (PBPs). It inhibits the final transpeptidation step of peptidoglycan synthesis in the bacterial cell wall.	Prototype; hydrolyzed by all β -lactamases	Short	Low, but rarely an allergic reaction may be life-threatening	Streptococcal species except enterococci and penicillin-resistant pneumococci, <i>Neisseria</i> spp., except lactamase-producing gonococci
Antistaphylococcal					
Methicillin	β -Lactam mechanism; also penicillinase-resistant and acid-stable	First antistaphylococcal drug	Short	Interstitial nephritis	Staphylococcal species (methicillin-sensitive) and streptococcal species, except <i>Enterococcus</i>
Oxacillin			Short	Interstitial nephritis	Narrow spectrum generally used for staphylococcal infections only
Nafcillin	β -Lactam mechanism	Hydrolyzed by all β -lactamases	Short	Interstitial nephritis	Streptococcal species, including many enterococci; <i>Neisseria</i> spp. (non-lactamase producing); <i>Haemophilus influenzae</i> (non-lactamase producing); some <i>Escherichia coli</i> and <i>Proteus mirabilis</i>
"Easy" gram-negative ampicillin			Short	Low; diarrhea and rash	
Amoxicillin	β -Lactam mechanism	Hydrolyzed by all β -lactamases	Medium	High sodium load; inhibition of platelet aggregation	Greatly expanded gram-negative spectrum while still active against streptococcal species, including enterococci; moderate antianaerobic activity; may not be reliable as sole agent for established gram-negative rod infections
Expanded-spectrum carbenicillin			Short		
Ticarcillin	β -Lactam mechanism	Same	Short	Low	Same, but less activity against enterococci
Very advanced spectrum mezlocillin	β -Lactam mechanism	Hydrolyzed by all β -lactamases	Short		Same as expanded-spectrum penicillins but with more activity against <i>Pseudomonas</i> , <i>Acinetobacter</i> , and <i>Serratia</i>
Piperacillin	β -Lactamase inhibitor combination	Same	Short	Low	Same as ticarcillin or amoxicillin plus staphylococci (methicillin-sensitive), lactamase-positive <i>H. influenzae</i> and some lactamase producing gram-negative rods and anaerobes
β -Lactamase inhibitor combination					
Clavulanic acid plus	Clavulanic acid mechanism: β -lactamase inhibitor that increases the antibacterial activity of β -lactam antibiotics	Oral only	Short	Low; same as constituent β -lactam	Same as ticarcillin or amoxicillin plus staphylococci (methicillin-sensitive), lactamase-positive <i>H. influenzae</i> and some lactamase producing gram-negative rods and anaerobes
Ticarcillin, amoxicillin					
Sulbactam plus	β -Lactam mechanism plus	IV only	Short		

Continued

Drug Class and Name	Mechanism of Action	Comment	Half-Life	Toxicity	Antibacterial Spectrum
Ampicillin	Sulbactam mechanism: Forms enzyme-sulbactam complex that inhibits β -lactamases		Short		Similar to cefoxitin with activity against enterococci
Tazobactam plus Piperacillin					Similar to piperacillin plus staphylococci (methicillin-sensitive), some lactamase-producing gram-negative rods, and anaerobes
Cephalosporins First-generation					Streptococcal species except enterococci, staphylococcal species (methicillin-sensitive), and "easy" gram-negative rods
Short half-life Cephalothin	β -Lactam mechanism	Prototype of class	Short	Low	Same as first-generation cephalosporins with expanded gram-negative activity, not including <i>Pseudomonas</i> , <i>Acinetobacter</i> , or <i>Serratia</i>
Cephapirin			Short	Low	
Longer half-life Cefazolin			Medium	Low	
Second-generation					
Poor anaerobic activity		Reduced anti-staphylococcal activity	Long	Low	Same as above, plus many anaerobes
Short half-life Cefamandole					
Cefuroxime					
Longer half-life Ceforanide					
Cefonicid			Long	Low	Same as above, plus many anaerobes
Good anaerobic activity					
Short half-life Cefoxitin					
Longer half-life Cefmetazole	β -Lactam mechanism		Medium	Low	Very active against most gram-negative rods except <i>Pseudomonas</i> , <i>Acinetobacter</i> , and <i>Serratia</i> ; poor against anaerobes; less activity against streptococcal and staphylococcal species than first- and second-generation cephalosporins
Cefotetan					
Third-generation					
Poor <i>Pseudomonas</i> activity, short half-life			Medium	Low	Same as above plus activity against many <i>Pseudomonas</i> , <i>Acinetobacter</i> , and <i>Serratia</i> spp.
Cefotaxime					
Ceftizoxime					
Cefepime			Medium	Low	Same as above with increased activity against gram-positive cocci

Monobactams					
Aztreonam	β -Lactam mechanism: Preference for PBP-3 of gram-negative bacteria; very stable against β -lactamases	Safe for most patients with penicillin allergy	Short	Low	Excellent activity against most gram-negatives, including <i>Pseudomonas</i> and <i>Serratia</i> ; inactive against gram-positive cocci, anaerobes, and most <i>Acinetobacter</i> strains
Carbapenems					
Imipenem, cilastatin	β -Lactam mechanism, plus Cilastatin mechanism: inactivates dehydropeptidases, which would normally break the β -lactam ring of imipenem in the proximal tubule	Provided in combination with cilastatin to prevent renal breakdown and renal toxicity	Short	Low; seizures in certain high-risk patients	Extremely broad gram-positive and gram-negative aerobic and anaerobic activity; modest activity against enterococci; inactive against <i>Stenotrophomonas</i> (formerly <i>Xanthomonas</i>) <i>maltophilia</i>
Meropenem		Provided alone without cilastatin	Short	Reduced potential for seizures	Same activity as imipenem
Ertapenem		Provided alone without cilastatin	Long	Low	Better activity against Enterobacteriaceae less activity against gram-positive cocci, <i>Pseudomonas</i> , <i>Acinetobacter</i> , and anaerobes
Quinolones					
Poor anaerobic activity	Inhibit bacterial enzyme DNA-gyrase, thus inhibiting DNA replication				
Norfloxacin		Oral only; urine levels only	Long	Low; interaction leads to accumulation of theophylline	Very broad gram-negative activity; gram-positive and very broad gram-negative activity, including <i>Pseudomonas</i> , <i>Acinetobacter</i> , and <i>Serratia</i> ; poor activity against anaerobes
Ciprofloxacin		Oral and IV (applies to all below)	Long		
Ofloxacin		Racemic mixture of levofloxacin (active) and dextrofloracin (inactive)	Long		
Levofloxacin		Better anaerobic activity	Long		
Gatifloxacin			Very long		As above, plus better gram-positive and anaerobe coverage
Moxifloxacin			Very long		Broad spectrum against gram-positive, gram-negative, and anaerobes
Aminoglycosides	Bind to a specific protein in the 30 S subunit of the bacterial ribosome, which leads to faulty alignment or recognition by RNA during initiation of microbial peptide chain formation	All have low ratio of therapeutic-to-toxic levels; all are frequently underdosed; all exhibit a significant postantibiotic effect*	Medium	Nephrotoxicity and nerve VIII toxicity, both auditory and vestibular	Extremely broad coverage of gram-negative rods; poor activity against streptococci; some synergism with penicillin or vancomycin against enterococci; no activity against anaerobes

Continued

Drug Class and Name	Mechanism of Action	Comment	Half-Life	Toxicity	Antibacterial Spectrum
Gentamicin Tobramycin		See above. See above.	Medium Medium	See above. Statistically but ques- tionably clinically significant decrease in nephrotoxicity	Most active against enterococci and <i>Serratia</i> spp. Most active against <i>Pseudomonas</i> spp.
Amikacin		See above.	Medium	See above (aminoglycosides).	Active against a significant number of gentamicin- and tobramycin-resistant organisms
Netilmicin		See above.	Medium	See above (aminoglyco- sides).	See above (aminoglycosides).
Other Antianaerobes					
Chloramphenicol	Inhibits bacterial protein synthesis by reversibly attaching to the 50 S subunit of the 70 S bacterial ribosome	Oral or IV	Long [†]	Dose-dependent, revers- ible bone marrow suppression; rare (1/25,000-40,000) irreversible bone	Many gram-positive and easy gram-negative rods, <i>H. influenza</i> , most anaerobes
Clindamycin	Inhibits bacterial protein synthesis by attaching to the 50 S subunit of the bacterial ribosome	Oral or IV	Long [†]	Linked to <i>Clostridium difficile</i> diarrhea	Streptococcal species except enterococci, staphy- lococci, most anaerobes; inactive against gram- negative rods
Metronidazole	Not fully elucidated; seems to produce cytotoxic effects on anaerobes by a reduction reaction (nitro group of metronidazole)	Oral or IV	Very long [†]	Disulfiram-type (Anta- buse) reaction; periph- eral neuropathy with prolonged use	Very active against most anaerobes; inactive against facultative and aerobic bacteria; active against protozoa (amoebae and <i>Giardia</i>)
Glycopeptides Vancomycin	Inhibits cell wall synthesis by binding to carboxyl subunits on peptide subunits containing free D-alanyl-D-alanine (different site from β -lactams, no cross resistance), plus may affect permeability of membrane, plus may inhibit RNA synthesis	Only IV; no oral absorption	Very long	Hypotension and histamine release phenomena (Redman syndrome) during infu- sion; nephrotoxicity, ototoxicity	Streptococcal species, including many entero- cocci, staphylococci (including methicillin- resistant strains), <i>Clostridium</i> spp.; no activity against gram-negative rods
Streptogramins					
Quinupristin-dalfopristin	Binds to different sites on the 50 S subunit of bacterial ribosomes; a 5- to 10-fold decrease in dissociation constant of quinupristin seen in the presence of dalfopristin	Significant postantibiotic effect*	Medium	Reversible transaminase elevations	Most gram-positive pathogens, including vancomycin-resistant <i>Enterococcus faecium</i> , methicillin-resistant <i>Staphylococcus aureus</i> and <i>Streptococcus epidermidis</i> , and penicillin- resistant <i>Streptococcus pneumoniae</i> but not <i>Enterococcus faecalis</i>

Oxazolidinones					
Linezolid	Attaches to the 50 S subunit of the bacterial ribosome and inhibits protein synthesis	Oral or IV	Long	Reversible monoamine oxidase inhibition with the potential to interact with adrenergic or serotonergic drugs and cause hypertension; reversible myelosuppression with thrombocytopenia, anemia, and leukopenia	
Macrolides	Attach to the 50 S subunit of the bacterial ribosome and may interfere with translocation reactions of the peptide chains	Oral or IV	Medium	Cholestasis with estolate (IV) form	Most gram-positive <i>Neisseria</i> , <i>Campylobacter</i> , <i>Mycoplasma</i> , <i>Chlamydia</i> , <i>Rickettsia</i> , <i>Legionella</i> spp.
Tetracyclines					
Tetracycline	Inhibit protein synthesis by attaching to the 30 S subunit of the bacterial ribosome	Oral or IV	Long	Stain teeth of children	Many gram-positive, easy gram-negative rods, some anaerobes, <i>Rickettsia</i> , <i>Chlamydia</i> , <i>Mycoplasma</i> spp.
Doxycycline		Oral or IV	Very long	Same	
Glycylcyclines					
Tigecycline	Inhibit protein synthesis by attaching to the 30 S subunit of the bacterial ribosome	IV	Long	No major toxicities described yet	Good against multidrug-resistant staphylococci and streptococci (including enterococci); no <i>Pseudomonas</i> coverage
Antifungal Triazoles					
Fluconazole	Inhibition of cytochrome P-450–dependent ergosterol synthesis	Oral or IV	Very long	Elevation of liver function test result	Most fungi except <i>Candida krusei</i> , <i>Candida glabrata</i>
Voriconazole			Long	Visual disturbances, fever	Most fungi
Polyenes					
Amphotericin B	Binds to sterols of cell wall and interferes with permeability	IV	Very long	Nephrotoxicity, fever, and chills	Most fungi
Echinocandins					
Caspofungin	Inhibits β -glucan synthase, disrupts integrity of the cell wall, causes cell lysis	IV	Very long	Fever; infusion-related complications	Most fungi

From Anaya D, Dellinger E. Surgical infections and choice of antibiotics. In: Townsend CM, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Saunders; pp 299–327. Drugs have been grouped into those with short, medium, long, and very long half-lives. Drugs with a short half-life usually have a half-life of 1 hr or shorter and are commonly administered every 3 to 6 hr, depending on the severity of the infection and the sensitivity of the pathogen. Drugs with a medium half-life usually have half-lives of 1 to 2 hr and are administered every 6 to 12 hr, generally every 8 hr. Drugs with a long half-life have half-lives longer than 2 hr and are usually administered every 12 to 24 hr. Drugs with a very long half-life usually have half-lives longer than 6 to 8 hr and can safely be administered every 24 hr in most cases. Amphotericin, with a half-life of approximately 24 hr, can be administered every other day.

*Postantibiotic effect is an effect of certain antibiotics that results in inhibition of bacterial growth for several hours *after* the antibiotic levels have fallen below the minimum inhibitory concentration.

†Chloramphenicol, clindamycin, and metronidazole all have half-lives longer than 2 hr but have traditionally been administered at 6- to 8-hr intervals because of historical factors rather than pharmacokinetics.

APPENDIX C

PAIN CONTROL PROTOCOLS: ADULT ACUTE PAIN MANAGEMENT PROTOCOL FOR OPIOID-NAÏVE PATIENTS

(Pharmacy will assess need for an opioid-dependent protocol.)

- Discontinue all existing orders for narcotic analgesics and diphenhydramine.
- NSAIDs must be ordered separately. If physician orders acute pain protocol with ketorolac, give ketorolac 30 mg IV × 1. Follow-up doses of IV ketorolac and oral ibuprofen will be determined by pharmacy.
- Supplemental O₂ to keep SpO₂ ≥92% per oxygen administration in non-intensive care units or as ordered by physician.
 - If patient is placed on PCA, monitor SpO₂ per PCA procedure.
- Unless specifically directed by the provider, or if there is information available to the nurse to indicate otherwise, the initial dose selected shall be at the lowest end of the dosage range. (See Medication Administration Policy for additional information.)
- Do not initiate protocol if patient receiving epidural analgesia unless ordered by anesthesiologist.
- Discontinue acute pain management protocol if other PRN (nonscheduled) narcotics ordered by physician.

If Patient Is Able to Tolerate PO Medications

- Patient pain score <4
 - Acetaminophen, 325 mg, one or two tablets PO every 4 hr PRN (max, 4 g/24 hr); may also give concurrently with oxycodone for patient pain score >6.

- Patient pain score = 4-6
 - Hydrocodone-acetaminophen, 5/325 mg, one or two tablets PO every 4 hr PRN (max acetaminophen, 4 g/24 hr or as ordered by physician)
- Pain score >6, patient intolerant of hydrocodone or hydrocodone ineffective
 - Oxycodone 5 mg, one to four tablets PO every 4 hr PRN

If Patient Is Not Able to Tolerate PO Medications or Patient Pain Score Remains >6 Despite PO Medications

- Discontinue PO opiates (notify pharmacy *in writing*).
- RN to notify pharmacy *in writing* of need to initiate PCA, specifying medication.
- Morphine by bolus or IV push (if patient cannot manage PCA, or a limited number of doses is expected)
 - 2 to 4 mg IV every 15 min PRN pain
 - 2 or 3 mg IV every 15 min PRN pain if patient >65 yr or weight <50 kg
- Morphine by PCA (if patient can self-manage and ongoing doses are expected)
 - 2 to 4 mg PCA dose, PRN pain, no basal, 10-min lockout, 12 mg max hourly rate (8 mg max hourly rate if patient >65 yr age or weight <50 kg)
- Notify physician if:
 - 12 mg and one breakthrough bolus received in 1 hr and patient's pain not controlled
 - 8 mg and one breakthrough bolus received in 1 hr, patient pain not controlled and patient >65 yr or weight <50 kg

Note: Use the following for reference only.

Dose Regimen for PCA or IV Push Opioids*

Opioid	Maintenance IV Push Dose for Non-PCA Patients	PCA settings	Breakthrough or Procedural Pain (IV push dose)	Max Hourly Dose (not including breakthrough)
Morphine				
Patient <65 yr and weight >50 kg	2-4 mg every 15 min	2-4 mg with 10-min lockout	2-4 mg every 1 hr; max, two doses in 4 hr	12 mg
Patient <65 yr or weight <50 kg	2-3 mg every 15 min	2-4 mg with 10-min lockout	2-3 mg every 1 hr; max, two doses in 4 hr	8 mg
Hydromorphone (Dilaudid)				
Patient <65 yr and weight >50 kg	0.2-0.6 mg every 15 min	0.2-0.6 mg with 10-min lockout	0.2-0.6 mg every 1 hr; max, two doses in 4 hr	2 mg
Patient >65 yr or weight <50 kg	0.2-0.4 mg every 15 min	0.2-0.6 mg with 10-min lockout	0.2-0.4 mg every 1 hr; max, two doses in 4 hr	1 mg
Fentanyl				
Patient >65 yr and weight >50 kg	25-50 µg every 15 min	20-40 µg with 10-min lockout	25-50 µg every 1 hr; max, two doses in 4 hr	150 µg
Patient >65 yr or weight <50 kg	10-30 µg every 15 min	20-40 µg with 10-min lockout	10-30 µg every 1 hr; max, two doses in 4 hr	90 µg

*When patient not able to tolerate PO medications or pain scale >6 despite PO medications.

PCA Opioid Concentrations

Morphine	Fentanyl	Hydromorphone
1 mg/mL	10 µg/mL	0.2 mg/mL

Naloxone per Naloxone IV (Narcan) Administration Policy

Dilute one vial of naloxone as follows:

1. Expel 1 mL from a 10-mL saline syringe.
2. Draw up 0.4 mg (1 mL) naloxone into the same saline syringe.
3. Give 1 mL/min (0.04 mg/min) and repeat every minute until
 - a. Respiratory rate >10/min
 - b. SpO₂ ≥92%
 - c. Level of sedation (LOS) <3

Use the following examples to notify pharmacy in writing on a progress and order sheet:

For breakthrough or procedural pain: (*insert IV med*) IV push per [Appendix C](#) for breakthrough or procedural pain, per physician (*insert physician*).

Nurse signature _____ Date _____ Time _____

To transition to PO medications from IV:

Discontinue (D/C) IV narcotics and start PO pain medications per [Appendix C](#), per physician (*insert physician*).

Nurse signature _____ Date _____ Time _____

To transition to IV medications from PO:

D/C PO narcotics and start IV pain medications per [Appendix C](#) per physician (*insert physician*).

Nurse signature _____ Date _____ Time _____

If Patient Has Morphine Intolerance (Nausea, Vomiting, Unrelieved Pruritus)

- Hydromorphone by bolus or IV push (if patient cannot manage PCA, or a limited number of doses is expected)
 - 0.2 to 0.6 mg IV every 15 min PRN pain
 - 0.2 to 0.4 mg IV every 15 min PRN pain if patient >65 yr or weight <50 kg
- Hydromorphone by PCA (if patient can self-manage and ongoing doses are expected)
 - 0.2 to 0.6 mg PCA dose, PRN pain, no basal, 10-min lockout, 2 mg max hourly rate (1 mg max hourly rate if patient >65 yr or weight <50 kg)
 - Bolus dose equal to demand dose to be given by RN at initiation of PCA (bolus doses not included in max hourly rate)
- Notify physician if:
 - 2 mg and one breakthrough bolus received in 1 hr and patient's pain not controlled
 - 1 mg and one breakthrough bolus received in 1 hr, patient's pain not controlled and patient >65 yr or weight <50 kg

If Patient Has True Morphine Allergy (e.g., Rash, Hives, Respiratory Distress)

- Fentanyl by bolus or IV push (if patient cannot manage PCA, or a limited number of doses is expected)
 - 25 or 50 µg IV every 15 min PRN pain
 - 10 to 30 µg IV every 15 min PRN pain if patient >65 yr or weight <50 kg

- Fentanyl by PCA (if patient can self-manage and ongoing doses are expected)
 - 20 to 40 µg PCA dose, PRN pain, 10-min lockout, no basal, 150 µg max hourly rate (90 µg max hourly rate if patient >65 yr or weight <50 kg)
 - Bolus dose equal to demand dose to be given by RN at initiation of PCA (bolus doses not included in max hourly rate)
- Notify physician if:
 - 150 µg and one breakthrough bolus received in 1 hr and patient's pain not controlled
 - 90 µg and one breakthrough bolus received in 1 hr, patient's pain not controlled, and patient >65 yr of age and weight <50 kg

Transition from IV to PO

When patient pain score <6 for 24 hr and/or patient is able to tolerate PO, notify pharmacy in writing and resume PO medications per protocol.

Breakthrough or Procedural Pain

Supplement current medication dosing with IV push morphine or current IV opioid, one dose/hr, max two doses every 4 hr PRN.

Oversedation

Level of Sedation Score

- 1 = alert, easy to arouse
 - 2 = occasionally drowsy, easy to arouse (e.g., by voice)
 - 3 = frequently drowsy
 - 4 = somnolent, difficult to arouse
- If patient develops a level of sedation score of 3:
 - Hold additional opioids (stop PCA), until score <3 or call physician if patient is still requesting additional opioids.
 - If patient develops a level of sedation score of 4 or a respiratory rate <10/min, inability to maintain SpO₂ at least 92% on 3 liters O₂:
 - Give naloxone per naloxone IV (Narcan) administration policy.
 - If patient unresponsive, apneic:
 - Initiate Code Blue and administer naloxone per naloxone IV (Narcan) administration policy (0.4 mg IV push, undiluted).

If Patient Develops Pruritus

- Diphenhydramine 12.5 to 25 mg IV or PO every 4 hr PRN (use with caution in patients ≥65 yr).

If diphenhydramine is not effective:

- Nalbuphine (Nubain) 1.25 mg IV every 6 hr PRN (may repeat × 1 for total dose of 2.5 mg/6 hr PRN)
- If pruritus associated with morphine and unresolved with diphenhydramine or nalbuphine, switch to hydromorphone.

Physician's Orders for PCA Therapy

MEDICATION AND TREATMENT		
Date	Time	References
If morphine PCA ordered and patient has received intrathecal morphine within last 24 hr. Notify physician before starting PCA of morphine.		Generally, a PCA should be started without a continuous rate. If needed, a usual continuous rate is no <i>more than</i> half the previous hour's total PCA dose as an hourly rate while patient is asleep.
1. Respiratory rate (RR) q2h × 8 hr, then q4h. Notify physician if:		<i>Naloxone (Narcan) Administration</i>
a. RR ≤10 and Sao ₂ <94 on 3 liters O ₂ <i>and/or</i>		1. Draw up 0.4 mg (1 mL) in 10-mL syringe; in the same syringe, draw up 9 mL or saline for a naloxone concentration of 0.04 mg/mL.
b. Level of sedation = 3		2. Give 1-mL IV push, flushing solution into vein, and repeat every minute until RR and LOS acceptable per policy.
2. Maintenance IV		3. Turn PCA off.
IV fluid _____		4. Notify ordering physician STAT.
Rate _____ mL/hr		5. Fill out electronic incident report.
3. PCA Medication _____		<i>Concentration</i>
4. Program pump as follows:		Morphine: 1 mg/mL
PCA dose: _____ mL		Fentanyl: 10 µg/mL
Lockout interval: _____ min		Hydromorphone: 0.2 mg/mL
Loading dose: _____ mL		<i>Usual Ranges</i>
Maximum hourly dose: _____ mL/hr		Usual lockout interval is 10 min, with range of 5-15 min.
Continuous rate: _____ mL/hr		<i>Recommended Maximum Hourly Dose</i>
		Morphine: 15 mg (15 mL)/hr
		Fentanyl: 200 µg (20 mL)/hr
		Hydromorphone: 3 mg (15 mL)/hr
		<i>Equivalent IV Opioid Doses</i>
5. Naloxone (Narcan): Per hospital policy or procedure		Morphine: 1 mg (1 mL)
Physician Signature: _____		Fentanyl: 10 µg (1 mL)
		Hydromorphone: 0.2 mg (1 mL)

26

Abnormal Uterine Bleeding Etiology and Management of Acute and Chronic Excessive Bleeding

Timothy Ryntz, Roger A. Lobo

Abnormal uterine bleeding (AUB) can present in many ways, from infrequent episodes, to excessive flow, or prolonged duration of menses and intermenstrual bleeding. Alterations in the pattern or volume of blood flow of menses are among the most common health concerns of women. Infrequent uterine bleeding is called **oligomenorrhea** if the intervals between bleeding episodes vary from 35 days to 6 months, and **amenorrhea** is defined by no menses for at least 6 months. These are discussed in [Chapter 38](#). Excessive or prolonged bleeding will be discussed in this chapter. An overview of several therapeutic modalities being used to treat excessive uterine bleeding will also be discussed here.

To define excessive abnormal uterine bleeding, it is necessary to define normal menstrual flow. The mean interval between menses is 28 days (± 7 days). Thus if bleeding occurs at intervals of 21 days or less or 35 days or more it is abnormal. The mean duration of menstrual flow is 4 days. Few women with normal menses bleed more than 7 days, so bleeding for longer than 7 days is considered to be abnormally prolonged. It is useful to document the duration and frequency of menstrual flow with the use of menstrual diary cards; however, it is difficult to determine the amount of menstrual blood loss (MBL) by subjective means. Several studies have shown that there is poor correlation between subjective judgment and objective measurement of MBL ([Chimbira, 1980](#)).

Although subjective methods are used in predicting blood loss, and some investigators have used a pictorial bleeding assessment chart, a more accurate system is the alkaline hematic method, which measures hematin. Average menstrual blood loss is 35 mL. Total volume, however, is twice this amount, being made up of endometrial tissue exudate. The amount of MBL increases with parity but not age in the absence of disease. An MBL of 80 mL or greater is defined as heavy menstrual bleeding, which occurs in 9% to 14% of women ([Shapley, 2004](#)).

Although mortality and serious complications of abnormal uterine bleeding are uncommon, their impact on health-related quality of life is burdensome. Direct costs are calculated at more than \$1 billion annually in the United States, and indirect costs due to lost work, social function, and vitality has been estimated at more than \$12 billion annually ([Liu, 2007](#)).

CAUSES OF ABNORMAL UTERINE BLEEDING

The causes of AUB can be described by a universally accepted systematic nomenclature. This system was reported by the International Federation of Gynecology and Obstetrics (FIGO) in 2011 ([Munro, 2011](#)). It subdivides causes of AUB into nine main categories, which are arranged according to the acronym **PALM-COEIN**: polyp, adenomyosis, leiomyoma, malignancy and hyperplasia, coagulopathy, ovulatory dysfunction, endometrial, iatrogenic, and not yet classified. The etiologies that constitute the first group (**PALM**) are structural or histologic causes that are diagnosed through imaging or biopsy. Those that compose the second group (**COEIN**) are nonstructural ([Fig. 26.1](#)). The term *dysfunctional uterine bleeding (DUB)* is no longer favored and should be discarded. In the past, this term has represented causes of abnormal bleeding when structural causes and other specific defects, such as coagulation defects, had been excluded. Cases that previously would have been described as DUB are now referred to as AUB due to ovulatory dysfunction or endometrial causes.

According to FIGO, this classification system should be notated in a consistent and systematic manner. The acronym AUB is followed by the letters PALM-COEIN and a subscript 0 or 1 associated with each letter to indicate the absence or presence, respectively, of the abnormality. For example, a patient with abnormal bleeding due to a polyp would be described as AUB-P₁A₀L₀M₀-C₀O₀E₀I₀N₀. Because patients may have abnormal bleeding due to more than one condition, this notation allows for description of simultaneous factors. For example, a patient with abnormal bleeding that is both irregular and heavy may have endometrial hyperplasia due to anovulation. As such, this patient's bleeding would be described as AUB-P₀A₀L₀M₁-C₀O₁E₀I₀N₀.

What follows is an introduction to each of the pathologies described by the PALM-COEIN system. Following this discussion, a diagnostic approach for women with AUB will be outlined. Treatments for acute and chronic bleeding due to these conditions conclude this chapter.

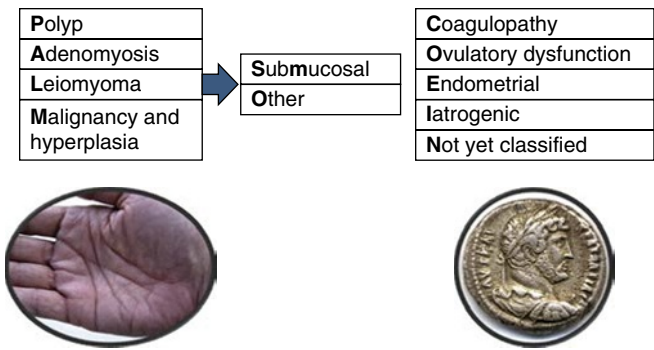

Figure 26.1 PALM-COEIN Classification System for Abnormal Uterine Bleeding. The basic system comprises four categories that are defined by visually objective structural criteria (PALM), four that are unrelated to structural anomalies (COEI), and one reserved for entities that are not yet classified (N). The leiomyoma category is subdivided into patients with at least one submucosal myoma (L_{SM}) and those with myomas that do not affect the endometrial cavity (L_0). (From Munro MG, Critchley HOD, Broder MS, Fraser IS. FIGO classification system [PALM-COEIN] for causes of abnormal uterine bleeding in nongravid women of reproductive age. *Int J Gynecol Obstet.* 2011;113[1]:3-13.)

ENDOMETRIAL POLYPS

Endometrial polyps (AUB-P) are localized overgrowths of endometrial tissue, containing glands, stroma, and blood vessels, covered with epithelium (Peterson, 1956). Endometrial polyps are most commonly found in reproductive-age women, and estrogen stimulation is thought to play a key role in their development. As such, polyps are rarely found before menarche. Molecular mechanisms involving overexpression of endometrial aromatase and gene mutations in HMGIC and HMGI[Y] have also been proposed (Maia, 2006; Tallini, 2000).

The majority of endometrial polyps are benign. A systematic review of the oncogenic potential of endometrial polyps demonstrated that symptomatic vaginal bleeding and postmenopausal status are associated with an increased risk of malignancy. Among symptomatic postmenopausal women with endometrial polyps, 4.5% had a malignant polyp compared with 1.5% in asymptomatic women (Lee, 2010). A strong correlation exists for both tamoxifen use and obesity and the development of malignancy in endometrial polyps. Diabetes mellitus and hypertension have not been reliably shown to increase the risk for malignancy in an endometrial polyp.

The importance of small and asymptomatic endometrial polyps is less clear. Transvaginal ultrasound detected asymptomatic polyps in up to 12% of women undergoing routine gynecologic examination; small endometrial polyps smaller than 1 cm appear to regress spontaneously (Hamani, 2013). Endometrial polyps were discovered in 32% of 1000 patients on office hysteroscopy about to undergo in vitro fertilization, suggesting a possible association between endometrial polyps and infertility (Hinckley, 2004). Women with symptomatic polyps can be treated safely and effectively with operative hysteroscopy (Video 26.1).

ADENOMYOSIS

Adenomyosis (AUB-A) is defined by the presence of endometrial glands and stroma in the uterine myometrium. The presence of ectopic endometrial tissue leads to hypertrophy of the surrounding

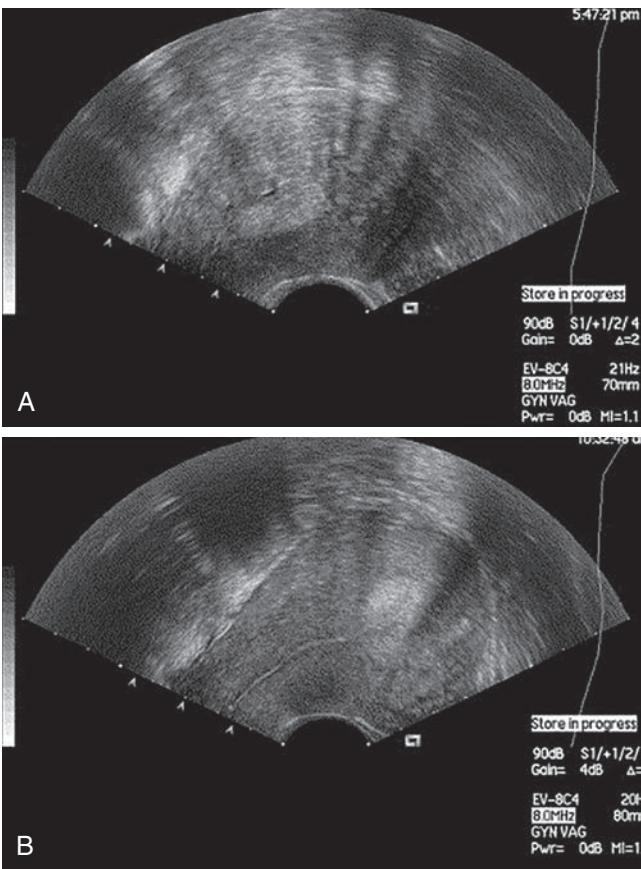

Figure 26.2 Transvaginal sonography of uterus with adenomyosis: heterogeneous and hypoechoic, poorly described areas in the myometrium with characteristic anechoic lacunae, and linear striations radiating out from the endometrium into the myometrium (A) and increased echo texture of the myometrium with an indistinct endomyometrial junction (B). (From Dueholm M. Transvaginal ultrasound for diagnosis of adenomyosis: a review. *Best Pract Res Clin Obstet Gynaecol.* 2006;20[4]:569-582.)

myometrium. Adenomyosis can occur as focal (adenomyoma) or diffuse, with a peak incidence in the fifth decade of life. Multiparity is considered the most significant risk factor for developing adenomyosis, but any process that allows for penetration of endometrial glands and stroma past the basalis layer (e.g., dilation and curettage, cesarean delivery, spontaneous abortion) is thought to contribute. There also appears to be a positive correlation between overexpression of immunoproteins interleukin-6, interleukin-18, and cyclooxygenase-2 and the presence of ectopic endometrial tissue, though these may not be causative (Leyendecker, 2004; Huang, 2010). Adenomyosis is a histologic diagnosis, but findings of an enlarged, asymmetric uterus on ultrasound and magnetic resonance imaging (MRI) are indicative. Anechoic avascular cysts scattered throughout the myometrium on sonography are considered pathognomonic for adenomyosis on ultrasound. MRI, which is both more sensitive and specific than ultrasound, will demonstrate thickening of the junctional zone, the area between the endometrium and the myometrium, equal to or greater than 12 mm (Figs. 26.2 and 26.3) (Dueholm, 2007). Abnormal bleeding due to adenomyosis is thought to be a result of altered uterine contractility and is commonly associated with profound dysmenorrhea.

Figure 26.3 Magnetic resonance image of asymmetric adenomyosis. (From Tamai K, Koyama T, Umeoka S, et al. Spectrum of MR features in adenomyosis. *Best Pract Res Clin Obstet Gynaecol*. 2006;20[4]:583-602.)

LEIOMYOMA

Leiomyoma (AUB-L), or fibroids, are benign tumors of the uterine myometrium with a complex and heterogeneous clinical presentation as varied as their biologic origins. Various genetic mutations are described in leiomyoma, but the pathogenesis is thought to initiate from myometrial injury leading to cellular proliferation, decreased apoptosis, and increased production of extracellular matrix. Critical in this pathway is the overexpression of transforming growth factor beta that leads to fibrosis of these tumors (Laughlin, 2011). Transforming growth factor beta also contributes to implantation failure in women with fibroids who are subfertile.

Although the prevalence of fibroids among women is approximately 70%, as many as 50% of these will be symptomatic (Gupta, 2008). Mechanisms by which fibroids cause abnormal bleeding are varied and depend on size, location, and number. Subclassification of leiomyomas describes their location throughout the myometrium (Fig. 26.4). Intracavitary fibroids (type 0) and submucosal fibroids, where more than 50% are intracavitary (type 1) or less than 50% are intracavitary (type 2), as well as intramural fibroids, which are large, may increase the overall surface area of the endometrial cavity or alter uterine contractility. These effects in turn lead to abnormal and excessive uterine bleeding. Whereas hysterectomy for fibroids remains among the leading indications for the procedure in the United States, treatments are diverse including hormonal or surgical ablation of the endometrium, uterine artery embolization, radiofrequency ablation,

and myomectomy through a variety of surgical approaches (Videos 26.2, 26.3, and 26.4).

According to the FIGO system, leiomyomas can be notated in the PALM-COEIN system with a subscript 0 in their absence or by the number 1 when present. Additionally, the letters *SM* can be inserted to indicate a fibroid's location as submucosal.

MALIGNANCY

Malignancies (AUB-M) associated with the female reproductive tract include vulvar, vaginal, cervical, endometrial, uterine, and adnexal (ovarian or fallopian tube) cancers. Although vaginal cancers can cause abnormal bleeding, there are only approximately 3000 new cases reported annually in the United States. Bleeding from cervical malignancy classically presents as coital bleeding or intermenstrual bleeding; thus a thorough cervical evaluation is an important part of the workup of any woman with these symptoms. In a series of 73 women with coital bleeding referred for evaluation, squamous cell carcinoma of the cervix was present in 1.4% of patients, and 15% had cervical intraepithelial neoplasia (Havenga, 2013).

AUB is the most common presenting symptom of endometrial cancer. Although endometrial cancer presents most often in the seventh decade, 15% of cases are diagnosed in premenopausal women, and 3% to 5% present in women under the age of 40 (Haidopoulos, 2010). Conditions that lead to increased circulating levels of estrogen are risk factors. Obesity is associated with increased estrone levels due to peripheral conversion by aromatase in adipose tissue; but the primary source of estrogen in premenopausal women remains the ovary. Impaired ovulation and the absence of progesterone withdrawal can result in sustained exposure of the endometrium to estrogen. This hyperestrogenic state can lead to the pathologic progression from normal endometrium to hyperplasia and ultimately to adenocarcinoma.

Lynch syndrome, or hereditary nonpolyposis colorectal cancer, is an autosomal dominant disease caused by a disruption in the mismatch repair (MMR) genes. Lynch syndrome also carries a 40% to 50% lifetime risk of endometrial cancer, with a significant proportion of endometrial cancers occurring before the age of 45. In addition, estrogen-producing ovarian tumors may become manifest by abnormal uterine bleeding. Granulosa theca cell tumors are the most common tumors to have this presentation, although many ovarian tumors can produce estrogen.

COAGULOPATHY

Systemic diseases, particularly disorders of blood coagulation (AUB-C) such as von Willebrand disease and prothrombin deficiency, may initially present as AUB (Minjarez, 2008). Routine screening for coagulation defects is mainly indicated for the adolescent who has prolonged heavy menses beginning at menarche. In adults, screening for these disorders is of little value unless otherwise indicated by clinical signs such as bleeding gums, epistaxis, or ecchymosis. Twenty percent of adolescent girls who require hospitalization for abnormal uterine bleeding have been reported to have coagulation disorders (Claessens, 1981). Coagulation defects are present in approximately 25% of those whose hemoglobin levels fall below 10 g/100 mL, in one third of those who require transfusions, and in 50% of those whose severe

Figure 26.4 Tertiary classification system of fibroids including submucosal, intramural, and subserosal fibroids. (From Munro MG, Critchley HOD, Broder MS, Fraser IS. FIGO classification system [PALM-COEIN] for causes of abnormal uterine bleeding in nongravid women of reproductive age. *Int J Gynecol Obstet.* 2011;113[1]:3-13.)

menorrhagia occurred at the time of the first menstrual period. Others report that a coagulation disorder is found in only 5% of adolescents hospitalized for heavy bleeding (Falcone, 1994).

Both studies indicated that the likelihood of a blood disorder in adolescents with heavy menses is sufficiently high that all adolescents should be evaluated to determine whether a coagulopathy is present.

Disorders of platelets are most often quantitative, but defects in platelet membrane or storage granules can result in normal circulating levels with altered function. Hemophilias A and B are X-linked recessive deficiencies of factor VIII and factor IX, respectively. Women who are carriers for these disorders can have reduced levels of factors VIII and IX, some less than 30% of normal and enough to be considered to have mild hemophilia. Rare inherited coagulopathies of the other clotting factors (V, VII, X, XI, XIII) include menorrhagia as a potential symptom. Other disorders that produce platelet deficiency, such as leukemia, severe sepsis, idiopathic thrombocytopenic purpura, and hypersplenism, can also cause excessive bleeding.

Chronic anticoagulation as a result of heparin, low-molecular-weight heparin, direct thrombin inhibitors, and direct factor Xa inhibitors is necessary for prevention of thrombosis in women with inherited thrombophilias, those with mechanical

heart valves, and those with rare anatomic disorders such as May-Thurner syndrome. In the absence of other gynecologic pathology, these patients present most often with heavy menstrual bleeding. Although it may seem that these patients could be considered as having iatrogenic abnormal bleeding due to prescribed medications, heavy bleeding is a result of a derangement in the coagulation cascade and is thus categorized here.

OVULATORY DYSFUNCTION

The predominant cause of ovulatory dysfunction (AUB-O) in postmenarchal and premenopausal women is secondary to alterations in neuroendocrine function. In women with AUB-O, there is continuous estradiol production without corpus luteum formation and progesterone production. The steady state of estrogen stimulation leads to a continuously proliferating endometrium, which may outgrow its blood supply or lose nutrients with varying degrees of necrosis. In contrast to normal menstruation, uniform slough to the basalis layer does not occur, which produces excessive uterine bleeding.

Anovulatory bleeding occurs most commonly during the extremes of reproductive life—in the first few years after menarche and during perimenopause. In the adolescent, the cause

of anovulation is an immaturity of the hypothalamic-pituitary-ovarian (HPO) axis and failure of positive feedback of estradiol to cause a luteinizing hormone (LH) surge. In the perimenopausal woman, a lack of synchronization between the components of the HPO axis occurs as the woman approaches ovarian decline at menopause.

The pattern of anovulatory bleeding may be oligomenorrhea, intermenstrual bleeding, or heavy menstrual bleeding. Why different patterns of bleeding occur within a distinct entity of anovulatory bleeding is unclear but is probably related to variations in the integrity of the endometrium and its support structure. Up to 20% of women reporting normal menses may also be anovulatory.

What are the causes of anovulation? Apart from the extremes of reproductive life, as noted, women in their reproductive years often have a cause for anovulatory bleeding. This is most frequently because of polycystic ovary syndrome (PCOS), which may be suggested by other symptoms and signs, such as acne, hirsutism, and increased body weight (see [Chapter 41](#)). If not PCOS, anovulation can result from hypothalamic dysfunction, which could have no known cause or be related to weight loss, severe exercise, stress, or drug use. In addition, abnormalities of other nonreproductive hormones can lead to anovulation. The most common hormones involved are thyroid hormone, prolactin, and cortisol.

Hypothyroidism, evidenced by an elevated thyroid stimulating hormone (TSH) level, can lead to anovulatory bleeding. Unexplained causes of endometrial problems in the face of normal ovulation (discussed later) may also be explained by subtle hypothyroidism. Hyperprolactinemia (prolactin [PRL] level >20 ng/mL) can also lead to anovulatory bleeding, as can hypercortisolism. However, Cushing syndrome is rare and may be considered only if other signs are present (e.g., obesity, moon facies, buffalo hump, striae, weakness). Accordingly, TSH and PRL assays should be part of the normal workup of anovulatory women.

IATROGENIC

Iatrogenic bleeding (AUB-I) is abnormal bleeding resulting from medications. The most common of these are hormonal preparations, including selective estrogen receptor modulators, and gonadotrophic releasing hormone agonists and antagonists. All hormonal long-acting reversible contraceptives result in some degree of anovulation and irregular or intermenstrual bleeding. However with time, most patients become amenorrheic. The prevalence of amenorrhea with depot medroxyprogesterone acetate users at 90, 180, 270, and 360 days are 12%, 25%, 37%, and 46%, respectively, as determined by a systematic review ([Hubacher, 2009](#)). And chronic progestogen therapy of various types can lead to irregular spotting and bleeding. Similarly, irregular bleeding is an expected consequence of levonorgestrel intrauterine devices initially, but 20% of users are amenorrheic by 1 year. Implantable progestin devices have similar amenorrhea rates, but over 40% of patients have irregular or prolonged bleeding. This pattern of bleeding is the most common reason for discontinuation of the subdermal implants within the first year ([Mark, 2013](#)).

Hyperprolactinemia can result from central nervous system dopamine antagonism of certain antipsychotic drugs.

The prevalence of hyperprolactinemia among women taking risperidone was 88%, and among women taking conventional antipsychotics it was 47% in one study. As previously described, elevations in prolactin are disruptive to the HPO axis and can contribute to anovulation, with 48% of those women on risperidone experiencing abnormal uterine bleeding (Kinon, 2003).

It is well known that commonly combined and progesterone-only oral contraceptives may result in breakthrough bleeding (BTB). BTB most likely reflects alterations in the structural integrity, vascular density, and vascular morphology of the endometrial vasculature due to alterations in the expression of steroid receptors and the integrity of the endometrial epithelial layer ([Smith, 2005](#)). Compliance issues and interactions between oral contraceptives and other medications, such as antibiotics and anticonvulsants may alter circulating levels of steroids, allowing follicular recruitment and increased endogenous levels of estrogen. These variations are a common cause of irregular bleeding in contraceptive users.

ENDOMETRIAL

Women who present with heavy menstrual bleeding in the absence of other abnormalities are thought to have underlying disorders of the endometrium (AUB-E) or are otherwise unclassified. In the past, this category has been called “ovulatory dysfunctional uterine bleeding.”

The primary line of defense to excessive bleeding during normal menses is the formation of the platelet plug. This is followed by uterine contractility, largely mediated by prostaglandin F_{2α} (PGF_{2α}). Thus prolonged and heavy bleeding can occur with abnormalities of the platelet plug or inadequate uterine levels of PGF_{2α}. It has been shown that in some women with heavy menstrual bleeding, there is excessive uterine production of prostacyclin, a vasodilatory prostaglandin that opposes platelet adhesion and may also interfere with uterine contractility. Deficiency of uterine PGF_{2α} or excessive production of PGE (another vasodilatory prostaglandin) may also explain ovulatory DUB ([Smith, 1982](#)). The ratio of PGF_{2α}/PGE correlates inversely with menstrual blood loss ([Fig. 26.5](#)). In addition to these, other uterine factors affecting blood flow, such as the endothelins and vascular endothelial growth factor, which controls blood vessel formation, may be abnormal in some women with heavy menstrual bleeding. Unfortunately, no commercially available assays exist, and endometrial causes of AUB remain a diagnosis of exclusion in most cases.

Chronic inflammatory changes of the endometrium as evidenced by plasma cell infiltration indicate endometritis. However the causal relationship between inflammatory changes and abnormal bleeding is unclear, resulting from a variety of factors including infection, vascular endothelial damage, or alterations in vasculogenesis. Subclinical infection with *Chlamydia trachomatis* has also been associated with AUB.

NOT OTHERWISE SPECIFIED

Abnormal bleeding not classified in the previous categories is considered AUB-N. Examples of such conditions may include foreign bodies or trauma. Treatment is tailored to the specific cause.

Figure 26.5 Correlation between ratio of endogenous concentrations of prostaglandin F₂α and prostaglandin E and menstrual blood loss (MBL); normal secretory endometrium; persistent endometrium. (From Smith SK, Abel MH, Kelly RW, et al. The synthesis of prostaglandins from persistent proliferative endometrium. *J Clin Endocrinol Metab.* 1982;55[2]:284-289.)

DIAGNOSTIC APPROACH

When a woman presents with a complaint of abnormal bleeding, it is essential to take a thorough history regarding the frequency, duration, and amount of bleeding, as well as to inquire whether and when the menstrual pattern changed. This history is important for describing the menstrual abnormality as oligomenorrhea, polymenorrhea, heavy menstrual bleeding, or intermenstrual bleeding. History and physical examination provide clues about the diagnosis of ovulatory disorders and other systemic illnesses. Providing the woman with a calendar to record her bleeding episodes is a helpful way to characterize definitively the bleeding episodes. A number of commercially available smart phone applications exist to track abnormal bleeding conveniently, although none of these have been validated. Symptoms present for the majority of the preceding 6 months are considered chronic, but symptoms lasting 3 months sufficiently indicate the need for investigation.

Because there is a poor correlation between a woman's estimate of the amount of blood flow and the measured loss, as well as great variation in the amount of blood and fluid absorbed by different types of sanitary napkins and tampons (and by the same type in different women), objective criteria should be used to determine if menorrhagia (blood loss >80 mL) is present.

As direct measurement of MBL is not generally possible, indirect assessment by measurement of hemoglobin concentration, serum iron levels, and serum ferritin levels are useful. The serum ferritin level provides a valid indirect assessment of iron stores in the bone marrow. Additional useful laboratory tests include a sensitive β-hCG level determination and a sensitive TSH assay, as well as PRL. If PCOS is suspected, androgen level measurements may be considered but are not necessary.

For adolescent girls with heavy menstrual bleeding, as well as older women with the constellation of systemic disease, easy bruising and petechiae, a coagulation profile including platelet count, prothrombin time, von Willebrand factor, and

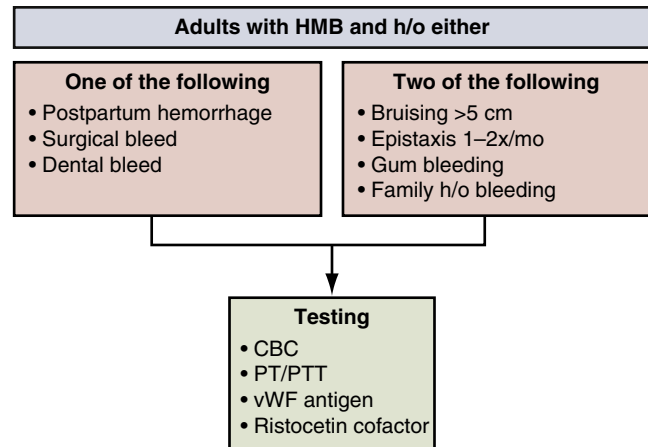

Figure 26.6 Diagnostic approach to adults with abnormal uterine bleeding due to coagulopathy. (Data from Kouides PA, Conard J, Peyvandi F, et al. Hemostasis and menstruation: appropriate investigation for underlying disorders of hemostasis in women with excessive menstrual bleeding. *Fertil Steril.* 2005;84[5]:1345-1351.)

ristocetin cofactor should be obtained to rule out a coagulation defect. Once thought to be extremely rare as a cause for abnormal bleeding, studies have found a fairly high prevalence of coagulation disorders in women presenting with heavy menstrual bleeding. Most abnormalities are platelet related. The single most common abnormality is a form of von Willebrand disease. It has been estimated that the prevalence of von Willebrand disease, the most common of these bleeding disorders, is 11% in women with heavy menstrual bleeding (Dilley, 2001). von Willebrand factor is responsible for proper platelet adhesion and protects against coagulant factor degradation. History is essential before a comprehensive hematologic workup is undertaken. This includes a history of menorrhagia, family history of bleeding, epistaxis, bruising, gum bleeding, postpartum hemorrhage, and surgical bleeding. In the absence of these clues, a comprehensive workup is probably unnecessary at the outset but should be considered in cases refractory to treatment. A hematologist should be consulted to assist in confirming the diagnosis and to suggest possible treatment (Fig. 26.6).

If the woman has regular cycles, it is helpful to determine whether she is ovulating. However, if bleeding is very irregular, it may be difficult to determine the phase of the cycle to document ovulatory function by means of serum progesterone level. Patients with chronic anovulation are at increased risk for endometrial hyperplasia and malignancy. If there is an enhanced risk for endometrial disease on the basis of history, endometrial sampling is indicated. Endometrial sampling is also recommended in patients with heavy menstrual bleeding over the age of 45 (NIH Clinical Excellence, 2007). Sampling is most often performed with a 3 mm Pipelle in the office, with little or no anesthesia. Sampling should include a measurement of the uterine length and subjective assessment of the quantity of tissue. When office endometrial biopsy is not possible or if the tissue sample is insufficient, dilation and curettage (D&C) should be performed under anesthesia. The sensitivity of endometrial biopsy was 68% when compared with hysterectomy specimens and was 78% when compared with D&C in one

Figure 26.7 Saline sonography demonstrating a 1.4-cm diameter endometrial polyp in a woman with heavy menstrual bleeding. (Courtesy of Dr. J. Lerner, Columbia University Medical Center, New York.)

meta-analysis, concluding that a sampling error occurred in 0% to 54% of cases (Rodriguez, 1993). It thus works best in cases where pathology is global. In cases of regular heavy menstrual bleeding, a biopsy at the time of bleeding can also help determine whether the bleeding is caused by ovulatory function if it reveals a secretory endometrium.

Apart from obtaining a careful history and physical examination, blood testing (as noted earlier), ultrasound, and endometrial biopsy (if indicated), it is often valuable to assess the uterine cavity through sonohysterogram (SHG) or flexible hysteroscopy. This is to rule out an intracavitary lesion before ascribing the diagnosis to endometrial disorders or ovulatory dysfunction.

For SHG, 10 to 15 mL of saline or sterile water is usually introduced through the cervix with an insemination catheter, or with a special catheter that has a balloon for inflation in the cervical canal, allowing continuous infusion. Office-based flexible hysteroscopy is an excellent diagnostic technique that provides direct visualization of the endometrium and has the potential advantage of being able to treat the abnormality at the same time, for example, as removal of a polyp. The sensitivity and specificity of SHG and hysteroscopy are equivalent in diagnosing intracavitary lesions, but both are superior to transvaginal pelvic ultrasound alone (Kelekci, 2005). Studies show that both studies are well accepted by patients (Van Dongen, 2008) (Fig. 26.7).

Evaluation of the myometrium includes imaging modalities capable of detecting leiomyomas and adenomyosis. Ultrasonography is a sensitive screening tool and performs similarly to MRI in the detection of uterine fibroids with a sensitivity of 99% (Dueholm, 2002). But with a wide array of treatment modalities available, assessment of the myometrium requires an exact understanding of fibroid position, size, and number. In most instances, MRI performs superiorly. Compared with findings at the time of hysterectomy, MRI, ultrasound and hysteroscopy perform equally well in the detection of submucous fibroids, but MRI performs superiorly in the evaluation of the extent of myoma invasion (Dueholm, 2001). In large uteri (>375 mL) or when fibroids number more than four, MRI is also superior to ultrasound in detecting and mapping fibroid location.

However, hysteroscopy and sonohysterography continue to offer less expensive alternatives to MRI for adequate determination of endometrial distortion.

TREATMENT OF ABNORMAL UTERINE BLEEDING

Treatment of abnormal bleeding requires an accurate diagnosis. Endometrial polyps that cause abnormal bleeding require surgical removal via hysteroscopy. The management of malignancy and hyperplasia is discussed elsewhere. Many of the following medical managements may be applied to leiomyoma, but large and complicated uteri or submucosal fibroids often require surgery. In the absence of an organic cause for excessive uterine bleeding, it is preferable to use medical instead of surgical treatment, especially if the woman desires to retain her uterus for future childbearing or will be undergoing natural menopause within a short time. There are several effective medical methods for the treatment of ovulatory or endometrial bleeding. These include estrogens, progestogen (systemic or local), nonsteroidal anti-inflammatory drugs (NSAIDs), antifibrinolytic agents, and gonadotropin-releasing hormone (GnRH) agonists. The type of treatment depends on whether it is used to stop an acute heavy bleeding episode or is given to reduce the amount of MBL in subsequent menstrual cycles. A definitive diagnosis is required before instituting long-term treatment, and should be made on the basis of hysteroscopy, sonohysterography, or directed endometrial biopsies, if indicated.

This section is organized into treatment options for chronic conditions followed by management of severe acute bleeding. Whereas these medical options treat the underlying pathology and manage the symptoms in patients with ovulatory dysfunction and endometrial causes, medical treatment options may be initiated in patients with adenomyosis or leiomyoma not severe enough to require surgery. Last, a brief overview of surgical options is presented.

ABNORMAL UTERINE BLEEDING: OVULATORY DYSFUNCTION

In adolescents, after ruling out coagulation disorders, the main direction of therapy is to temporize because with time and maturity of the HPO axis, the problem will be corrected. A cyclic progestogen—for example, medroxyprogesterone acetate, 10 mg for 10 days each month for a few months—is all that is needed to produce reliable and controlled menstrual cycles. This may be continued for up to 6 months with the situation reevaluated thereafter. Alternatively, some clinicians prefer to use an oral contraceptive (OC), although this may not be necessary and does not allow the HPO to mature on its own. If the problem persists beyond 6 months, OCs become an option in that the condition may be more chronic.

In the perimenopausal woman who has dysregulation of the HPO axis, there is much variability and unpredictability of cycles because the HPO axis is in flux, moving toward ovarian failure. Although most of the bleeding in this setting is caused by anovulation, occasional ovulation can occur, with or without a normal luteal phase, which is highly variable and erratic. Here, it is more efficient to use a low-dose (20-μg) OC in a

nonsmoking woman. Progestogens used cyclically, although preventing endometrial tissue from building up because of anovulation, will help the endometrium but will not reliably control bleeding, because of the unpredictability of the hormonal situation.

During reproductive life, chronic anovulatory bleeding is primarily caused by hypothalamic dysfunction or PCOS. OCs work well in this setting, although an alternative is cyclic progestogens, as noted previously. Some of these women may also wish to conceive, in which case ovulation induction is indicated.

ABNORMAL UTERINE BLEEDING: ENDOMETRIAL

For women with heavy menstrual bleeding, for whom there is no known cause and anatomic lesions have been ruled out, the aim of therapy is to reduce the amount of excessive bleeding. As noted, some women with AUB-E have abnormal prostaglandin production and some have alterations of endometrial blood flow.

Options for treatment to reduce blood loss include a more prolonged regimen of progestogens (3 weeks each month); shorter cyclic therapy does not work here. Doses in excess of 10 mg daily of medroxyprogesterone acetate (MPA) have been used, but large doses can cause side effects and weight gain when used for several months and may not be necessary. OCs will reduce the blood loss by at least 35% in women with AUB-E (Shabaan, 2011). Another beneficial option is the use of the levonorgestrel intrauterine system (IUS), whereby menorrhagia can be substantially reduced (discussed later). It should be noted that in ovulatory heavy menstrual bleeding, although all obvious lesions have been ruled out, some anatomic abnormalities cannot be easily diagnosed. These include endometriosis and, in particular, adenomyosis, although the diagnosis may be improved with MRI. Thus other options also have to be considered for reducing blood loss.

Local Progestogen Exposure

The levonorgestrel-releasing intrauterine system (LNG-IUS) has an effective duration of action of more than 5 years. Research on the use of this IUS as treatment for heavy menstrual bleeding found that at the end of 3 months, it caused an average 80% reduction in MBL, which increased to 100% at the end of 1 year. This reduction in MBL was significantly greater than that achieved with an antifibrinolytic agent or a prostaglandin synthetase inhibitor in studies by the same investigators (Milsom, 1991) (Fig. 26.8). Other studies have shown that the LNG-IUS reduces MBL by 74% to 97% and is effective in increasing hemoglobin levels, decreasing dysmenorrhea, and reducing blood loss caused by fibroids and adenomyosis.

Although endometrial ablation achieves a more rapid return to normal flow, studies comparing the LNG-IUS to endometrial ablation show similar bleeding profiles after 1 year, with similar patient satisfaction scores (Kaunitz, 2009). In addition, the LNG-IUS has also been compared with hysterectomy for menorrhagia and has been considered to be a viable alternative.

Patients with AUB due to coagulopathy, especially secondary to anticoagulation therapy, also can be managed successfully with the LNG-IUS. In one series of 23 patients, MBL was reduced in 59% of LNG-IUS users on oral anticoagulation (Pisoni, 2006). Similar results have been demonstrated in patients with von Willebrand disease (Kingman, 2004). Importantly, a systematic review

Figure 26.8 Reduction in menstrual blood loss (MBL) expressed as a percentage of the mean of two control cycles for each form of treatment. Significance of difference between treatment with levonorgestrel-releasing intrauterine device (LNG-IUD) and tranexamic acid (TA) and flurbiprofen (FLURB), indicated by double asterisks ($P < .01$) and triple asterisks ($P < .001$), and between treatment with TA and FLURB indicated by a single asterisk ($P < .05$). (From Milsom I, Andersson K, Andersch B, et al. A comparison of flurbiprofen, tranexamic acid, and a levonorgestrel-releasing intrauterine contraceptive device in the treatment of idiopathic menorrhagia. *Am J Obstet Gynecol.* 1991;164:879.)

has failed to answer whether the risk of thrombosis is decreased in hormonal contraceptive users while taking oral anticoagulation (Culwell, 2009). The World Health Organization states that combined oral contraceptives should not be used in patients with active deep venous thrombosis, but the benefits of progesterone-only methods outweigh the risks (Mohllajee, 2005). As such, the LNG-IUS has become an appropriate initial therapy in patients with heavy menstrual bleeding due to anticoagulation therapy.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs are prostaglandin synthetase inhibitors that inhibit the biosynthesis of the cyclic endoperoxides, which convert arachidonic acid to prostaglandins. In addition, these agents block the action of prostaglandins by interfering directly at their receptor sites. To decrease bleeding of the endometrium, it would be ideal to block selectively the synthesis of prostacyclin alone, without decreasing thromboxane formation, because the latter increases platelet aggregation. Presently, there are no NSAIDs that possess this ability. All NSAIDs are cyclooxygenase inhibitors and thus block the formation of both thromboxane and the prostacyclin pathway. Nevertheless, NSAIDs have been shown to reduce MBL, primarily in women who ovulate. However, the mechanisms whereby prostaglandin inhibitors reduce MBL are not yet completely understood, and their therapeutic action may take place through some as yet undiscovered mechanism. Several NSAIDs have been administered during menses to groups of women with menorrhagia and ovulatory DUB and have been found to reduce the mean MBL by approximately 20% to 50% (Vargyas, 1987). Drugs used in various studies have included mefenamic acid (500 mg, three times daily), ibuprofen (400 mg, three times daily), meclofenamate sodium (100 mg, three times daily), and naproxen sodium (275 mg, every 6 hours after a loading dose of 550 mg), as well as other NSAIDs. These drugs are usually given for the first 3 days of menses or throughout the bleeding episode. All appear to have similar levels of effectiveness.

Not all women treated with these agents have reduction in blood flow, but those without a decrease usually did not have excessive bleeding to begin with. The greatest amount of MBL reduction occurs in women with the greatest pretreatment blood loss. The treatment of heavy menstrual bleeding with mefenamic acid in 36 women for longer than 1 year resulted in a significantly sustained reduction in the amount of MBL and in a significant increase in serum ferritin levels (Fraser, 1983). Thus this approach can be used for long-term treatment because side effects, mainly gastrointestinal (GI), are mild.

Although NSAIDs have been studied as sole therapy to treat women with MBL who ovulate, they can also be given in combination with OCs or progestogens. With this combined approach, a reduction in MBL can be achieved more effectively than with the use of any of these agents alone.

Antifibrinolytic Agents

ϵ -Aminocaproic acid (EACA), tranexamic acid (AMCA), and para-aminomethyl benzoic acid (PAMBA) are potent inhibitors of fibrinolysis and have therefore been used in the treatment of various hemorrhagic conditions. Nilsson and Rybo have compared the effect on blood loss of EACA, AMCA, and oral contraceptives in 215 women with menorrhagia. EACA was given in a dose of 18 g/day for 3 days and then 12, 9, 6, and 3 g daily on successive days. The total dose was always at least 48 g. AMCA was administered in a dose of 6 g/day for 3 days, followed by 4, 3, 2, and 1 g/day on successive days. The total dose of AMCA was at least 22 g. There was a significant reduction in blood loss after treatment with EACA, AMCA, and OCs, and use of each of these agents resulted in approximately a 50% reduction in MBL (Nilsson, 1971) (Table 26.1). Of interest was the finding that the greatest reduction in blood loss with antifibrinolytic therapy occurred in women who exhibited the greatest pretreatment MBL. Preston and colleagues have compared the effects of 4 g of AMCA daily for 4 days each cycle with 10 mg of norethindrone for 7 days each cycle in a group of women with ovulatory menorrhagia with a mean MBL of 175 mL. AMCA reduced MBL by 45%, but there was a 20% increase with norethindrone. The side effects of this class of drugs, in decreasing order of frequency, are nausea, dizziness, diarrhea, headaches, abdominal pain, and allergic manifestations. These side effects are much more common with EACA than with AMCA. Other investigators have compared the use of AMCA with placebo in double-blind studies and have found no significant differences in the occurrence of side effects. Renal failure, pregnancy, and history of thrombosis are contraindications to the use of antifibrinolytic agents.

Antifibrinolytic agents clearly produce a reduction in blood loss and may be used as therapy for women with menorrhagia who ovulate. However, their use is somewhat limited by side effects. These are mainly GI side effects and can be minimized by reducing the dose and limiting therapy to the first 3 to 5 days of bleeding. Antifibrinolytics may have value in treating bleeding due to structural causes as well. Tranexamic acid administered in doses of 3.9 g/day demonstrated a statistically significant reduction of MBL in women with fibroids, with greatest reductions on days 2 and 3 (Eder, 2013). Due to the increased risks of thrombosis and myocardial infarction, antifibrinolytic agents should not be combined with oral contraceptives. Combined treatment with tranexamic acid and the oral contraceptive pill has been implicated in coronary ulcerated plaque and acute myocardial infarction (Iacobellis, 2004).

Table 26.1 Mean Menstrual Blood Loss and Reduction with Treatment

Agent Used	MEAN BLOOD LOSS (mL)		
	Before Treatment	After Treatment	Decrease (%)
EACA	164	87	47
AMCA	182	84	54
Oral contraceptives	158	75	52
Methylergobaseimaleate	164	164	0

AMCA, Tranexamic acid; EACA, ϵ -aminocaproic acid.

Gonadotropin-Releasing Hormone Agonists

GnRH agonists may be used to inhibit ovarian steroid production, as estrogen production is necessary for endometrial proliferation. In a small study of four women, daily administration of a GnRH agonist for 3 months markedly reduced MBL from 100 to 200 mL per cycle to 0 to 30 mL per cycle. Unfortunately, after therapy was discontinued, blood loss returned to pretreatment levels (Shaw, 1984) (see Fig. 26.8). Two other observational studies, one using sequential add-back in 20 women and another using goserelin in 60 women, also showed some benefit (Thomas, 1996; Cheung, 2005). Because of the expense and side effects of these agents, their use for heavy menstrual bleeding is limited to women with severe MBL who fail to respond to other methods of medical management and wish to retain their childbearing capacity. More commonly, GnRH agonists are an effective means of bridging patients to surgical treatment, allowing for correction of anemia. Use of an estrogen or progestogen (add-back therapy) together with the agonist will help prevent bone loss.

MANAGEMENT OF ACUTE BLEEDING

In women who are bleeding heavily and are hemodynamically unstable, the quickest way to stop acute bleeding is with curettage. This should also be the preferred approach for older women and those with medical risk factors for whom high-dose hormonal therapy may pose a great risk.

PHARMACOLOGIC AGENTS FOR ACUTE BLEEDING

To stop acute bleeding that does not require curettage the most effective regimen involves high-dose estrogen. This treatment, aimed at stopping acute bleeding, is diagnosis-independent and is merely a temporary measure.

There has also been some experience with using high dose progestogens alone for the management of acute bleeding (discussed later).

Estrogens

The rationale for the therapeutic use of estrogen for the treatment of DUB is based on the fact that estrogen in pharmacologic doses causes rapid growth of the endometrium. This strategy is for the acute management of abnormal bleeding. The bleeding that results from most causes of abnormal bleeding will respond to this therapy because a rapid growth of endometrial tissue

occurs over the denuded and raw epithelial surfaces. This effect is independent of the cause of abnormal bleeding. To control an acute bleeding episode, the use of oral conjugated equine estrogen (CEE) 10 mg/day, in four divided doses, is a therapeutic regimen that has been found to be clinically useful. It is possible that in addition to the rapid growth mechanism of action, these large doses of CEE may alter platelet activity, thus promoting platelet adhesiveness. Six hours after infusion of an average dose of 30 mg of CEE to individuals with a prolonged bleeding time caused by renal failure, the bleeding time was significantly shortened (Livio, 1986). In this study, measurements of various clotting factors were unchanged after CEE infusion. Acute bleeding from most causes is usually controlled, but if bleeding does not decrease within the first 24 hours, consideration must be given to an organic cause and curettage should be considered.

Intravenous (IV) administration of estrogen is also effective in the acute treatment of menorrhagia. Compared with women given a placebo, a significantly greater percentage of women had cessation of bleeding 2 hours after the second of two 25-mg doses of CEE was administered IV, 3 hours apart. There was no significant difference in cessation of bleeding between women administered estrogen and those given a placebo 3 hours after the first infusion (DeVore, 1982). This study indicated that at least several hours are required to induce mitotic activity and growth of the endometrium, whether the estrogen is administered orally or parenterally. Thus IV estrogen therapy accompanied by its rapid metabolic clearance does not appear to offer a significant advantage compared with a comparable dose of estrogen given orally as long as the oral dosing can be tolerated in terms of symptoms such as nausea. From a practical standpoint, if IV therapy is chosen, it usually requires that women remain in the office or clinical setting for 4 to 6 hours to receive at least a second dose.

Usually, estrogen therapy reduces the amount of uterine bleeding within the first 24 hours after treatment is initiated. However, because most women with an acute heavy bleeding episode bleed because of anovulation, progestogen treatment is also required. Therefore after bleeding has ceased, oral estrogen therapy is continued at the same dosage and a progestogen, for example, MPA, 10 mg once daily, is added. Both hormones are administered for another 7 to 10 days (or longer if desired and tolerated by the woman), after which treatment is stopped to allow withdrawal bleeding, which may have an increased amount of flow but is rarely prolonged. After the withdrawal bleeding episode, one of several other treatment modalities should be used. Before instituting long-term treatment, a definitive diagnosis should be made after reviewing the endometrial histology. Definitive treatment should be based on these findings. OCs are usually the best long-term treatment in the absence of contraindications.

A more convenient method to stop acute bleeding than the sequential high-dose estrogen-progestin regimen is the use of a combination oral contraceptive containing both estrogen and progestin. Four tablets of an oral contraceptive containing 30 to 35 µg of estrogen taken every 24 hours in divided doses will usually provide sufficient estrogen to stop acute bleeding and simultaneously provide progestin. Treatment is continued for at least 1 week after the bleeding stops. This regimen is successful and convenient and is thus the preferred method of some clinicians. Not well documented is the expectation that the IV regimen is more effective than using OCs. A theoretic reason for this suggestion

may be that the combined use of estrogen and progestin does not cause as rapid endometrial growth as estrogen alone, because the progestin decreases the synthesis of estrogen receptors and increases estradiol dehydrogenase in the endometrial cell, thus inhibiting the growth-promoting action of estrogen.

It must be noted that high-dose estrogen, even for a short course, may be contraindicated for some women (e.g., those with prior thrombosis, certain rheumatologic diseases, estrogen-responsive cancer). In these cases, the options are therapy with progestogen alone given continuously or intermittently. Although invasive, curettage remains the fastest way to stop acute bleeding and should be used in women who are volume-depleted and severely anemic (hemodynamically unstable).

When ultrasound is available, it is more logical to use estrogen therapy if there is prolonged heavy bleeding in the setting of a thin endometrium (<5-mm stripe). Conversely, if the endometrium is thick (>10 to 12 mm) or if an anatomic finding is suspected, curettage should be considered. Unless bleeding is extremely heavy (where estrogen therapy is preferred), progestogens may be used initially and will help by organizing the endometrium. In the setting of a thickened irregular endometrium, if curettage is not performed, an endometrial biopsy should be obtained.

Progestogens

Progestogens not only stop endometrial growth but also support and organize the endometrium so that an organized slough occurs after their withdrawal. In the absence of progesterone, erratic unorganized breakdown of the endometrium occurs. With progestogen treatment, an organized slough to the basalis layer allows a rapid cessation of bleeding. In addition, progestogens stimulate arachidonic acid formation in the endometrium, increasing the PGF₂α/PGE ratio. Some studies support the efficacy of progestogens alone in the management of acute bleeding.

In one randomized trial, medroxyprogesterone acetate (MPA) at a dose of 60 mg daily (20 mg three times daily) for 7 days followed by 20 mg per day for 3 weeks stopped bleeding in 76% of women in 3 days and had equal efficacy to an OC given as three tablets a day for 7 days, followed by one tablet a day for 3 weeks (Munro, 2006). In another uncontrolled short-term study, Depo-MPA 150 mg intramuscularly followed by oral MPA 60 mg (20 mg three times daily) for 3 days stopped bleeding in all 48 women within 5 days (Ammerman, 2013).

High-dose progestogens in this setting may be expected to exert direct stabilizing effects on the endometrium in a rapid sequence. Similarly, large doses of norethindrone acetate (30 mg per day) may be expected to perform equally well. In addition, higher doses of norethindrone may be efficacious on the basis of some conversion to ethinyl estradiol (thus mimicking the use of a low-dose OC) (Chu, 2007). For longer-term management of abnormal bleeding, the mainstay of progestogen therapy is opposing the effects of estrogen in anovulatory women. For women with a history of bothersome intermenstrual bleeding, it is advisable to use intermittent progestogens for several months or an OC.

MPA 10 mg/day for 10 days each month is a successful therapeutic regimen that produces regular withdrawal bleeding in women with adequate amounts of endogenous estrogen to cause endometrial growth. 19-norprogestogens, such as norethindrone or norethindrone acetate (2.5 to 5 mg) may be used in the same regimen. Although more androgenic progestogens are

less favorable for metabolic parameters (e.g., high-density-lipoprotein [HDL] cholesterol, carbohydrate tolerance), when used as prolonged therapy, short-term cyclic therapy is not harmful.

ANDROGENS

Danazol is a synthetic androgen used in doses of 200 mg daily for the treatment of heavy menstrual bleeding (Hingham, 1993). A Cochrane review has noted that, although nine randomized controlled trials (RCTs) were identified with danazol, studies have been generally underpowered. Nevertheless, danazol appears to be more effective than placebo, oral progestogens, oral contraceptives, and NSAIDs. However, compared with NSAIDs, the side effects of weight gain and skin problems were sevenfold and fourfold greater, respectively, when compared with progestogens (Beaumont, 2002). Consequently, its use is limited.

Surgical Therapy: Dilation and Curettage

The performance of a D&C can be diagnostic and is therapeutic for the immediate management of severe bleeding. For women with markedly excessive uterine bleeding who may be hypovolemic, a D&C is the quickest way to stop acute bleeding. Therefore it is the treatment of choice in women who suffer from hypovolemia. A D&C may be preferred as an approach to stop an acute bleeding episode in women older than 35 when the incidence of pathologic findings increases.

The use of D&C for the treatment of anovulatory bleeding has been reported to be curative only rarely. Temporary cure of the problem may occur in some women with chronic anovulation, because the curettage removes much of the hyperplastic endometrium; however, the underlying pathophysiologic cause is unchanged. D&C has not proved useful for the treatment of women who ovulate and have heavy menstrual bleeding. More than 1 month after D&C, there is no difference or an increase in MBL in women with menorrhagia who ovulate (Nilsson, 1971). Therefore D&C is only indicated for women with acute bleeding resulting in hypovolemia and for older women who are at higher risk of having endometrial neoplasia. All other women, after having an endometrial biopsy, sonohysterography, or diagnostic hysteroscopy to rule out organic disease, are best treated with medical therapy, as outlined earlier, without D&C.

Surgical Therapy: Endometrial Ablation

Abnormal bleeding may be treated by endometrial ablation (EA) if medical therapy is not effective or is contraindicated. Exceptions are women who have very large uteri caused by fibroids or abnormal pathology, such as endometrial hyperplasia or cancer. Various endometrial ablation methods are

available. These methods are an alternative to hysterectomy or to the use of the levonorgestrel IUS, which is also highly effective (discussed earlier).

Although the concept of EA was developed in 1937, the hysteroscopic technique was first used in 1981 with the introduction of the neodymium-yttrium-aluminum-garnet (Nd:YAG) laser. Laser-based approaches were largely replaced with resectoscopic techniques to resect, vaporize, or electrodesiccate the endometrium. Currently, most commonly, various global endometrial ablation (GEA) devices have been approved by the U.S. Food and Drug Administration (FDA) for this type of treatment.

Endometrial resection is usually carried out with a loop electrode, roller ball, or grooved or spiked electrode to vaporize the endometrium. Hysteroscopic surgical techniques have the advantage of dealing definitively with associated pathology (e.g., polyps, submucous fibroids), although they require greater surgical skill, have longer procedure times, and have higher complication rates compared with nonresectoscopic methods.

Various GEA methods are given in Table 26.2, which lists the success rates and limitations based on anatomy. Most systems, except the Hydro ThermAblator (Boston Scientific, Marlborough, MA), are carried out without hysteroscopic monitoring. Cryotherapy may be performed in approximately 10 minutes using a 4.5-mm disposable cryoprobe (Her Option, Cooper Surgical, Trumbull, CT), which is moved from one uterine cornual recess to the other. The Hydro ThermAblator uses heated normal saline delivered through a 7.8-mm sheath. The uterus is distended and causes a closed circuit process, heating the saline to 90° C and maintaining this temperature for 10 minutes, followed by a 1-minute cooling process. The closed system is automated to shut down if there is 10 mL or more leakage of fluid via the cervix or fallopian tubes. Microwave endometrial ablation is carried out with an 8-mm reusable or disposable probe. Once the port is inserted into the fundus, transmission of endometrial tissue temperature is available, and the microwave system is activated when the tissue temperature is 30° C. Movement within the uterus of the microwave probe allows endometrial destruct to occur within 2 to 4 minutes.

The NovaSure radiofrequency electricity system (Hologic, Bedford, MA) uses a 7.2-mm probe with a bipolar gold mesh electrode that opens to conform to the shape of the uterus. A fixed volume of CO₂ is injected and monitored to confirm the integrity of the endometrial cavity. Suction is carried out during the application of radiofrequency energy to remove debris stream. The vaporization and desiccation is carried out until a current resistance of 50 ohms is met or until 90 seconds have passed.

The ThermoChoice system (Ethicon, Somerville, NJ) uses a balloon-tipped catheter (5.5 mm) through which heated 5%

Table 26.2 Characteristics and Outcomes at 1 Year for Nonresectoscopic Endometrial Ablation

Option	Maximum Uterine Size (cm)	Use with Fibroids (<3 cm)	Amenorrhea (%)	Diary Success (%)*	Satisfaction†
ThermaChoice III (balloon)	10	Yes	37	81	96
Her option (cryotherapy)	10	—	22	67	86
Hydro ThermAblator (heated fluid)	10.5	Yes	35	68	—
Microwave EA system	14	Yes	55	87	99
NovaSure (radiofrequency)	10	Yes	36	78	93

*Score <75 using pictorial blood loss assessment chart (% patients).

†Similar rate of satisfaction as with levonorgestrel intrauterine system but both significantly better than medical therapy.

dextrose in water is injected up to a pressure of 160 to 180 mm Hg. A controller unit heats the fluid and monitors the pressure and treatment time. Destruction of the endometrium is carried out in approximately 8 minutes.

Prior to any EA techniques, endometrial sampling is required as part of the workup evaluation of the woman with abnormal bleeding. The uterine cavity should be evaluated for size and presence of pathology that may limit some of the techniques. With the possible exception of the use of the NovaSure system, a review by Sowter has confirmed the benefit of pretreatment with danazol or a GnRH agonist before an ablation. GEA is more successful when a thin endometrial lining is present. Most systems typically treat to a depth of 4 to 6 mm. In the evaluation, it is important to note that there is no thinning of the myometrium from some other cause, such as prior surgery, particularly with the microwave method. The myometrium should be no less than 10 mm anywhere in the uterus. Most methods of GEA, with the exception of the Her Option, may be beneficial in treating submucous fibroids up to 3 cm in size, with the strongest data coming from the use of the microwave and ThermoChoice systems (see Table 26.2). Complications are infrequent with GEA if adherence to the manufacturer's guidelines is maintained. Cervical lacerations and perforations occur more commonly with endometrial resection. Lower genital tract burns may occur, as well as endometritis ($\approx 1\%$), and there is a syndrome of tubal pain post-EA caused by trapping of endometria at the cornual recesses. This is more likely in women with a tubal ligation. If pregnancy occurs unexpectedly, there is a high incidence of poor outcomes, including prematurity and placenta accreta. Contraception is recommended for all sexually active patients after GEA.

Use of GEA in patients with AUB-O should be judicious. Women with ovulatory dysfunction often have numerous risk factors for endometrial cancer. The length of time between ablation procedure and diagnosis of endometrial cancer was 6 months to 10 years in a systematic review (AlHilli, 2011). Although the length of time did not affect the ability to diagnose endometrial cancer and all cancers were stage 1, the issue remains that destruction of the uterine cavity may prevent early presentation of symptoms or impede accurate sampling of the lining for prompt diagnosis.

GEA procedures can be safely performed in an office setting with paracervical block and conscious sedation. Although amenorrhea may not always occur (only up to 55% of the time), bleeding is significantly improved for most women. Of note, the success is slightly worse in women with a retroverted uterus. Up to 20% of patients will pursue hysterectomy after endometrial ablation, with the most common reasons being persistent bleeding and pain. A history of dysmenorrhea, cesarean delivery, structural abnormalities, and office-based procedure increased the risk of subsequent hysterectomy (AlHilli, 2011).

Surgical Therapy: Hysterectomy

The decision to remove the uterus should be made on an individual basis and should usually be reserved for the woman with other indications for hysterectomy, such as leiomyoma or uterine prolapse. Hysterectomy should only be used to treat persistent abnormal uterine bleeding after all medical therapy has failed, medical therapy is contraindicated, and the amount of MBL has been documented to be excessive by direct measurement. Although the number of hysterectomies performed for the treatment of fibroids, endometriosis, and other benign causes has declined from 1998 to 2010, the number of hysterectomies performed for the treatment of benign abnormal uterine bleeding has remained stable at 200,000 cases per year.

AUB is now the leading cause of hysterectomy in the United States and elsewhere (Wright, 2013). A Cochrane review on the treatment showed medical and conservative surgical treatments have similar efficacy at 1 year, with more side effects in hormone users. Although hysterectomy can reliably provide complete cessation of bleeding and improved mental health at 6 months over conservative treatments, it is associated with greater number of serious complications (Marjoribanks 2006).

Uterine artery embolization is not particularly effective unless fibroids are the cause of excessive bleeding.

If hysterectomy is chosen, many options are available, including vaginal hysterectomy, laparoscopic-assisted vaginal hysterectomy (LAVH), laparoscopic or supracervical hysterectomy, laparoscopic total hysterectomy, robotic hysterectomy, and abdominal supracervical hysterectomy.

SUMMARY OF APPROACHES TO TREATMENT

Having reviewed the various options, an important perspective is to approach the woman according to her acute and chronic needs or short-term and long-term therapy. Acute bleeding, which necessitates immediate cessation of bleeding, requires the use of pharmacologic doses of estrogen or curettage; the latter is used more liberally in older women with risk factors or in those who are hemodynamically compromised. This approach is not dependent on whether the woman is anovulatory or ovulatory. Although estrogen will be temporarily helpful, even if there are abnormal anatomic findings such as fibroids, it is preferable to perform curettage if pathology is suspected.

In our view, there is less experience with large doses of progestogens used acutely to stop bleeding. However, this is an option and may be preferable for some women who could be sensitive to, or have contraindications to, the use of estrogens.

After the acute episode, it is imperative to determine the exact cause or causes for a woman's abnormal bleeding. Causes most commonly are structural, hormonal, or both. Less common causes are coagulopathies, idiopathic, endometrial, or unclassified. In the adolescent, 10 mg of MPA, 10 days each month for at least 3 months, should be prescribed and observed carefully thereafter. In this group, additional diagnostic studies should be performed to detect possible defects in the coagulation process, particularly if bleeding is severe. For the woman of reproductive age, long-term therapy depends on whether she requires contraception, induction of ovulation, or treatment of anovulatory bleeding alone. In the latter case, oral OCs or MPA can be administered monthly for at least 6 months, whereas OCs and clomiphene citrate are used for the other indications. For the perimenopausal woman who characteristically has fluctuating amounts of circulating estrogen, use of cyclic progestogen alone is frequently not curative. In these women, abnormal bleeding is best treated by low-dose OCs.

The most difficult type of abnormal bleeding to treat is chronic ovulatory heavy menstrual bleeding due to an endometrial defect. If anatomic abnormalities are absent, long-term treatment is necessary to reduce MBL. For these women, NSAIDs, progestins, oral contraceptives, anti-fibrinolytics, and GnRH analogues are all useful therapeutic modalities. A combination of two or more of these agents is often required to obviate the need for endometrial ablation or hysterectomy. The LNG-IUS has become one of the most successful options and is the first-line therapy in patients with bleeding due to anticoagulation.

KEY POINTS

- The mean amount of menstrual blood loss in one cycle in normal women was previously reported to be approximately 35 mL but may be as much as 60 mL, with an average loss of 13 mg of iron.
- Heavy menstrual bleeding occurs in 9% to 14% of healthy women, and most have a normal duration of menses.
- A systematic and standardized nomenclature exists for the characterization of abnormal uterine bleeding.
- Pregnancy should always be ruled out in women presenting with AUB.
- Diagnostic tests in women with menorrhagia include measurement of hemoglobin, serum iron, serum ferritin, β -hCG, TSH, and PRL levels, endometrial biopsy and hysteroscopy, sonohysterography, and hysterosalpingography. MRI may be helpful in the diagnosis of adenomyosis or surgical planning for leiomyoma but is not part of the initial evaluation.
- High doses of oral or IV estrogen will usually stop acute bleeding episodes in most cases of abnormal bleeding. An alternative regimen is high-dose oral progestogen for a week, with tapering of the dosage thereafter.
- Patients who are being treated for abnormal uterine bleeding due to endometrial causes (and who are ovulatory) may be given oral contraceptives, NSAIDs (antiprostaglandins), antifibrinolytics or a prolonged course of progestogens, or levo-norgestrel released locally from an IUS. Those treated with the LNG-IUS have similar outcomes at 1 year to those treated by surgery.
- NSAIDs administered during menses reduce MBL by 20% to 50% in women with ovulatory DUB.
- LNG-IUS is the first-line therapy for heavy menstrual bleeding due to anticoagulation or inherited bleeding disorders.
- D&C should be used to stop the acute bleeding episode in patients with hypovolemia or those older than 45 years. D&C only treats the acute episode of excess uterine bleeding, not subsequent episodes.
- Various endometrial ablation techniques achieve a 22% to 55% amenorrhea success rate at 1 year but an 86% to 99% satisfaction rate with regard to normalizing menstruation.
- Within 4 years after endometrial ablation, approximately 25% of women treated will have a hysterectomy.
- Abnormal uterine bleeding has become the leading cause for hysterectomy in the United States.

Principles of Radiation Therapy and Chemotherapy in Gynecologic Cancer: Basic Principles, Uses, and Complications

Judith Ann Smith, Anuja Jhingran

This chapter describes the underlying concepts and principles of radiation therapy and chemotherapy as they pertain to the treatment of gynecologic malignancies. The rationale and logistics of individual cancer treatments are detailed separately in other chapters specifically dedicated to each gynecologic malignancy.

Included with the basic concepts of radiation physics are discussions of atomic and nuclear structure, particles, and nomenclature; radiation production; interactions of radiation with bodily tissues; the biologic effects of radiation on cells; and the factors that modify these effects. Common radiation sources and their properties are illustrated as they relate to the treatment of specific gynecologic malignancies. Basic principles of normal tissue tolerance and the complication risks of radiation therapy as they relate to gynecologic malignancies are also presented.

Cell growth, division, and metabolism are modified by cancer-related changes in gene expression and protein regulation and by chemotherapeutic alteration of cellular metabolism. Treating physicians must recognize the various classes of chemotherapeutic agents, their actions in gynecologic malignancies, and their treatment-related toxicities. General approaches are to be followed in administering chemotherapy, specifically including the monitoring of patients receiving these agents. This chapter reviews all of these factors.

RADIATION THERAPY

RADIATION THERAPY PRINCIPLES

Radiation therapy is the safe clinical application of radiation for the local treatment of abnormally proliferating benign or malignant tumors. The principles of radiation physics and radiobiology underlying treatment are discussed, but several key therapeutic goals deserve mentioning first. The dose response of tumor cells after radiation treatment follows a sigmoid curve, with increasingly effective tumor cell kill or arrest of division associated with increasing dose (Fig. 27.1). A similar treatment response exists for normal tissues, and the ability of radiation therapy to control malignancy depends on the greater tolerance

of normal tissues to radiation exposure and a diminished capacity of cancer cells to recover from radiation-induced damage. Thus if one were to treat up to the total radiation dose that causes no normal tissue damage, only a small proportion of a tumor would be controlled by radiation-induced damage. Conversely, if one were to treat to a total dose that could eradicate almost the entire tumor, irreparable damage to normal tissue would often occur. This would lead to an unacceptable series of complications or even patient death after radiation treatment. The therapeutic goal of radiation therapy is to balance attempts at maximum local tumor control while minimizing adverse symptoms of treatment and normal tissue damage. Basic radiation therapy principles are detailed throughout the chapter but briefly include the following (Hall, 2000):

- *Fractional cell kill:* Each radiation dose kills a constant fraction of the tumor cell population. Tumor cell kill follows a linear-quadratic relationship with the potential for cell-mediated repair of radiation-induced damage between radiation dose fractions.
- *Radiation dose rate:* Large radiation doses per fraction produce the greatest number of tumor cell kills; these same large radiation doses also produce the greatest damage burden on normal tissues, leading to early and late adverse complications.
- *Radiation resistance:* Although all tumor cells are sensitive to the effects of radiation, select malignant tumor cells show reduced radiosensitivity, resulting in slow tumor regression or renewed tumor repopulation during or after radiation treatment. Radiation resistance is associated with (1) enhanced cell-mediated repair of radiation-induced damage, (2) active concentration of chemical radioprotectors, or (3) cellular hypoxia or nutritional deficiency.
- *Cell cycle dependency of cell kill:* Actively proliferating tumor cells are most often killed by radiation therapy. Ionizing radiation imparts its greatest cell kill effect during the mitotic phase (M phase) and, to a lesser extent, during the late Gap1 phase and early DNA synthesis phase (G1/S). Radiation has little effect during the late synthetic phase (S phase). Before each phase of the cell cycle, genomic integrity is monitored and, if found intact, a cell then progresses through the next

Figure 27.1 Therapeutic ratio. The concept of the therapeutic ratio for radiation therapy compares the radiation dose-response curves for tumor control and normal tissue side effect rate. Optimally, the tumor control curve lies to the left of the normal tissue curve. For every incremental increase in total dose needed to control tumor, there is a corresponding increase in the likelihood of normal tissue side effects from treatment. The magnitude of the difference between effective tumor cell kill and the likelihood of treatment-related side effects corresponds to the therapeutic ratio (gray arrow). Improved tumor-directed, image-guided radiotherapy planning, use of radiation sensitizers, and use of chemotherapeutic agents (which push the tumor control curve to the left) or the use of radioprotectors (which push the normal tissue curve to the right) can widen the therapeutic ratio.

phase. If, however, genomic damage is detected, a cell arrests the cell cycle so that the damage may be repaired. If the normal monitors of genomic integrity are faulty, as in the case of most cancers, then a cell traverses the cell cycle with radiation-induced damage, leading to mitotic cell death or loss of critical genomic information vital to future cell survival.

With these basic fundamental principles of radiation therapy discussed, it is important to examine in depth the effects of electromagnetic radiation on biologic systems as they pertain to the treatment of gynecologic malignancies.

BASIC RADIATION PHYSICS

Matter is made up of subatomic particles bound together by energy to form atoms. The simplest representation of the atom consists of a central core of one or more positively charged protons ($+1$; 933 MeV [mega electron volt]) and zero or more uncharged neutrons (± 0 ; 933 MeV) surrounded by a cloud of negatively charged orbital electrons (-1 ; 0.511 MeV). As Bowland described, four fundamental forces hold these subatomic particles together: the strong force (10^1 N), electromagnetic or coulomb force (10^{-2} N), weak force (10^{-13} N), and gravitational force (10^{-42} N). The strong nuclear force acts over a short range (10^{-14} m), keeping an atom's protons from repelling one another because of the similar electrostatic charge. The coulomb force of attraction binds orbital electrons to the nucleus so that the closer an electron is to the nucleus, the higher the binding energy of the

electron. As described later, the strength of the binding energy of orbital electrons relates to the interaction of radiation on matter and its subsequent biologic effects. The chemical identity of an atom relates to its number of protons, and this number identifies the atom's atomic number (Z). The neutron number (N) varies among atoms and increases as the atomic number increases to stabilize the nucleus. An atom's atomic mass number (A) is approximately the sum of the proton number and the neutron number ($A = Z + N$). Radionuclides are represented by the following notation: AX .

When an atom is neutral, it has no electric charge, meaning that the number of protons equals the number of electrons. If incident energy is transferred to an atom, an ionization event can occur whereby the atom acquires a positive or negative charge. When a charge is acquired, an atom is said to be ionized. Removal of an orbital electron results in an atom with a positive charge; the energy required to strip an electron off an atom must exceed the binding energy of that particular electron. Addition of an orbital electron results in an atom with a negative charge. This can occur when an electron passes close enough to an atom to experience a strong attractive force from the nucleus. Atoms can also undergo excitation, a process whereby an incident particle's energy is not sufficient to eject an atom's orbital electron but rather raises one or more electrons to a higher orbital energy state. It is through these types of interactions in atoms that radiation therapy elicits biologic consequences within tissues.

Radiation itself can be defined as the emission and propagation of energy through space or a physical medium. Radiation can be particulate, meaning that units of matter with discrete mass and momentum propagate energy (e.g., alpha particles, protons, neutrons, electrons), or it can be electromagnetic (photons), meaning that energy travels in oscillating electric and magnetic fields that have no mass and no charge, with a velocity of the speed of light ($c = 3.8 \times 10^8$ m/sec). Both particulate radiation and electromagnetic radiation can ionize atoms, events that occur randomly throughout the medium.

In the treatment of gynecologic malignancies, the most common source of radiation is electromagnetic (photon) radiation. Photons are generally referred to as *x-rays* (extranuclear or from the atom) or *gamma rays* (from the nucleus) based on their origin. Important properties of a photon include its wavelength (λ), frequency (ν), speed $c = (\lambda\nu)$, and energy $E = (h\nu)$, where h is Planck's constant. A photon's energy (E) is proportional to its frequency—that is, higher energies are transmitted at a higher frequency. Because the frequency of a photon is inversely proportional to the wavelength, electromagnetic radiation with a shorter wavelength has a higher frequency and thus a higher energy. As Kahn described in his textbook on the physics of radiation therapy, the energy that is produced is measured in electron volts, $1 \text{ eV} = 1.6 \times 10^{-19} \text{ J}$, and it takes approximately 34 eV to generate one ion pair in water. The photons used to treat gynecologic malignancies can be generated externally at a distance from the woman's tumor (teletherapy) or internally, close to the woman's tumor (brachytherapy). Teletherapy x-ray radiotherapy units can deliver a range of photon energies from 50,000 eV (50 keV) to more than 30 MeV, depending on their radiation source or linear accelerator design. Nuclear decay of radioactive isotopes generates the gamma ray photons used in brachytherapy; such decay or disintegration was measured historically in a unit called a *curie (Ci)*. One Ci is defined as 3.7×10^{10} disintegrations/

Figure 27.2 Inverse square law. Radiation intensity decreases with the square of the distance away from a point source of radiation. The intensity (I) of radiation at any given radius (r) is the source strength (S) divided by the area (A) of the sphere. For example, the energy intensity three times as far from a point source is spread over nine times the area—hence, one ninth the intensity.

sec, which is equivalent to the rate of disintegration of 1 g of radium. The modern standard unit for activity is the becquerel (Bq), which is 1 disintegration/sec, or 2.7×10^{-11} Ci.

Regardless of the source of electromagnetic or photon radiation, the transmitted energy diverges as the distance it travels from the source increases. This divergence causes a decrease in energy, a relationship described by the inverse square law. The inverse square law states that the energy dose of radiation per unit area decreases proportionately to the square of the distance from the site to the source ($1/r^2$). For example, the dose of radiation 3 cm from a point source is only one ninth of the value of the dose at 1 cm (Fig. 27.2) (Bowland, 2000; Kahn, 2003).

THERAPEUTIC RADIATION PRODUCTION

In general, two techniques are used in radiation therapy treatment: teletherapy (external) and brachytherapy (internal). Teletherapy in the form of external beam radiation treatment produces ionizing radiation through radioactive decay of unstable radionuclides such as cobalt (^{60}Co) or, more commonly, through acceleration of electrons. In a typical ^{60}Co teletherapy unit, the shielded ^{60}Co source resides in a treatment head mounted to a gantry that has a 360-degree rotation around the patient. Collimators consisting of interleaved bars or custom-made blocks of high Z materials can shape the treatment beam to conform the dose to the target volume. With the decay of each ^{60}Co atom, two gamma ray photons are emitted at 1.17 and 1.33 MeV (average, 1.25 MeV). Over a specified time limit of exposure, these gamma ray photons deliver a specific radiation dose. Absorbed radiation dose is measured in a unit called a *gray* (1 Gy = 1 J/kg). Typical dose rates are 3 Gy/min at 80 cm from the source. The ^{60}Co source decays with a half-life of 5.263 years; thus the source must be replaced every 5 to 7 years.

In a typical linear accelerator teletherapy unit, electrons are “boiled” off a filament and accelerated under vacuum along an accelerating waveguide using alternating microwave fields. These accelerated electrons can be used to treat the patients themselves or can hit a high Z material transmission target to produce photons of various energies by an interaction known as *bremsstrahlung*, which

means braking radiation. Currently, most treatment machines generate photon energies of 4 to 20 MeV and, similar to ^{60}Co teletherapy units, have 360-degree gantry rotation around a patient. Typical linear accelerator dose rates are 3 Gy/min at 100 cm from the source. It is important to realize key differences between these two types of treatment machines: (1) a ^{60}Co unit is always “on” when the source is not shielded because radioactive decay always occurs, whereas a linear accelerator is “on” only when energized because there is no radionuclide source; (2) the photon spectra are different in that ^{60}Co has a discrete average monoenergetic energy, whereas linear accelerators produce photons of variable energies and an average energy of one third the maximum generated energy; and (3) ^{60}Co produces treatment beams using only gamma ray photons, whereas a linear accelerator produces treatment beams of electrons or x-ray photons, depending on its treatment mode.

Alternate forms of teletherapy treatment are available, but they are rarely used to treat gynecologic malignancies. A teletherapy radiation dose can be delivered using alpha particles (helium nucleus), neutrons, or protons. Alpha particles produce a large number of ionizations over a short distance, but they have limited use as a mode of therapy because of their short range in tissue. Neutrons are highly penetrating into tissue because of their lack of charge; they cause high-energy collisions with atomic nuclei, principally of hydrogen, to produce recoil protons that then lose energy in surrounding tissues by ionization. Accelerated protons, as positively charged particles, used as therapy deposit a radiation dose sparingly along their path until near the end of their range, where the peak dose is delivered, the so-called *Bragg peak*. Neutron and proton therapies are used to treat cancer but are not used routinely in the treatment of gynecologic malignancies.

To produce a consequential radiobiologic effect in tissues or tumor, incident photons or other forms of radiation must interact with matter. Kahn has noted that there are five possible electromagnetic (photon) interactions with matter (Kahn, 2003):

1. *Coherent scattering* (<10 keV) occurs when an incident photon scatters off an atom's outer orbital electron without losing energy. This produces no radiobiologic effect.
2. *Photoelectric effect* (10 to 60 keV) occurs when an incident photon interacts with an inner orbital electron and the photon's energy is completely absorbed by that electron. If enough energy is transferred to the orbital electron to exceed the binding energy of the inner orbital electron, it is ejected, leaving a vacancy that an outer orbital electron fills. When an outer orbital electron fills the vacancy, a characteristic x-ray is produced with energy equal to the difference in binding energy between the two electron orbitals. The probability of a photoelectric effect event happening is proportional to Z^3/E^3 . Diagnostic radiographic or computed tomography (CT) images that are acquired at relatively low photon energies have high tissue–bone contrast detail because the Z^3/E^3 ratio is maximized.
3. *Compton effect* (60 keV to 10 MeV) occurs when an incident photon (E_γ) loses some or all of its energy to an outer orbital electron. The photon, if it remains, is scattered at some angle away from the atom. An electron that has acquired energy exceeding its binding energy (E_{BE}) leaves the atom with sufficient kinetic energy ($E_{KE} = E_\gamma - E_{BE}$) to penetrate tissue and

produce molecular damage through downstream ionizations. For simplicity, at common therapeutic photon energies (4 to 18 MeV), the Compton effect is biologically most important in that incident photons interact predominantly with cellular water. Human and mammalian tissues are principally composed of water ($\approx 90\%$) and functional biomolecules such as proteins and DNA (Fig. 27.3). Incident photons ionize water to produce an ion radical (H_2O^+) and a free electron (e^-). The ion radical is highly reactive (half-life of 10^{-10} second) and can interact with another molecule of water to form a hydroxyl radical ($\dot{\text{O}}\text{H}$). Hydroxyl radicals are also highly reactive (half-life of 10^{-9} second) and can break chemical bonds in target molecules such as proteins and DNA ($\dot{\text{C}}\text{R}$). Breaks in the chemical bonds of DNA can lead to DNA base damage, DNA cross-links, DNA single-strand breaks, and DNA double-strand breaks. As discussed later, DNA strand breaks can result in the loss of vital genomic material during subsequent cell divisions, potentially leading to mitotic death of the damaged cell. In this way, therapeutic radiation leads to significant radiobiologic effects by functionally modifying cellular proteins and damaging DNA.

4. *Pair production* (>1.022 MeV) occurs when an incident photon has an energy greater than 1.022 MeV. This threshold is required because the photon disappears to form an electron-positron pair, with each particle having an energy of 0.511 MeV. Once formed, free electrons slow by nuclear attraction and are quickly stopped in tissue. However, the formed positron is highly reactive and short-lived in that it is annihilated with surrounding electrons to create two photons of 0.511 MeV, each traveling 180 degrees apart from

one another. Positron emission tomography (PET) scanners build images based on the coincident detection of photons formed by this process.

5. *Photodisintegration* (>10 MeV) occurs when an energetic photon penetrates the nucleus of an atom and dislodges a neutron. Emitted neutrons cannot ionize tissue themselves because they have no charge; rather they collide with surrounding atomic nuclei to produce recoil, positively charged protons that elicit radiobiologic effects through subsequent ionizations.

Radiation Biology

Munro has shown that nuclear DNA is unquestionably one essential target of therapeutic radiation (Munro, 1970). In his textbook on radiobiology, Hall reported that one third of radiation-induced DNA damage is from the direct interaction of incident photons ionizing atoms within DNA itself (Hall, 2000). Two thirds of radiation-induced DNA damage is a consequence of the indirect damage done by freely diffusing hydroxyl radicals ($\dot{\text{O}}\text{H}$). However, Hall and Hei described a bystander effect whereby lethal damage to cellular proteins, organelles, or the cell membrane in an irradiated cell can lead to neighboring cell death in cells that would not have died on their own (Hall, 2003). The bystander effect suggests that damage to cellular proteins or organelles in one cell may also result in cell lethality. Note that not all radiation damage is lethal to the cell; some damage to DNA can undergo repair—namely, sublethal DNA damage repair. Sublethal DNA damage repair occurs in normal cells and malignant cells, but it occurs much less so in malignant cells because these often have abnormal

Figure 27.3 Compton effect. Cells are composed of biomolecules dissolved in an aqueous solution ($\approx 90\%$ water by weight). Incident photons (p) randomly ionize (left) cellular water to produce an ion radical (water^+) and a free fast electron (e^-) that can damage biomolecules such as DNA. The water ion radical interacts with another molecule of water to form a hydroxyl radical ($\dot{\text{O}}\text{H}$). Most often ($\approx 66\%$), formed hydroxyl radicals diffuse throughout the cell, breaking chemical bonds in target molecules such as proteins and DNA (right). Breaks in the chemical bonds of DNA can lead to DNA base damage, DNA cross-links, DNA single-strand breaks, and DNA double-strand breaks, contributing to the loss of vital genomic material during subsequent cell divisions and possibly mitotic death of the damaged cell.

DNA repair mechanisms. A variety of complex and redundant repair mechanisms have been identified, including base excision repair and nucleotide excision repair for damage to the DNA base and deoxyribose backbone, homologous recombination repair for DNA single-strand breaks, and nonhomologous end-joining repair for DNA double-strand breaks. As the time interval between radiation doses lengthens, cell survival increases because of the prompt repair of radiation-induced damage. The repair process is usually complete within 1 to 2 hours, although this period may be longer in some slowly renewing cellular tissues. Before discussing the consequences of DNA damage, it is important to understand key factors that can modify the rate at which DNA damage accumulates.

Intracellular molecular oxygen importantly modifies radiation-induced DNA damage as it fixes damage done by free hydroxyl radicals. Palcic and Skarsgard reported that molecular oxygen, when present during or within microseconds of photon-induced ionization events, reacts with the altered chemical bonds of ionized molecules ($\dot{C}R$) to produce organic peroxides (RO_2), a nonreparable form of the target molecule (Palcic, 1984). Molecules fixed in this manner are permanently altered and may function abnormally. Thus tumor and tissue oxygenation have practical implications in radiation therapy insofar as a rapidly proliferating gynecologic malignancy may have a poor blood supply, which decreases tumor cell oxygenation, particularly at the center of large tumors. Tumor tissue hypoxia leads to radiation resistance, as reflected by increased cell survival after radiation treatment (Dunst, 2003). Laboratory experiments have shown that the radiation dose necessary to kill the same proportion of hypoxic cells as compared with aerated cells approaches 3:1 (Siemann, 2003). This ratio is commonly referred to the *oxygen enhancement ratio*. For oxygen to have its maximal effect, the dissolved oxygen concentration in a tumor must be approximately 3 mm Hg (venous blood is 30 to 40 mm Hg), according to Hall (Hall, 2000). In the treatment of gynecologic malignancies, Dunst and coworkers found that cervical cancer patients undergoing radiation therapy with a serum hemoglobin level greater than 10 mg/dL have improved tumor oxygenation, resulting in superior local control and superior clinical outcomes compared with patients whose hemoglobin level is less than 10 mg/dL (Dunst, 2003). Also, hypoxic cell sensitizers such as the nitroimidazoles, as studied by Adams and colleagues, and the bioreductive drug tirapazamine, as reported by Goldberg and coworkers, improve the radiosensitivity of hypoxic cells within tumors (Adams, 1991; Goldberg, 2001). The potential benefit of these agents in the treatment of gynecologic cancers has been explored in clinical trials.

The rate at which energy is lost per unit path length of medium, or linear energy transfer (LET), also has an effect on the accumulation of radiation-induced DNA damage. For photons, energy loss is infrequent along its path length, typical of low-LET radiation. Sparsely ionizing, low-LET radiation produces one or more sublethal events and thus multiple hits are needed to kill the cell. Heavy particulate radiation from alpha particles or protons is densely ionizing because energy is deposited more diffusely along its path length. This is typical of high-LET radiation. Because the probability of producing a lethal event in a cell is much higher with high-LET radiation, cell death in this case is independent of tumor oxygenation. Thus research efforts have been directed toward the development of heavy particle

generators that can overcome the limitation of poor oxygenation of cancer cells.

Within the cell, molecules that have sulfhydryl moieties at one end and a strong base such as an amine at the other end are capable of scavenging free radicals produced by radiation-induced ionization events. These molecules can also donate hydrogen atoms to ionized molecules before molecular oxygen can fix the damage done by radiation-induced hydroxyl radicals. As Utley and associates reported, amifostine is a nonreactive phosphorothioate that accumulates (1) readily in normal tissues by active transport to be metabolized into an active compound to scavenge free radicals and (2) slowly in tumors by passive diffusion, with limited or no conversion to the active compound (Utley, 1976). It is reasonable to conclude that the presence of a radioprotector such as amifostine would decrease radiation-induced DNA damage and limit normal tissue radiation-related side effects. Clinical trials have been investigating the radioprotective effect of amifostine in gynecologic malignancies but, at present, amifostine has shown the most promise as a chemoprotectant and has been approved to reduce the renal toxicity associated with repeated administration of cisplatin chemotherapy in women with advanced ovarian cancer.

What constitutes cell death in the traditional sense—cessation of cellular respiration and vital function—is not the same in radiation biology. Death in radiation biology is the loss of reproductive integrity or the inability to maintain uninterrupted cellular proliferation with high fidelity. Thus radiation kills without the actual physical disappearance of malignant cells, although body macrophages often remove the dead cells, causing tumors to shrink in size. Malignant cells may remain a part of a tumor but have discontinued cellular metabolism and proliferation. Most cells, when exposed to radiation, die a mitotic death, meaning that cells die at the next or a subsequent cell division, with all progeny also dying. Inflammation can accompany mitotic cell death, potentially resulting in local adverse side effects. Jonathan and associates noted that alternative forms of loss in reproductive capacity caused by radiation include terminal differentiation, senescence, and apoptosis (Jonathan, 1999). In apoptosis, cells undergo a complex process of programmed cellular involution and phagocytosis by neighboring cells. There is no inflammatory response resulting from apoptosis. One remarkable example of apoptosis is the formation of the spaces between the digits of the hand during human fetal development.

Returning to radiation-induced DNA damage, electromagnetic radiation (x-ray or gamma) deposits energy in cells, which may damage DNA directly or indirectly through hydroxyl radicals (OH). In relative terms, more than 1000 DNA base-damaging events, 1000 DNA single-strand breaks, and 40 DNA double-strand breaks occur with each typical radiation dose fraction. Although base and DNA single-strand breaks must be repaired so that mutations are not propagated, DNA double-strand breaks are believed to be the most crucial radiobiologic effect of radiation therapy. There is an increased statistical probability that a cell will be unable to repair a DNA double-strand break, resulting in the loss of genetic material at cell division. Also, attempts by cells to repair the DNA double-strand breaks often result in bizarre chromosome arrangements that interfere with the normal division of the cell. Cell death ensues through loss of critical genes or impaired cell division.

Cell death following radiation therapy is modeled by a linear-quadratic relationship (Fig. 27.4). The initial slope of the cell survival curve is shallow and curvilinear, whereas the terminal slope is more linear. In the low-dose region of the survival curve typical of daily-dose fractions used in radiation therapy, the fraction of cells surviving is high because of the repair of single-event sublethal damage (e.g., multiple base damage or DNA single-strand breaks). In the high-dose region of the survival curve, the fraction of cells surviving is low because of multiple event damage in the form of DNA double-strand breaks or the accumulation of too many sublethal events that can be repaired before the next cell division. Capacity to repair sublethal damage depends on radiation quality (LET), tissue oxygenation, and cell cycle time.

As shown in Figure 27.5 and as described by Deshpande and associates and Pawlik and Keyomarsi, there are four highly regulated phases of the cell cycle (Deshpande, 2005; Pawlik, 2004). After completing mitosis, cells enter a gap phase (G₁), variable in time span, in which the cell performs protein synthesis and other functional metabolic and biologic processes. Under the influence of complex, finely regulated intercellular and intracellular signaling, cells then enter the DNA replication phase (S phase) in which the cell must exactly replicate its DNA to produce an identical set of chromosomes. Entry into the S phase is controlled by sequentially activated, highly regulated cyclin-dependent kinases (CDKs) responsible for differentially recruiting and amplifying specific gene products necessary for DNA replication. Moreover, there are corresponding cell cycle inhibitory proteins (CDKIs) that negatively regulate cell cycle progression. After DNA replication, the cell enters a second gap phase (G₂), in part to ensure high DNA replication fidelity in the newly formed

chromosomes. At the completion of the G₂ phase, cells undergo mitosis, whereby two identical daughter cells are produced.

To maintain genetic integrity through the cell cycle, the cell has multiple checkpoints through which it must pass, notably at the G₁/S and G₂/M transitions, as described by Pawlik and Keyomarsi (Pawlik, 2004). The G₁/S checkpoint prevents the replication of damaged DNA, as in the case of radiation therapy. Malumbres and Barbacid have reported that proteins critical to the G₁/S checkpoint include p53, p21, and the retinoblastoma protein (Rb), all of which modulate the activity of CDKs responsible for the transition to S phase (Malumbres, 2001). Briefly, Rb lacks phosphorylated subunits in its active form, binding to the E2F transcription factors and preventing E2F translocation to the nucleus to recruit genes needed for the S phase. Sequential phosphorylation of RB by CDK 4/6-cyclin D and CDK2-cyclin E complexes releases the E2F transcription factors. Radiation-induced DNA damage results in the accumulation of the G₁ checkpoint regulatory protein p53, which in turn activates the CDKI p21; p21 inhibits the phosphorylation of RB, delaying the G₁/S transition. The G₂/M checkpoint prevents the segregation of aberrant chromosomes at mitosis. Two molecularly distinct checkpoints have been identified, one that is regulated by the ataxia-telangiectasia mutated gene product (ATM) and one that is ATM-independent. ATM has multiple phosphorylation products that modulate CDKs at the G₂/M transition (Chk1 and Chk2) as well as p3 expression through modification of its degradation pathway. According to Xu and associates, phosphorylation of Chk1 and Chk2 inhibits the cdc2 protein kinase, blocking cells at the G₂/M transition (Xu, 2002). ATM's essential role in DNA damage recognition is highlighted by the extreme radiosensitivity of patients with mutated ATM. Malignant cells that often have mutated cell cycle checkpoint proteins have an impaired ability to repair damage done to nuclear DNA

Figure 27.4 Cell survival curves. A radiation survival curve plots cell survival on a logarithmic scale against radiation dose on a linear scale. Survival represents the number of cells retaining reproductive capacity to form approximately 50 cell colonies (i.e., approximately five to six cell divisions) after a specified radiation dose. The initial slope is shallow, forming a shoulder in the low-dose region (1 to 3 Gy/fraction) caused by repair of sublethal damage. Occasionally, a single hit will produce a DNA double-strand break, resulting in the loss of genetic material (open arrow). In the high-dose region (>3 Gy/fraction), the slope steepens because of multiple damaging events leading to DNA double-strand breaks. If not repaired, significant vital genetic material may be lost at a subsequent cell division and the cell may die. e, Electron; p, photon.

Figure 27.5 Phases of the cell. After mitosis (M), there is an interval of variable duration during which there is RNA and protein synthesis and a diploid DNA content (G₁ [Gap1]). The cell may also enter a prolonged or resting phase (G₀) and then reenter the cycle during DNA synthesis, the S phase, in which DNA is duplicated. During the G₂ (Gap2) phase, there again is protein and RNA synthesis. During the M phase, the cell divides into two cells, each of which receives diploid DNA content. CDK, Cyclin-dependent kinase.

and thus accumulate lethal DNA-damaging events that lead to cell kill in a few cell cycles.

Cells show different radiosensitivities during the cell cycle. M-phase cells are particularly radiosensitive because the DNA is packaged tightly into chromosomes, so ionization events have a high likelihood of causing lethal DNA double-strand breaks. S-phase cells are particularly radioresistant because enzymes responsible for ensuring high-fidelity DNA replication are relatively overexpressed and recognize altered DNA bases or inappropriate strand breaks. Cells in the G1 or G2 phase of the cell cycle are relatively radiosensitive compared with the S phase. Chemotherapies that inhibit cell cycle-dependent pathways or impede DNA repair enhance the radiobiologic effect of radiation (Amorino, 1999; Lawrence, 2003).

RADIATION TREATMENT: BRACHYTHERAPY AND TELETHERAPY

In general, two techniques are used in radiation treatment: brachytherapy (internal) and teletherapy (external). Brachytherapy involves the placement of radioactive sources within an existing body cavity (e.g., the vagina) in close proximity to the tumor. In the treatment of gynecologic malignant tumors, radioactive sources can be placed within hollow needles that are implanted directly into the tissue to be irradiated (interstitial implant) or within a hollow cylinder, or they can be inserted

in tandem into the uterus through the cervical os, respectively. For the treatment of cervical cancer, two vaginal ovoids, one on each side of the tandem, are positioned in the vaginal fornices (intracavitary therapy). The most widely used intracavitary applicator is the Fletcher-Suit applicator, which is useful for the treatment of a cervical tumor or a tumor located near the cervix (Fig. 27.6). For interstitial and intracavitary brachytherapy, the radiation dose delivery to the tumor and surrounding tissues follows the inverse square law as modified by source and tissue photon attenuation. With the increased use of high-dose rate brachytherapy, a tandem and ring may be used where the ring replaces the ovoids (see Fig. 27.6). In the past, interstitial or intracavitary brachytherapy needles or applicators without radioactive sources are placed first in the operating room with the patient under anesthesia. After postanesthesia patient recovery, the position of the needles or applicators is confirmed by radiographic imaging. These radiographic images help guide radiotherapy planning. With the increased use of high-dose brachytherapy described later, the majority of patients are just sedated or spinal anesthesia is used during the procedure. The instruments are placed and then the patient undergoes imaging, usually a CT or magnetic resonance imaging (MRI) scans, and planning is done on these images instead of plain films. Once the plan is completed, the patient is treated in the radiation oncology department and then released to go home. The approximately time for the entire procedure varies from 3 to 5

Figure 27.6 Brachytherapy. For the treatment of gynecologic malignancies, brachytherapy usually consists of the placement of radiation sources (dark circles) in close proximity to the tumor (A). This can be accomplished by the intracavitary placement of hollow applicators such as the Fletcher-Suit applicator (inset) (B) or tandem and ring (C) placed within the uterine cavity and vaginal vault or by the interstitial placement of hollow needles through the tissues themselves. The radiation dose decreases as the square of the distance away from the radiation source.

hours. The entire procedure is done on an outpatient basis and is usually repeated three to six times, usually twice a week.

Several radioisotopes with various photon energies and half-lives are used in gynecologic brachytherapy. Although uncommon, radioisotopes with a short half-life (e.g., ^{198}Au [gold]) may be placed within the woman and left permanently. Radioisotopes with a long half-life (e.g., ^{137}Cs [cesium]) are placed temporarily within interstitial or intracavitary needles or applicators and are removed after a prescribed radiation dose has been administered. Historically, brachytherapy for most gynecologic malignancies consisted of temporary low-dose rate (40 to 70 centigray [cGy]/hr) sources in place for 1 to 3 days. A low-dose rate requires that the woman be in a shielded hospital room with medical personnel supervision, on bed rest, with prolonged analgesia and prophylactic anticoagulation, and limited family contact during radiation dose administration. High-dose rate, catheter-based brachytherapy has become popular because the procedure can be performed in 1 day on an outpatient basis. The high-dose rate uses a thin wire tipped with iridium (^{192}Ir) to deliver radiation doses at rates exceeding 200 cGy/min. Unlike low-dose rate therapy, high-dose rate therapy is performed in a shielded treatment room requiring patient immobilization for a short period and minimal patient analgesia and anesthesia. Table 27.1 indicates the half-lives of some of the isotopes commonly used in treating gynecologic cancers. It is also important that a uniform distribution of radiation be achieved in the adjacent tissues to avoid hot spots, which can damage normal tissue, as well as cold spots, which can lead to reduced dose delivery to the tumor.

Teletherapy in the form of external beam radiotherapy means that the source of radiation is at a distance from the woman, sometimes located at a distance 5 to 10 times more than the depth of the tumor being irradiated. This distance is referred to as the *source-to-surface distance (SSD)* and is used to calculate dose using the inverse square law. When using an SSD patient treatment setup, the SSD is used along with tumor depth, radiation beam energy, depth of the point of maximum dose, and output parameters for a given treatment field size to determine the daily radiation dose. Alternatively, with the use of different angles and ports of treatment, the concept of source-axis distance has been introduced; it denotes the distance from the radiation source to the central axis of machine rotation. The woman is positioned so that this axis passes through the center of the tumor, and treatment ports are arranged around this axis to optimize tumor dose. When using a source-axis distance patient treatment setup, the daily radiation dose is calculated using machine output and beam attenuation at the depth for a given treatment field size.

Conventional external beam radiation is delivered with beams of uniform intensity. Advances in computer-guided planning and treatment have made the use of beams of varying intensity more commonplace. This approach of planned dose intensification allows the high-dose region to be conformed precisely to the shape of the planned treatment volume, a technique called *intensity-modulated radiotherapy (IMRT)*. The advantage of this technique is that there may be more sparing of normal tissue, especially small bowel, and therefore hopefully decrease both short-term and long-term toxicity (Fig. 27.7). Advances in radiotherapy delivery systems have allowed linear accelerators to be coupled with helical CT scanners. Image-guided radiation therapy using this type of device is called *helical tomotherapy*. In conventional therapy, and in intensity-modulated radiotherapy and helical tomotherapy,

Table 27.1 Half-Lives of Commonly Used Radioisotopes for Gynecologic Malignancies

Radionuclide	Half-Life
Gold (^{198}Au)	2.7 days
Phosphorus (^{32}P)	14.3 days
Iridium (^{192}Ir)	73.8 days
Cobalt (^{60}Co)	5.26 years
Cesium (^{137}Cs)	30 years
Radium (^{226}Ra)	1620 years

beams from the external radiation source can be sculpted using high electron-dense material collimators. Collimators limit scatter radiation and block portions of the treatment beam from delivering an intolerant radiation dose to critical tissues (Fig. 27.8). In general, the higher the energy source of the radiation, the deeper the beam can penetrate into tissue. Thus high-energy radiation has its predominant effect in deeper tissues and spares the surface of the skin of a radiation effect.

An isodose curve is a line that connects points in the tissue that receive equivalent doses of irradiation. Figure 27.8 contrasts the isodose curves for 6- and 22-MeV machines. For the 6-MeV machine, the maximum dose is near the surface, with a more rapid falloff in the deeper tissues. For the 22-MeV machine, the maximum dose is deep to the surface, sparing the effects of radiation on the overlying skin. In addition to the energy of the beam, the energy of radiation absorbed at various depths is affected by the size of the field being treated. Larger fields contain more scattered radiation, which leads to a greater dose at a given depth. Figure 27.8 shows the effect of increasing the size of the field with an increasing dose at a given depth for three different types of energy sources.

Thus the radiation dose delivered to the tumor is affected by the energy of the source, depth of the tumor beneath the surface, and size of the field undergoing irradiation. With external therapy, usually 180 to 200 cGy/day is given five times per week.

Tissue Tolerance and Radiation Complications

Adverse radiation effects are commonly divided into two broad categories, early and late, which demonstrate markedly different patterns of response to radiation dose fractionation. It is important for the treating physician to understand critical tissues and organ systems at risk of radiation damage. Table 27.2 presents the approximate tolerance of tissues to radiation therapy.

Early or acute effects manifest as the result of death in a large population of cells and can occur within days to weeks after the initiation of radiation therapy. For early effects, the total dose of radiation and, to a lesser extent, the dose per fraction determine the severity of the side effect. Radiation acutely affects tissues undergoing rapid cell division to replace lost normal functioning cells. This is most pronounced in areas such as the skin, intestinal mucosa, mucosa of the vagina and bladder, and hematopoietic system, in which precursor stem cells are renewing functional mature cells. The radiation dose given in multiple small fractions reduces the untoward adverse effects of cell damage on normal tissue and allows normal healing to occur between treatment fractions through sublethal DNA damage repair (the shallow curvilinear portion of the cell survival curve). During the treatment of gynecologic malignancies, most adverse early treatment-related toxicities can be managed with medication. It is preferred practice that radiation treatment not be interrupted for treatment-related

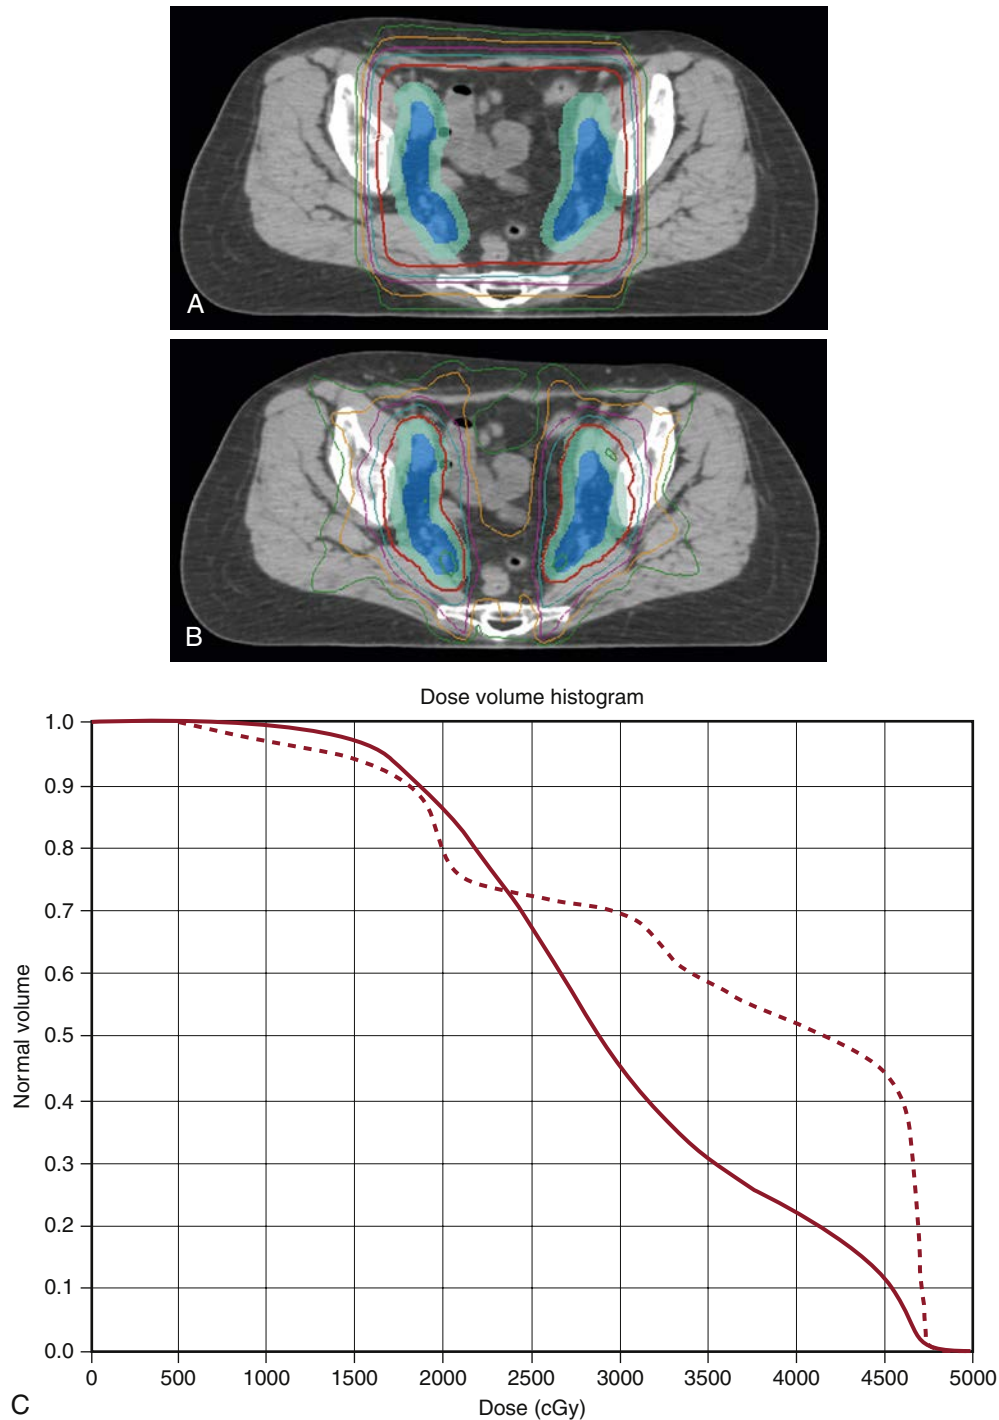

Figure 27.7 Treatment plan. **A**, The distribution of dose with a standard three-dimensional (3D) plan. The red line is the 45 Gy isodose line and, as shown, everything within the red line gets 45 Gy, including all the bowel. **B**, The distribution of dose using IMRT. Again, the red line is the 45 Gy isodose line and what can clearly be seen is the sparing of bowel using IMRT. **C**, The dose to bowel—the dotted line is the bowel dose using the 3D plan and the solid line is the bowel dose using the IMRT plan. As shown, with IMRT, the bowel gets a less high dose compared to the 3D plan.

toxicities caused by radiation-induced tumor accelerated repopulation. Only rarely does a treatment program have to be temporarily discontinued for treatment-related toxicities.

Late effects occur after a delay of months or years after radiation therapy. Late effects are often the product of parenchymal

connective tissue cell loss and vascular damage. Late effects may be seen in slowly renewing tissues such as the lung, kidney, heart, and liver and in the central nervous system. In the treatment of gynecologic malignancies, late adverse effects include tissue necrosis and fibrosis, as well as fistula formation and ulceration.

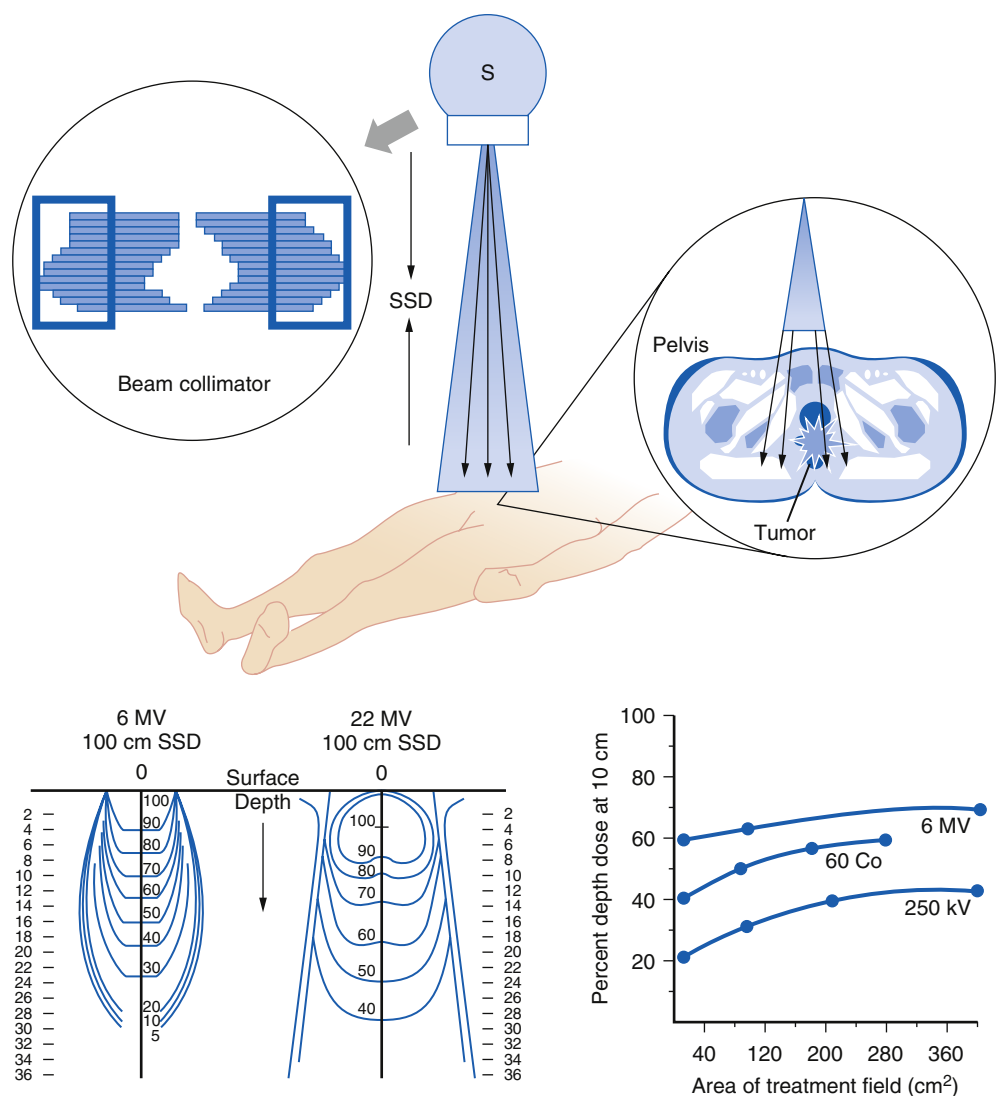

Figure 27.8 Teletherapy. Conventional external beam radiotherapy is the delivery of radiation dose to tissues at a distance (SSD) away from the radiation source (S). As the beam emerges from the treatment machine, the beam diverges and can be shaped by high-Z material leaflets of a beam collimator (*top*) or custom blocks. As the treatment beam hits the patient, photon interactions occur, producing ionization events (*inset*). Energy deposition within tissue creates isodose curves. Isodose curves and depth-dose distributions for 6- and 22-MV photons are shown (*bottom left*). Note that the higher-energy machine delivers radiation to a greater depth for the same surface dose, resulting in skin sparing. As treatment field size varies, the dose delivered at a specified depth varies (*bottom right*).

Table 27.2 Normal Tissue Tolerance to Radiation Therapy

Tissue	Tolerance (Gy)
Kidney	20-23
Liver	25-35
Small bowel	45-50
Rectum	60-70
Bladder	60-70
Vaginal mucosa	70-75
Cervix	>120

In contrast to early effects, late effects depend primarily on the dose per fraction. Fractionated radiation therapy using a daily radiation dose of 180 to 200 cGy minimizes the risk of late effects. Second cancers (mostly sarcomas) induced after radiation are rare (1 in 500 to 1000 cases) and do not usually appear until 15 to 20 years after radiation exposure. Arai and associates noted an excess of rectal cancer, bladder cancer, and leukemia in women with carcinoma of the cervix treated by radiation in comparison with those treated by surgery (Arai, 1991).

The skin overlying the tumor being treated visibly reveals the effects of radiation-induced normal tissue damage. Skin effects

are manifest by reddening of the skin and loss of hair where the radiation treatment beam enters the body. Erythema may progress to dry or moist skin breakdown or desquamation caused by loss of the actively proliferating basal layer of the epidermis that renews the overlying epithelium. This is less common now than in prior years because higher energy radiation beams, which spare the surface dose, are used. However, during the treatment of vulvar malignancies, the skin surface and superficial groin nodes are the radiotherapeutic target, so desquamation is more commonly observed. Medical treatments consisting of non-metal-containing creams and emollients during therapy reduce discomfort and allow healing within 2 to 4 weeks after completion of radiation therapy. Late skin fibrosis may produce a rough, leathery texture to the skin in the irradiated field. Chiao and Lee as well as Gothard and coworkers have reported on the use of pentoxifylline and vitamin E to promote healing of late subcutaneous and deep tissue fibrosis after radiation (Chiao, 2005; Gothard, 2005).

In the treatment of gynecologic malignancies, other sites at risk of radiation-induced normal tissue damage are the bladder, rectum, and large and small bowel. The bladder epithelium consists of a basal layer of small diploid cells covered by large transitional cells. Radiation damage to the diploid cells results in slow renewal of the overlying transitional cells that are periodically sloughed off during urination. Radiation cystitis manifested as dysuria and urinary frequency results in bladder irritation. Treatment with analgesics such as phenazopyridine (Pyridium) can alleviate symptoms. Hematuria may also occur. Therapy with sclerosing solutions or fulguration through a cystoscope may be necessary. McIntyre and colleagues noted that ureteral stricture after radiation for stage I carcinoma of the cervix is 1% at 5 years and 2.5% at 20 years, a rare but important complication (McIntyre, 1995). In rare cases, urinary diversion may be required. Bladder fibrosis and reduced bladder capacity are late effects of pelvic radiation therapy.

In the intestine, the renewing stem cells are found at the bottom of the crypts of Lieberkuhn. Within 2 to 4 days after the start of radiation, these cells can become depleted, leading to atrophy of intestinal mucosa. Damage to the bowel usually occurs in the form of inflammation (sigmoiditis or enteritis), which commonly results in increased bowel motility or diarrhea but also, rarely, may be associated with severe bleeding and cramping pain. Less severe cases can often be controlled with a low-roughage diet and antispasmodic medications. Although uncommon, severe cases may require bowel resection or permanent bowel diversion through a colostomy. Covens and coworkers noted that those who require operation for radiation damage to the bowel have an approximately 25% risk of dying in 2 years, with ileal damage being the most risky (Covens, 1991). Those with complications not requiring surgery frequently have decreased vitamin B₁₂ and bile acid absorption. Late bowel toxicities include radiation proctitis caused by small vessel vascular damage in the epithelium, which may progress to intermittent rectal bleeding. Bowel stenosis or obstructions resulting from fibrosis and adhesion formation may occur, especially in patients who have had previous pelvic or abdominal surgery. Occasionally, enteric fistulas can develop, and bowel perforation may occur. In the latter case, surgical therapy is required, usually to bypass the affected area of the intestine. As a rule, extensive

dissection of irradiated tissue is avoided. Montana and Fowler have shown that the risks of proctitis and cystitis are dose related (Montana, 1989). For example, they found severe proctitis and cystitis at doses of 6750 and 6900 cGy, respectively, whereas such complications were not observed in patients whose median dose was 6300 and 6500 cGy.

A lowering of circulating lymphocytes, granulocytes, platelets, and red blood cells can be seen with pelvic radiation therapy for gynecologic malignancies. The stem cells of the bone marrow in an adult reside in the axial skeleton (vertebrae, ribs, and pelvis). Usual external beam radiation therapy treatment fields for gynecologic malignancies encompass the sacrum and lower vertebrae and pelvis, thereby reducing precursor stem cells for circulating blood cells. This is an important consideration if the woman is to receive concurrent radiosensitizing chemotherapy or subsequent cytotoxic chemotherapy. Growth factor support with synthetic erythropoietin or granulocyte colony-stimulating factor (G-CSF) is often required for patients receiving multiagent chemotherapy following treatment with pelvic radiation therapy.

Finally, fistulas between the vagina and bladder or between the vagina and rectum may develop when there has been extensive radiation damage to the intervening tissues. This usually takes place during therapy for large carcinomas of the cervix. As a rule, such complications will occur 6 to 24 months after treatment, although they may occur many years after primary therapy. Diverting surgery or resection of the fistulas is often needed to correct these serious complications.

CHEMOTHERAPY

Although many patients with gynecologic cancers present initially with a clinically appreciable mass or tumor, only a minority of patients have localized disease, curable with surgery or radiation treatment alone. More often, the cancer has spread to regional lymph nodes or disseminated to other organs, even though these sites may not be clinically appreciated at the time of initial diagnosis.

Chemotherapy regimens for gynecologic cancers have evolved since the 1940s. Initially, Li and colleagues demonstrated the first successful effort in gynecologic cancer using the antimetabolite methotrexate, which could cause permanent remission of metastatic trophoblastic disease (Li, 1956). Shortly thereafter, treatment regimens emerged with single-agent melphalan followed by single-agent cyclophosphamide. When cisplatin was introduced into clinical practice, it added significant improved activity to cyclophosphamide; this combination then became the standard of care. In the 1980s, clinical studies to evaluate paclitaxel for treatment of ovarian cancer were undertaken. Paclitaxel soon replaced cyclophosphamide and paclitaxel plus cisplatin became the standard of care for ovarian cancer and, since then, has become a popular treatment option for all gynecologic malignancies (McGuire, 1996; Piccart, 2003). Because of toxicity associated with cisplatin, numerous studies were conducted to justify substitution with carboplatin for cisplatin because of its improved toxicity profile, but controversy remains over which taxane or platinum agent is preferred (Ozols et al, 2003). Overall, the consensus is that primary chemotherapy should include a taxane and a platinum agent (Ozols, 2006).

Box 27.1 Clinical Pearls

- The use of intraperitoneal (IP) chemotherapy as first-line treatment of advanced ovarian cancer has been recommended by the National Comprehensive Cancer Network guidelines. The key lesson learned from the study by Armstrong and colleagues is that patient selection is critical for tolerability of this regimen. Those who are younger, with optimal tumor debulking, no significant bowel resection, and good organ function, will tolerate IP therapy better.
- Patient assessment prior to each regimen of chemotherapy is essential to minimize toxicity. This includes evaluation of complete blood count, liver function tests, and calculation of renal function. Consider the use of growth factors or dose adjustments as appropriate.

Historically, there has been no clear difference or advantage in regard to which taxane or platinum agent was used or which dose intensity was selected until the clinical trial by Katsumata and colleagues. This study suggested that there is an advantage with a weekly schedule or dose density compared with the standard platinum-taxane, every 3-week regimen (Katsumata, 2009). However, there are concerns about the toxicity associated with the dose-dense regimen; questions about the feasibility of this regimen have arisen with the typical older women seen in clinical practice, so a confirmatory Gynecologic Oncology Group (GOG 262) phase III study is ongoing.

In addition to dosing schedule, the route of chemotherapy administration has also been an area of research interest. For decades, many researchers have conducted numerous clinical trials of intraperitoneal (IP) chemotherapy. In 2006, Armstrong and colleagues published the first IP therapy clinical trial to demonstrate a survival advantage over the standard intravenous (IV) regimen (Box 27.1) (Armstrong, 2006). However, these advances in chemotherapy for the treatment of advanced ovarian cancer have not translated into major changes in overall 5-year survival, which remains less than 20%.

A number of general principles have been developed during the study of chemotherapeutic agents. These provide guidelines for their recommended use and administration (see Box 27.1).

CHEMOTHERAPY PRINCIPLES AND GUIDELINES

Some of the concepts used in antibiotic therapy for infections have been applied to the chemotherapeutic approach to cancer management. However, major differences exist. Infections are frequently caused by a single virus or even multiple types of bacteria with specific growth patterns and sensitivities to antibiotics. Although it is believed that a cancer can originate from a single cell, clinically evident disease is composed of a heterogeneous population of cells with different cell cycle durations, varying growth fractions, and diverse expression of genes, potential mutations, and proteins responsible for cell proliferation and metastasis. Intrinsic and acquired drug resistance remains one of the daunting challenges in the treatment of gynecologic cancers.

Basic principles for cancer chemotherapy arose from experiments in murine tumor models, notably mice leukemias, conducted by Skipper and colleagues at the Southern

Research Institute (Skipper, 1965). These principles include the following:

- *Fractional cell kill*: Each dose of chemotherapy kills a constant fraction of the tumor cell population. Tumor cell kill usually correlates in a linear relationship with the pharmacokinetic parameter of the area under the drug concentration curve (AUC).
- *Dose intensity*: High chemotherapy doses interspersed with short rest periods produce the greatest tumor cell kill in rapidly proliferating malignancies.
- *Drug resistance*: Single-agent chemotherapy administration selectively isolates drug-resistant tumor cells, leading to an outgrowth of hardy, resistant malignant cells. Chemotherapy drug resistance has been associated with the following: (1) cell-mediated modification of drug targets, (2) active drug transport out of the cell, and (3) alteration of drug activation or targeting.
- *Cell cycle dependency of cell kill*: Actively proliferating tumor cells are most often killed by chemotherapy agents; drugs inhibiting DNA processing act during the S phase and those impairing cell division act during the M phase. If the normal monitors of genomic integrity are intact, a cell may suspend the cell cycle to repair any detected damage. If, however, these monitors are abnormal, a cell may continue progression through the cell cycle, which may lead to unrecoverable cell cycle arrest or irreparable damage to critical genes vital for future cell survival. Malignant cancer cells often demonstrate abnormal monitors of genomic integrity, in part permitting their rapid proliferation but also increasing their sensitivity to chemotherapies.

APPROACHES TO TREATMENT

The dose of an anticancer chemotherapy agent is usually calculated as a function of body surface area (square meters), which provides a better measure of potential toxicity than body weight. This is partly because of the observation that body surface area more closely reflects cardiac output and blood flow than body weight alone. Chemotherapeutic agents have varying toxicities (discussed later). A major problem with most agents is bone marrow toxicity, requiring careful monitoring of mature and stem cell turnover in the hematopoietic system. Most gynecologic cancer chemotherapy agents are administered intravenously in cycles varying from weekly to 3- or 4-week intervals between each cycle. If mature white blood cells (i.e., absolute neutrophil count) and platelets have not recovered adequately by the time the next cycle is due, treatment delay or a dose reduction is often considered. In patients with a history of prolonged myelosuppression or with regimens associated with significant myelosuppression, the proactive use of growth factor support is often helpful in allowing chemotherapy treatments to continue at full dose and on time, as scheduled.

Additional considerations about the toxicity of chemotherapeutic agents relate to hepatic metabolism or renal excretion. It may be necessary to modify the dose of the drug administered when renal or hepatic function is compromised. For example, consider the following:

- Doxorubicin (Adriamycin) and paclitaxel are metabolized in the liver, and dose reductions must be made if the drug is administered to a woman with hepatic dysfunction.

- Methotrexate and cisplatin effects are increased in patients with renal damage, necessitating dose reduction in these patients.
- Cisplatin not only has its effects intensified in patients with renal insufficiency but also is toxic to the kidney, requiring particular caution if administered to those with compromised renal function or those undergoing therapy with other renal toxic medications.

Plasma protein binding (PPB) can also alter toxicity profile. For example, paclitaxel and topotecan both are associated with PPB greater than 80%. When PPB drugs are displaced, the unbound or free fraction of drug increases, which may increase toxicity or the effects of chemotherapy. Furthermore, a low serum albumin level leads to an increase in the free fraction of the chemotherapeutic agent, which is one reason why malnourished patients have a heightened toxicity to chemotherapy.

Various chemotherapeutic agents can be differentially toxic to other organ systems of the body, including the gastrointestinal, nervous, pulmonary, and reproductive systems. The primary toxicities affecting gynecologic cancer patients are nausea and vomiting, prolonged myelosuppression, and neuropathies. Acute nausea and vomiting can usually be prevented with the combination of a serotonin antagonist with a steroid. Despite the introduction of newer agents such as aprepitant and palonosetron, delayed nausea and vomiting continue to constitute therapeutic challenges. Unfortunately there are limited options for the prevention and management of chemotherapy-induced neuropathy other than dose reduction or switching chemotherapeutic agents.

Myelosuppression is a manageable toxicity with most chemotherapy regimens. Prevention of myelosuppression with the use of a myeloid growth factor (e.g., G-CSF) has better efficacy than waiting until prolonged neutropenia develops. Although not often relevant for patients with gynecologic cancer, loss of ovarian function and fertility is often an important consideration when selecting adjuvant treatments for younger women with other cancers. The goal of treatment is to provide as high a dose of the chemotherapeutic agent at a planned frequency, as defined by clinical trial data to produce maximum chemotherapeutic effectiveness without causing unacceptable toxicity or side effects.

There are four ways in which chemotherapy is generally used for the treatment of gynecologic cancers: (1) as an induction treatment for advanced disease (neoadjuvant therapy) in a gynecologic setting, it is used to shrink tumor prior to surgery to improve the potential for optimal tumor debulking, which is followed by additional chemotherapy; (2) as an adjunct to radiation therapy; (3) as primary treatment for cancer in the gynecologic cancer setting, it is often administered after completion of tumor debulking surgery; or (4) as consolidation after a complete response is achieved to target undetectable microscopic disease.

In assessment of the effect of chemotherapeutic agents, a number of definitions are used to describe the response of the tumor being treated. Clinical response should be assessed on an individual basis, with tumors in some patients monitored by physical examination and in some patients through imaging, typically with CT or MRI. Other means of assessing response to therapy include serial assessment of specific tumor markers (e.g., cancer antigen 125 [CA-125] for ovarian cancer or β -human

Table 27.3 Response Evaluation Criteria in Solid Tumors (RECIST) Criteria to Assess Clinical Response to Therapy

Criterion	Features
CR (complete response)	Disappearance of all target lesions
PR (partial response)	30% decrease in sum of greatest diameters of target lesions
PD (progressive disease)	20% increase in sum of greatest diameters of target lesions
SD (stable disease)	Small changes that do not meet the above criteria

chorionic gonadotropin for gestational trophoblastic disease) or identification of changes in hypermetabolic foci by PET.

In 2000, an international committee endorsed a technique for measuring tumors by CT and MRI that is easy and highly reproducible. This is known as RECIST (response evaluation criteria in solid tumors) and is applicable for subjects with at least one measurable target lesion. The greatest diameters of all target lesions are summed, and changes in this sum during treatment are used to assign response (Table 27.3).

CHEMOTHERAPEUTIC AGENTS

A large number of chemotherapeutic drugs have been used in the treatment of gynecologic cancers (Fig. 27.9). In general, these agents can be classified into platinum compounds, taxanes, antitumor antibiotics, topoisomerase I inhibitors, alkylating agents, antimetabolites, vinca alkaloids, biologic and targeted therapy, and anticancer hormones. Agents currently used alone or in combination for the treatment of gynecologic cancer are discussed here.

Platinum Analogues

Cisplatin and carboplatin are two of the most active and widely used chemotherapeutic agents in the treatment of gynecologic malignancies and are used in the primary treatment of ovarian, tubal, peritoneal, endometrial, cervical, and vulvar cancers, as well as some cases of metastatic gestational trophoblastic disease.

Platinum (PLT) analogues form PLT-DNA adducts that intercalate the DNA, interrupting DNA synthesis. Although its cell cycle specificity has not been clearly defined, cisplatin's radiosensitizing mechanisms include the formation of toxic intermediates in the presence of radiation-induced free radicals, radiation-induced increased cellular platinum uptake, inhibition of radiation-induced DNA repair, and cell cycle arrest at the G2-M transition. For the treatment of most gynecologic malignancies, cisplatin is given by an IV or IP infusion. Cisplatin is emetogenic but can be appropriately managed with serotonin antagonists. Hypomagnesemia is a problem in patients receiving cisplatin, often requiring frequent magnesium replacement. Because cisplatin is nephrotoxic, copious hydration and mannitol infusion usually accompany cisplatin administration to prevent renal tubular necrosis because the drug is excreted in the urine in its active form. Cisplatin also induces myelosuppression and high-frequency ototoxicity. Audiograms may be obtained before and during treatment to assess ototoxicity. Cisplatin induces severe peripheral neuropathy, which may improve somewhat after cessation of therapy but tends to be long lasting.

Figure 27.9 Chemotherapy cell cycle activity. Chemotherapeutic agents demonstrate variable antitumor cytotoxic and radiosensitizing activities, depending on their mechanism of action during the cell cycle. Alkylating agents facilitate the transfer of alkyl groups to DNA, disrupting the G1/S transition (*top left*). Agents derived from bacteria deregulate normal DNA and RNA processing, slowing progression through the G1/S and G2/M transitions (*top right*). Antimetabolites result in faulty base insertion into replicated DNA or specifically inhibit rate-limiting enzymes such as ribonucleotide reductase that are needed to produce deoxyribonucleotides for DNA replication during the S phase (*center*). Taxane and vinca alkaloid agents alter the mitotic spindle during mitosis, preventing cell division (*bottom left*). Platinum agents show activity throughout the cell cycle and form DNA structural adducts, limiting progression at various cell cycle checkpoints. Chemotherapeutic agents themselves are cytotoxic but also increase tumor cell sensitivity to ionizing radiation during critical periods of the cell cycle in which radiation has a maximal effect. The safe combination of these various classes of chemotherapeutic agents and radiation is an area of active clinical research.

Carboplatin is an analogue of cisplatin; a study conducted by Ozols and colleagues has reported that it has activity in ovarian epithelial carcinoma comparable with that of cisplatin (Ozols, 2003). Its mechanism of action and antitumor activity throughout the cell cycle are similar to those of cisplatin, but carboplatin is less potent in producing DNA interstrand cross-links compared with cisplatin. Yang and coworkers found that the cellular uptake of carboplatin increases after ionizing radiation treatment with a concomitant increase in drug-DNA binding (Yang, 1995).

Carboplatin is dosed based on the woman's specific renal function. Often, the calculated creatinine clearance is used in place of the measured glomerular filtration rate (GFR) to estimate renal function. Carboplatin is dosed based on a target area under the curve (AUC) from 5 to 7 mg/mL *min; the dose is calculated using the Calvert formula:

$$\text{Dose (mg)} = \text{target AUC} \times (\text{GFR} + 25)$$

Although carboplatin is renally eliminated because of this dose algorithm, it is not associated with the degree of nephrotoxicity as cisplatin; thus rigorous prehydration is not required, allowing

for it to be administered on an outpatient basis. The adverse drug effects associated with carboplatin include neurotoxicity, nausea, and vomiting, but to a lesser extent compared with cisplatin. Myelosuppression, primarily thrombocytopenia, is the dose-limiting toxicity (DLT) associated with carboplatin.

The DLT of carboplatin is myelosuppression, primarily thrombocytopenia, although neutropenia and anemia also occur. Typically, after dosing single-agent carboplatin, the nadir occurs between 15 and 20 days. Because carboplatin's typical dose is individualized based on the woman's specific renal function, it appears to have an improved toxicity profile. It is important to keep in mind that appropriate parameters must be used to estimate renal function to minimize toxicity. Less common toxicities include alopecia, hepatotoxicity, neurotoxicity, and ototoxicity.

Both platinum analogues can be associated with delayed hypersensitivity reactions. Because carboplatin is used more often in a recurrent setting, there are more hypersensitivity reactions reported with carboplatin. There is a high cross-sensitivity, so patients who react to one platinum agent will be at significant risk for another reaction if exposed to another platinum analogue. Desensitization protocols with complete histamine blockade (H1 and H2) and steroids have been successful and allow continuation of treatment with the platinum agent.

Taxanes

Paclitaxel is a taxane that is naturally derived from the bark of the Pacific or Western yew (*Taxus brevifolia*). Docetaxel are derived from the bark of the English yew (*Taxus baccata*). Both chemotherapeutic agents promote microtubule assembly, stabilizing microtubules to prevent and inhibit depolymerization of tubulin during mitosis (M phase). By arresting cell division through a functional block of the M phase, paclitaxel and docetaxel are potent chemotherapeutic agents, with activity in most solid tumors. Although administration of both taxanes can be accompanied by severe hypersensitivity reactions and hypotension, these responses are more commonly observed with paclitaxel because of its diluent, polyethoxylated castor oil (Cremophor EL) and ethanol. Thus premedication with antihistamines and steroids are recommended to minimize infusion-related hypersensitivity reactions. Neutropenia is the major toxic side effect, but sensory peripheral neuropathy is also a serious problem. Bradycardia and severe cardiac problems have been reported with the administration of paclitaxel, but they are rare. A rare complication has been the report of bowel perforation in a few individuals while on paclitaxel therapy, as noted by Rose and Piver (Rose, 1995). In addition to its use in the treatment of ovarian cancer, paclitaxel or docetaxel is being used in the treatment of other cervical cancers, endometrial cancer, and uterine sarcomas.

Antitumor Antibiotics

Antitumor antibiotics are derived from products of bacterial or fungal cultures. The chemotherapeutic agents generally used for gynecologic malignancies are actinomycin D (dactinomycin), doxorubicin, and bleomycin (Blenoxane).

Actinomycin D is derived from the bacteria *Streptomyces parvulus* and is used primarily in the treatment of gestational trophoblastic disease. It lodges between adjacent purine-pyrimidine (guanine-cytosine) base pairs, blocking DNA-dependent ribosomal RNA synthesis by RNA polymerase. Actinomycin D is

Table 27.4 Side Effects of Drugs Often Used or Being Tested in Gynecologic Oncology

Agent	Common Toxicities
Altretamine	Nausea and vomiting, diarrhea, abdominal cramping, myelosuppression
Bevacizumab	Hypertension (DLT), proteinuria, congestive heart failure, increase risk of bleeding, thromboembolism, GI perforation
Bleomycin	Interstitial pneumonitis, pulmonary fibrosis (DLT), mucocutaneous toxicity, fever
Capecitabine	Diarrhea (DLT), paresthesias, palmar-plantar erythrodysesthesia (PPE), dermatitis, hyperbilirubinemia, fatigue, anorexia
Carboplatin	Nausea and vomiting, myelosuppression (DLT), nephrotoxicity, electrolyte wasting, diarrhea, stomatitis, hypersensitivity reactions
Cyclophosphamide	Hemorrhagic cystitis, SIADH, alopecia, myelosuppression (DLT)
Dactinomycin	Myelosuppression (DLT), hepatotoxicity, alopecia, fatigue, myalgia, pneumonitis, malaise, lethargy
Docetaxel	Myelosuppression, fluid retention, hyperlacrimation, nail disorders
Etoposide	Myelosuppression, nausea and vomiting, hypotension, anorexia, alopecia, headache, fever
5-Fluorouracil	Nausea and vomiting, diarrhea, anorexia, myelosuppression, PPE, cardiotoxicity
Gemcitabine	Myelosuppression (DLT), flulike symptoms, headache, somnolence, nausea and vomiting, stomatitis, diarrhea, constipation, rash
Letrozole	Nausea and vomiting, bone pain, arthralgias, hot flashes
Leuprolide acetate	Peripheral edema, gynecomastia, hot flashes, hyperphosphatemia, nausea and vomiting, weight gain
Liposomal doxorubicin	Myelosuppression, stomatitis, mucositis, alopecia, flushing, shortness of breath, hypotension, headaches, cardiotoxicity, hand-foot syndrome
Methotrexate	Stomatitis, nausea and vomiting, myelosuppression, nephrotoxicity, elevation in hepatic enzymes, interstitial pneumonitis
Paclitaxel	Hypersensitivity reactions, peripheral neuropathy (DLT), nausea and vomiting, alopecia
Tamoxifen	Thromboembolism, hot flashes, decreased libido, nausea and vomiting, thrombocytopenia, anemia
Topotecan	Myelosuppression (DLT), nausea and vomiting, diarrhea, stomatitis, abdominal pain, alopecia, SGOT and SGPT elevation
Vincristine	Neurotoxicity, constipation (DLT), alopecia
Vinorelbine	Myelosuppression (DLT), neurotoxicity, constipation, asthenia, fatigue

DLT, Dose-limiting toxicity; GI, gastrointestinal; SGOT, serum glutamic pyruvic transaminase; SGPT, serum glutamic pyruvic transaminase; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

maximally effective in the G1 phase of the cell cycle, but data suggest that this drug may act throughout the entire cell cycle. Because bound actinomycin D dissociates slowly from DNA, cells actively progressing through the cell cycle are stopped from doing so at the G1/S checkpoint for genomic integrity, leading to cell death. If radiation is delivered in the presence of the drug, treated cells show a radiosensitizing effect. The drug causes severe myelosuppression, often leading to leukopenia and thrombocytopenia (nadir, 7 to 10 days). Toxicity to the gastrointestinal mucosa is associated with vomiting within 20 hours, stomatitis, and nonbloody diarrhea. Reversible alopecia may also occur. Dermatitis resulting from radiation recall has also been noted, meaning that skin erythema and inflammation arise in skin areas previously irradiated.

Doxorubicin and its newer liposomal formulation (Doxil) are anthracyclines derived from the bacteria *Streptomyces peuce-tius*, var. *caesius*. Within the cell nucleus, doxorubicin wedges between stacked nucleotide pairs in the DNA helix and, because of its bulk, inhibits binding of enzymes needed for DNA-directed RNA and DNA transcription, as well as DNA replication. Doxorubicin therefore has maximal activity in the G1 and S phases of the cell cycle. A second mechanism of action noted for doxorubicin includes the inhibition of topoisomerase II in the G2 phase of the cell cycle. Topoisomerase II assists in the coiling and supercoiling of DNA prior to mitosis by facilitating enzymatic DNA double-strand breaks. Doxorubicin has been shown to stabilize the double-strand break generated by topoisomerase II, thereby promoting loss of genetic material during mitotic division. Doxorubicin must be administered carefully by IV injection because extravasation leads to soft tissue and skin necrosis and ulceration. Doxorubicin is metabolized by the liver,

and dosages must be reduced in patients with compromised hepatic function. Myelosuppression occurs regularly with therapeutic doses. Complete but reversible alopecia is a side effect (Table 27.4). Because the doxorubicin metabolism creates free radicals that bind to cardiac myocytes, it can cause significant cardiac toxicity, leading to irreversible congestive heart failure. Therefore cardiac function is assessed routinely before administration, and cumulative doses are kept to less than 450 mg/m². Liposomal doxorubicin has a synthetic lipid-like membrane around the doxorubicin molecule that is proposed to promote tumor uptake and protect against cardiotoxicity. Cardiomyopathy is less common with liposome-encapsulated doxorubicin, but skin toxicity, notably palmar plantar erythrodysesthesia (PPE), is more common.

Bleomycin is derived from the bacteria *Streptomyces verticillus* and, when complexed with ferrous iron, is a potent oxidase, producing single-strand DNA breaks by hydroxyl radical formation. Bleomycin may be administered intravenously, intramuscularly, or subcutaneously. It is excreted via the kidney, and some dose reduction is made if renal function is compromised. The drug does not produce significant myelosuppression, in contrast to most of the other cytotoxic agents. It is, however, highly toxic to the lungs in that pneumonitis and pulmonary fibrosis occurs in 10% of patients. Thus particular care must be used in persons with compromised lung function. To prevent this complication, cumulative doses of less than 400 units are given. If pneumonitis develops, as evidenced by symptoms of low-grade fever and nonproductive cough, treatment is a tapered course of oral corticosteroid therapy. Bleomycin is also toxic to skin and can produce erythema, peeling, and pigmentation. It has been used as part of combination therapy, with particular effectiveness against

ovarian germ cell tumors, and has been tried for a variety of other gynecologic malignancies, particularly carcinoma of the cervix.

Topoisomerase I and II Inhibitors

As noted, topoisomerases are DNA enzymes that control the topology of DNA double-helix cellular functions during transcription and replication of genetic material. There are two classes of topoisomerases, I and II. Drugs that prevent these functions are referred to as *topoisomerase inhibitors*.

Topotecan

Topotecan is in the class of camptothecins and is used for the treatment of cervical and epithelial ovarian cancers. Camptothecins inhibit topoisomerase I, causing stabilization of the cleavable complex and resulting in an accumulation of single-strand and double-strand DNA breaks, and ultimately cell death. It has been approved by the U.S. Food and Drug Administration (FDA) to be used in combination with cisplatin for the treatment of platinum-sensitive recurrent cervical cancer.

Topotecan is a semisynthetic analogue of camptothecin, a chemical derived from the *Camptotheca acuminata* tree native to China. This drug stabilizes single-strand breaks made by topoisomerase I, an enzyme that relaxes DNA structural tension by facilitating single-strand breaks and subsequent relegation. Topotecan has the greatest activity during the G1/S phases of the cell cycle. Toxicities include bone marrow suppression, nausea and vomiting, alopecia, mucositis, and diarrhea.

Etoposide

Etoposide is an epipodophyllotoxin derived from the root of the mayapple or mandrake plant that stabilizes DNA strand breaks made by topoisomerase II during coiling and supercoiling of DNA during mitosis. The primary toxicity of etoposide is myelosuppression, leading to depression of leukocytes and platelets. Other common toxicities include anorexia, nausea and vomiting, stomatitis, and severe hypotension if infused in less than 30 minutes. Uncommon toxicities include cardiotoxicity, bronchospasm, and somnolence. It is important to recognize that oral etoposide has an erratic absorption, with significant interpatient variability, from 0 to 100% bioavailability. Oral etoposide is typically used in the recurrent setting after failure of other second-line agents. Oral etoposide should never be used in place of the IV formulation when there is a curative intent—that is, a BEP regimen (bleomycin sulfate, etoposide phosphate, and cisplatin) for germ cell tumors.

Alkylating Agents

Alkylating agents are chemical compounds that facilitate the replacement of hydrogen for an alkyl group, potentially disrupting normal function of the altered molecule. As chemotherapeutic agents, alkylating agents interact directly with DNA by transferring positively charged alkyl groups to negatively charged chemical groups intrinsic to the DNA molecule. Examples of this class include cyclophosphamide and ifosfamide. In general, the effectiveness of these agents appears to be similar, but there are some variations in toxicity. As a drug class, alkylating agents affect rapidly dividing cells and are particularly toxic to bone marrow, leading to severe myelosuppression.

Cyclophosphamide and its structural analogue ifosfamide are bifunctional cyclic phosphamide esters of nitrogen mustard.

Both drugs interact with the N7 position of guanine in the DNA helix to form cross-link bridges between the same strand of DNA (intrastrand), opposite strands of DNA (interstrand), and DNA and cellular proteins. By forming intrastrand and interstrand DNA bridges, cyclophosphamide and ifosfamide impair the functional binding of enzymes used to process and replicate DNA, disrupting the G1/S phase transition of the cell cycle. These drugs are inactivated in the liver and exclusively excreted by the kidney. Their urinary metabolite acrolein may accumulate within the urinary system, causing severe urothelial damage that may result in hemorrhagic cystitis within 24 hours or weeks after administration. Prophylactic hydration (3 L/day) to increase dilute urinary output and administration of 2-mercaptoethane sulfonate (mesna), a compound that binds to acrolein and prevents urotoxicity, can be used to prevent this complication. Administration of these agents also leads to leukopenia (nadir, 8 to 14 days) and thrombocytopenia (nadir, 18 to 21 days), alopecia, nausea and vomiting, and amenorrhea. Therapy with alkylating agents has been associated with a subsequent risk of developing acute leukemia. This risk may range from 2% to 10% and appears to be related to the dose of and duration of alkylating agent treatment. They may be administered intravenously or orally but are only rarely used in the primary treatment of gynecologic malignancies.

Antimetabolites

Antimetabolites interfere with cell metabolism by competing with naturally occurring purines or pyrimidines, whose chemical structure they resemble. In this way, they interfere or prevent vital biochemical reactions.

5-Fluorouracil (5-FU) is a fluorinated pyrimidine analogue resembling the DNA nucleoside thymine; it differs from the RNA nucleoside uracil by a fluorinated carbon in the fifth position in the nucleoside ring, as described by Grem. Conversion of 5-FU into fluorodeoxyuridine monophosphate blocks DNA synthesis by covalently binding to thymidylate synthase. This inhibits the formation of de novo thymidylate, a necessary precursor of hydymine triphosphate essential for DNA synthesis and cell division. The conversion of 5-FU into fluorouridine triphosphate results in the erroneous incorporation of fluorouridine triphosphate into RNA strands, which interferes with RNA processing and protein synthesis. By these actions, 5-FU perturbs normal progression through the G1/S transition, bringing about impaired cell division caused by altered nucleotide pools and DNA repair. As such, 5-FU is a potent radiosensitizer. One advantage of the drug is that 5-FU can be administered as a bolus or continuous IV infusion or orally as a prodrug (e.g., capecitabine) that is metabolized to 5-FU. Common toxicities associated with 5-FU have been reported and include myelosuppression, stomatitis, diarrhea, alopecia, nail changes, dermatitis, acute cerebellar syndrome, cardiac toxicity, hyperpigmentation over the vein used for infusion, and PPE (see [Table 27.4](#)). The 5-FU given intravenously is normally used in conjunction with cisplatin as a radiation sensitizer in the treatment of advanced cervical and vulvar cancers. Oral 5-FU (capecitabine) is often used in the treatment of recurrent ovarian and endometrial cancers.

Methotrexate is a folic acid analogue that binds tightly to dihydrofolate reductase, which plays a critical role in intracellular folate metabolism. This prevents the metabolic transfer

of one carbon unit within the cell and thereby arrests DNA, RNA, and protein synthesis. Cells exhibit sensitivity to this drug predominantly in the S-phase portion of the cell cycle. The effects of methotrexate can be overcome by the administration of folinic acid (citrovorum factor) 24 hours after methotrexate, which replenishes the tetrahydrofolate. Some chemotherapeutic protocols have used very high doses of methotrexate to treat the tumor, followed by citrovorum rescue to avoid severe toxic side effects (see [Table 27.4](#)). Methotrexate is administered intravenously, intramuscularly, or orally using a variety of dose regimens. It is excreted in the urine and dose adjustments must be made if there is decreased renal function. Methotrexate results in severe myelosuppression (nadir, 6 to 13 days). Stomatitis, nausea, and vomiting are reported. Hepatotoxicity resulting in liver enzyme elevation may be seen within 12 hours after high-dose treatment. Therapeutic serum methotrexate levels are evident long after treatment in patients with ascites or pleural effusion because these act as a reservoir for the drug. The predominant use of the drug for gynecologic malignancies has resulted in the effective treatment of trophoblastic disease.

Gemcitabine, a synthetic deoxycytidine nucleoside analogue, targets ribonucleotide reductase (RR), the rate-limiting enzyme in deoxyribonucleotide metabolism during the S phase. Gemcitabine is triphosphorylated in tumor cells by the enzyme deoxycytidine kinase, inhibiting DNA polymerase activity and interrupting DNA replication. As a nucleoside analogue, gemcitabine is incorporated as a fraudulent base pair in DNA; as a diphosphate, it inhibits the regulatory subunit of the RR enzyme, which leads to the depletion of deoxyribonucleotide pools needed for DNA synthesis in the S phase of the cell cycle. Reported treatment toxicities include myelosuppression, transient elevation of liver enzyme levels, nausea, vomiting, flulike symptoms, and fatigue (see [Table 27.4](#)). Gemcitabine is used in the treatment of recurrent ovarian cancer, endometrial cancer, and uterine sarcomas.

Vinca Alkaloids

The vinca alkaloids bind to the β -tubulin subunits of the mitotic spindles, blocking polymerization of the microtubules in mitosis. For gynecologic malignancies, the vinca alkaloids used most often include vinorelbine and vincristine. Vincristine is derived from the periwinkle plant (*Vinca rosea*) and acts in a cell cycle-dependent manner, blocking the assembly of tubulin and causing toxic destruction of the mitotic spindle, which arrests cellular mitosis. Vinorelbine is a semisynthetic vinca alkaloid derived from vinblastine. By affecting the late G2 and M phases of the cell cycle, these drugs are potent cytotoxins and increase cell radiosensitivity by slowing the G2/M transition in which radiation effects are maximal. Vincristine is severely neurotoxic and can produce numbness, motor weakness, and constipation as a result of its autonomic effects. The DLT of vinorelbine is myelosuppression (see [Table 27.4](#)).

Altretamine

Altretamine has been used for a number of years but in recent years has been replaced with more active agents. The exact mechanism of action of altretamine is not known. It does not act as an alkylating agent in vitro but is possibly activated to one in vivo. Altretamine is metabolized by cytochrome P450 (CYP450) and the reduced form of nicotinamide adenine

dinucleotide phosphate (NADPH) to N-hydroxymethyl pentamethylmelamine, which has been shown to bind covalently to DNA. Additional N-methylmelamines formed may also mediate some of the cytotoxicity of this agent.

It is an oral agent that is usually given in four divided doses. Altretamine therapy may be associated with some nausea, vomiting, diarrhea, abdominal cramping, and myelosuppression (see [Table 27.4](#)). In addition, a pharmacist should monitor for potential CYP450-drug interactions in patients on multiple prescriptions and alternative medications.

Biologic and Targeted Agents

Since the early 2000s, there have been major efforts toward the incorporation of monoclonal antibodies such as bevacizumab and cetuximab and small-molecule tyrosine inhibitors such as sunitinib, gefitinib, and sorafenib into first-line and recurrent treatment regimens for gynecologic cancers. Although as single-agent therapy the biologic agents have not demonstrated significant activity against gynecologic cancers, there are mounting clinical data to support the implementation of agents such as bevacizumab into first-line and maintenance regimens to improve progression-free survival, specifically for ovarian cancer.

Bevacizumab

Bevacizumab is a recombinant humanized monoclonal antibody that targets and inactivates vascular endothelial growth factor (VEGF) to inhibit the angiogenesis pathway. As a single agent in the recurrent ovarian cancer setting, bevacizumab has had only a moderate response ranging from 16% to 21% ([Cannistra, 2007](#); [Monk, 2006](#)). However, in combination with chemotherapy, bevacizumab has had promising response rates, ranging from 15% to 80% ([Micha, 2007](#); [Penson, 2009](#)). There are significant limitations to incorporating bevacizumab with chemotherapy regimens because of the high risk of bowel perforation in ovarian cancer patients that was first observed in phase II studies. Hence, the current recommendation is that patients should not have had recent bowel surgery or a history of significant bowel resections.

Bevacizumab has been evaluated in combination with oral cyclophosphamide, paclitaxel, and gemcitabine for the treatment of recurrent ovarian cancer. The integration of bevacizumab into a first-line treatment regimen has focused on the benefits with paclitaxel plus carboplatin followed by maintenance with bevacizumab alone. Based on the encouraging results of ICON7 that incorporated bevacizumab into front-line therapy, the GOG initiated a confirmatory phase III study comparing six cycles of standard paclitaxel plus carboplatin to six cycles of the same regimen with bevacizumab to determine whether bevacizumab improves efficacy of front-line treatment ([Oza, 2015](#)). However, the duration of maintenance bevacizumab remains an area of therapeutic and pharmacoeconomic controversy.

Targeted Agents

Tyrosine kinase inhibitors (TKIs) such as sorafenib, sunitinib, pazopanib, and cediranib also target the VEGF angiogenesis pathway via inhibition of the VEGF receptor (VEGFR). Current research efforts have been focused on combination regimens of these TKIs with cytotoxic agents for first-line treatment and also for the treatment of recurrent ovarian cancer. Another agent of interest is aflibercept (VEGF Trap), which is a fusion protein that

targets VEGF-A. Initial studies have demonstrated that it is beneficial in the treatment of malignant ascites. Unfortunately, the popular epidermal growth factor receptor (EGFR) agents such as erlotinib, which have had so much benefit in the treatment of other cancers, have not demonstrated activity alone or in combination with chemotherapy or with bevacizumab for the treatment of gynecologic cancers. Finally, the newer classes of targeted therapies, such as latelet-derived growth factor (PDGF) inhibitors and poly (ADP-ribose) polymerase (PARP) inhibitors, are being incorporated into numerous clinical studies in an attempt to improve progression-free and overall survival. Olaparib, a PARP inhibitor was recently approved for treatment of recurrent, platinum sensitive ovarian cancer patients who express the breast cancer gene *BRCA-1*; however, emerging data suggest there will be benefit in patients with “*BRCA*-ness” like pathology (Ledermann, 2012).

Anticancer Hormone Therapy

Hormone therapy has been effectively developed for the treatment of breast cancer. Estrogen and progesterone receptors have been clearly identified in endometrial carcinomas and have been found in other types of gynecologic cancers, particularly ovarian epithelial carcinomas. Progestins such as megestrol (Megace), depot medroxyprogesterone acetate (Depo-Provera), and 17-hydroxyprogesterone caproate (Delalutin), as well as antiestrogens such as tamoxifen and raloxifene, have been used in the treatment of endometrial carcinomas and seem to have their best effects against well-differentiated tumors.

DRUG RESISTANCE

A daunting challenge is overcoming drug resistance, which occurs fairly often in the recurrent setting of all gynecologic malignancies. Platinum sensitivity is defined by a disease-free interval longer than 6 months after treatment with a platinum agent. If platinum-sensitive, patients can be retreated with a platinum agent, which usually will be single-agent carboplatin because it is tolerated better. Platinum resistance is present when there is tumor progression while receiving a platinum agent or disease relapse within less than 6 months after the completion of chemotherapy, and alternative agents must be considered. Taxane resistance follows the same parameters.

The optimal chemotherapeutic agent or regimen in the treatment of platinum-resistant disease is currently unknown. Ideally, the agent should be active in gynecologic cancer and should be non-cross-resistant with taxanes or platinum agents. Overall, regardless of the agent, the response rate is low for all the agents in platinum-refractory (resistant) cancer. Typically, it is recommended to give three cycles prior to evaluation for response to the new agent unless there is a more than 50% doubling of CA-125. Because tumor regression is so rare in the recurrent setting, even achieving stable disease is considered a treatment success. If no response is observed after three cycles, an alternative chemotherapy regimen may be selected.

EVALUATION OF NEW AGENTS

In the development of new oncology drugs, serial evaluations are necessary to assess the effectiveness of the drug and ascertain its toxicity. A number of trials are necessary to move a new agent from the point of evaluation to allow it to be used in regular

Table 27.5 Assessment of Performance Status

Score	Karnofsky Performance Status Scale
100	Normal, no complaints; no evidence of disease
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort; some signs or symptoms of disease
70	Cares for self but unable to carry on normal activity or do active work
60	Requires occasional assistance but is able to care for most personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospitalization indicated, although death not imminent
20	Very sick; hospitalization necessary; active support treatment necessary
10	Moribund; fatal process progressing rapidly
0	Dead

Grade	Gynecologic Oncology Group Performance Status Scale
1	Fully active, able to carry on all predisease performance without restriction
2	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature (e.g., light housework, office work)
3	Capable of only limited self-care, confined to bed or chair >50% of waking hours
4	Completely disabled; cannot carry on any self-care; totally confined to bed or chair
5	Dead

medical practice. Unlike other areas of drug development, clinical trials for cytotoxic agents can only be conducted in those with active cancer, often those who have already failed current standard therapy treatment options.

A standard method frequently used to measure a patient’s general functional condition before enrollment in clinical chemotherapy trials of new agents is the Karnofsky Performance Status Scale (Table 27.5). In general, patients are poor candidates from clinical trials if their score is 50 or less. Cooperative research groups, such as the GOG, have modified the Karnofsky scoring system to reflect a five-point graded classification.

After extensive preclinical evaluation, investigational new drug (IND) applications are filed to move new drugs into human studies. The human clinical trial process is a fairly rigorous and costly process to determine not only safety and efficacy but also improvement over the current standard of care for each new agent proposed, sometimes alone or in various combination regimens. A general outline of phase trials is as follows:

- *Phase I trial:* A phase I trial tests new drugs at various doses to evaluate toxicity and determine tolerance to the drug. At the various doses tested, some therapeutic effects may be observed, although this is not the primary aim of the trial.
- *Phase II trial:* A phase II trial tests the therapeutic effectiveness and extent of toxicity of the drug at doses expected to be effective against a specific tumor type.

- **Phase III trial:** A phase III trial compares new treatment therapies against the current treatment standard of care. For example, this trial design assesses whether a new drug therapy is superior, equivalent, or inferior to the chemotherapeutic agent currently used.

Numerous programs have been implemented to facilitate drug approval and access to investigational drugs, such as the Fast Track Drug Approval Program and Orphan Drug Approval. Special consideration for either program requires preapplication and approval by the FDA. Often, in the gynecologic oncology setting, FDA approval for new gynecologic indications is not sought because of small patient populations and the inability to

conduct phase III studies in a timely fashion. Compendia listings are often granted based on peer-reviewed published literature, which expands reimbursement for treatment recommendations.

Progress has been slow and unsuccessful in finding a cure for ovarian cancer and recurrent endometrial or cervical cancers. In the absence of a curative treatment for recurrent disease, selecting an investigational trial treatment still remains the best option for ovarian cancer patients. Research is needed to identify and develop new approaches for preventing recurrence and new options for treating advanced primary and recurrent disease. Efforts should especially focus on agents to modulate or overcome drug resistance or new molecular targets to optimize chemotherapy outcomes.

KEY POINTS

- Electromagnetic radiation is a form of energy that has no mass or charge and travels at the speed of light.
- The inverse square law states that the energy measured from a radiation source is inversely proportional to the square of the distance from the radiation source.
- Each delivered radiation dose kills a constant fraction of tumor cells irradiated. Oxygen can render radiation-induced DNA damage permanent.
- The effect of photon radiation (low LET) on tissues is altered by tissue oxygenation, whereas neutron radiation (high LET) is independent of oxygenation.
- The cell replication cycle consists of M (mitosis), G1 (Gap1 = RNA and protein synthesis), S (DNA synthesis), and G2 (Gap2 = RNA and protein synthesis). When the cell is not in the replication cycle, it is in the G0 phase.
- The dose of radiation delivered to a tumor depends on the energy of the source, the size of the treatment field, and the depth of the tumor beneath the surface. Increasing the dose increases the depth of maximum dose beneath the skin surface.
- Radiation acts on cells primarily in the M phase, making rapidly proliferating cells the most radiosensitive.
- Normal tissues repair the radiobiologic effects of radiation more effectively than tumor tissue.
- Radiation side effects usually involve erythema of the skin, without desquamation and mild fatigue.
- Uncommon side effects include lowering of the circulating blood cells, dysuria and urinary frequency, diarrhea, bowel injury, and fistula formation.
- Cytotoxic chemotherapeutic agents act on various phases of the cell cycle, primarily affecting rapidly proliferating cells, and at a given dose destroy a constant fraction of tumor cells.
- Growth factors or G-CSF are used to limit the hematologic toxicity of chemotherapy.
- After the completion of the staging and primary surgical treatment, the current standard of care is six cycles of a taxane-platinum-containing chemotherapy regimen.
- If recurrence is less than 6 months after completion of chemotherapy, the tumor is defined to be platinum or taxane resistant.
- The antitumor activity of second-line chemotherapy regimens is similar; the choice of treatment for recurrent disease depends on residual toxicities, physician preference, and patient convenience. Participation in a clinical trial is also a reasonable option for these patients.

Intraepithelial Neoplasia of the Lower Genital Tract (Cervix, Vagina, Vulva) Etiology, Screening, Diagnosis, Management

Mila Pontremoli Salcedo, Ellen S. Baker, Kathleen M. Schmeler

Cervical cancer is a leading cause of cancer and cancer-related deaths among women worldwide, with more than 500,000 new cases and 250,000 deaths annually. More than 85% of these cases and deaths occur in low- and middle-income countries (LMICs), primarily due to a lack of organized screening programs (Torre, 2015). Cervical cancer was previously the leading cause of cancer-related death among women in the United States. However, the incidence and mortality has decreased by approximately 70% since the 1970s. This decline is largely due to the introduction in 1941 of the Papanicolaou (Pap) smear, which has led to a systemic effort to detect early cervical cancer and precancerous lesions (Papanicolaou, 1941). In stark comparison, cervical cancer continues to be one of the leading causes of cancer and cancer-related death among women in LMICs and many underserved parts of the United States due to the lack of organized screening and early detection programs. Cervical cancer is a preventable disease, with excellent tools for prevention (vaccination) and screening (Pap and human papillomavirus testing). Furthermore, there is a treatable preinvasive phase that lasts several years before progressing to invasive cancer.

ETIOLOGY: THE HUMAN PAPILLOMAVIRUS

It is now known that virtually all cases of cervical cancer are caused by persistent infection with high-risk types of the human papillomavirus (HPV) (Walboomers, 1999). HPV is the most common sexually transmitted disease, and it is estimated that 80% of women will be infected with HPV at some point in their lifetime. The initial infection usually occurs during adolescence or early adulthood, with the majority of women clearing the infection within 18 to 24 months (Wheeler, 1996; Moscicki, 1998; Moscicki, 2004; Moscicki, 2008). However, in 3% to 5% of women, the HPV infection persists and they develop significant preinvasive disease, and in <1% invasive cancer develops. HPV infection is therefore necessary but not sufficient for cervical cancer development. HPV infection is also the causative agent of other malignancies, including cancer of the oropharynx, anus, penis, vulva, and vagina.

HPV is a double-stranded DNA virus that replicates within epithelial cells (Chang, 1990; Wolf, 2001). To date, more than 120 HPV types have been identified, and approximately 40 HPV

viruses are known to infect the genital tracts of men and women. Of these, approximately a dozen are considered high-risk types, with HPV 16 and 18 being responsible for more than 70% of cervical cancers. High-risk HPV causes neoplastic cellular changes when viral DNA becomes integrated into the host cell genome. When this happens, certain repressor areas of the viral genome are lost. Consistently, the loss of these control mechanisms allows for the expression of the viral E6 and E7 genes. The production of oncoproteins results in the inactivation of the p53 and retinoblastoma tumor suppressors (Munger, 2004). These changes are believed to lead to cell immortalization and rapid cell proliferation. However, in most cases, the transformed cells are managed by the individual's immune system, and the infection clears or intraepithelial neoplasia regresses. In some women, the transformed cells replicate and, if left untreated, a cancer can develop after a period of several years.

RISK FACTORS

The mean age at diagnosis of cervical cancer in the United States is 48 years. The lifetime risk of developing cervical cancer by age 74 is 0.9% in developed countries compared with 1.6% in LMICs. Similarly, the lifetime risk of death from cervical cancer is 0.3% in developed countries compared with 0.9% in LMICs (Torre, 2015). Despite widespread infection with HPV, most women do not develop cervical cancer (Fig. 28.1). The search for a predictive measure to distinguish between women who are infected and will clear the virus and those in whom the infection will persist and who will develop cancer has been difficult. Although it is clear that women who have a compromised immune system from any cause (e.g., genetic, iatrogenic, infectious) have a greater risk of developing a persistent HPV infection (Aldieh, 2001), there is no way to predict which healthy women are unable to clear the virus spontaneously. The majority of risk factors associated with cervical cancer are those associated with acquiring HPV infection and include early onset of sexual activity, multiple sexual partners, history of sexually transmitted infections, oral contraceptive use, and a history of vulvar or vaginal dysplasia, which is also associated with HPV infection (International Collaboration of Epidemiological Studies of Cervical Cancer, [ICESCC] 2007). Smoking has

Figure 28.1 Image of a cervix with an active human papillomavirus infection. The patient had a cytology sample reported as a low-grade squamous intraepithelial lesion. She was followed without treatment, and the lesions regressed over the next year.

been associated with the development of squamous cell carcinoma of the cervix but not adenocarcinoma (McIntyre-Seltman, 2005; ICSGCC, 2006; ICSGCC, 2007).

PRIMARY PREVENTION: HUMAN PAPILLOMAVIRUS VACCINATION

Three very effective preventive vaccines are currently commercially available. The bivalent vaccine (Cervarix) targets two high-risk HPV types (16 and 18), which account for 70% of the cervical cases worldwide. The quadrivalent vaccine (Gardasil) targets high-risk HPV types 16 and 18, as well as two low-risk HPV types (6 and 11), which cause genital warts. The nonvalent vaccine (Gardasil-9) has been approved for use in the United States and targets the same HPV types as the quadrivalent vaccine (6, 11, 16, and 18) as well as types 31, 33, 45, 52, and 58 (FUTURE II Study Group, 2007; Paavonen, 2009; Jaura, 2015). All three vaccines have been shown in randomized clinical trials to have 93% to 98% efficacy in the prevention of cervical dysplasia (and presumably cervical cancer) in women not previously infected with HPV 16 and 18. In addition, several studies have shown the vaccines to be safe with no scientific evidence that HPV vaccination increases the risk of serious adverse events. The vaccines do not work on existing infection or associated preinvasive or invasive disease, and it is therefore most effective if given prior to sexual debut and exposure to HPV.

The Centers for Disease Control and Prevention (CDC) recommend that the HPV vaccine be given to both boys and girls between the ages of 11 and 12 years, but it can be administered as early as 9 years. Catch-up vaccination should be offered for females aged 13 to 26 years who have not been previously vaccinated (Markowitz, 2014). Unfortunately, the uptake of HPV vaccination in the United States has been poor, with only about one third of eligible children completing the three vaccine series. The uptake in other developed countries (Canada, Australia, the United Kingdom) has been much higher at approximately 70%, likely due to government supported school-based programs. Several LMICs

have instituted HPV vaccination programs as the Global Alliance for Vaccination and Immunization (GAVI) has made the HPV vaccine available to low-income countries for US\$4 to \$5 per dose (compared with \$150 per dose in the United States). However, economic, political, and logistical barriers in many low-income countries have limited universal mass vaccination programs. Studies are underway to determine whether two doses of the vaccine provide sufficient protection. In addition, it is not yet known whether vaccination protection is lifelong or whether a booster dose will be required. Because the vaccines currently available do not provide protection against all cancer-associated HPV types, and because the duration of immunity is not yet known, routine screening is still recommended in vaccinated women.

SECONDARY PREVENTION

CERVICAL CYTOLOGY TESTING

Cervical cytology testing (Pap test) became available in the 1950s after the studies of Papanicolaou demonstrated that cancer and its precursors could be identified by examining a properly prepared and stained cellular sample scraped from the uterine cervix (Papanicolaou, 1941). The 1941 monograph by Papanicolaou and Traut remains one of the sentinel breakthroughs in the history of preventive medicine. Their work led to the demonstration that local therapy of precancerous lesions can prevent the development of cancer. Despite the fact that Pap testing has a low sensitivity, widespread Pap testing has reduced the incidence of cervical cancer by 50% to 70%. In part, the success of this screening technique relies on the fact that it takes many years for invasive cancer to develop following a persistent HPV infection and development of dysplasia, and that most women are tested repeatedly. Generally, in the United States, women who develop invasive cervical cancer have never been screened or have not been screened for many years.

The Pap test is performed by placing a speculum into the vagina and scraping cervical cells using a spatula and endocervical brush (Figs. 28.2 and 28.3). Cells are sampled from the transformation zone, which is the area of the cervix where cervical cancer can develop. The transformation zone includes the squamocolumnar junction, which is the area where the squamous epithelium of the ectocervix meets the columnar epithelium of the endocervix. The transformation zone is dynamic throughout a woman's lifetime, and the squamocolumnar junction migrates from the ectocervix into the endocervical canal as woman ages and reaches menopause. In the past, the collected sample was placed on a glass slide and fixed with alcohol. This method has been replaced by a liquid-based approach. The sample is now placed in a liquid medium for transport to the laboratory where the slide is prepared. The transport medium also can be used for HPV DNA testing.

PRIMARY HUMAN PAPILLOMAVIRUS TESTING

There is increasing evidence that HPV testing is effective for cervical cancer screening. A number of studies have demonstrated that HPV testing is more sensitive than Pap testing, with only a small loss in positive predictive value (PPV) (Dillner, 2008; Huh, 2015; Monsonego, 2015). Although the Pap test is still the most widely used screening test in developed countries, co-testing with HPV is now also recommended. Furthermore, primary HPV testing alone is gaining acceptance. In addition, the World Health Organization (WHO) recommends HPV testing as the

preferred screening method in countries where Pap testing is not feasible and HPV testing is available (WHO, 2015).

CERVICAL CANCER SCREENING GUIDELINES

The current guidelines in the United States recommend screening women for cervical cancer between the ages of 21 and 65 (Saslow, 2012). Cervical cancer screening should not be performed in women younger than 21 years of age, regardless of age of onset of sexual activity. The screening guidelines are as follows:

- 21 to 29 years: Pap testing every 3 years. No HPV testing.
- 30 to 65 years: Co-testing with Pap and HPV every 5 years (preferred) or Pap testing alone every 3 years.
- Screening is *not* recommended for women >65 years of age who have had three consecutive negative Pap tests or two consecutive negative HPV tests, provided they have had no history of high-grade dysplasia (CIN2/3) or cancer (CIN2+) in the past 20 years. However, women presenting at age 65 years of age or older who have not had previous screening should undergo Pap and HPV testing.
- Screening with Pap test or HPV testing is *not* recommended for women who have had a hysterectomy with removal of the cervix and who do not have a history of CIN2+.

Of note, these guidelines do not apply to those special populations with additional risk factors and other complicating history.

CERVICAL CYTOLOGY REPORTING: THE BETHESDA SYSTEM

In 1988, the National Cancer Institute convened a conference in Bethesda, Maryland, to develop a uniform terminology for the reporting of Pap test results, the Bethesda System (TBS) (Solomon, 2002). Almost all laboratories in the United States and many in countries throughout the world use this terminology. [Figure 28.4](#) shows how TBS, CIN, and dysplasia categories correspond to tissue changes.

The first part of a TBS report states whether the sample is satisfactory or unsatisfactory. A sample may be unsatisfactory if there is lack of a label, loss of transport medium, scant cellularity, and contamination by foreign material. Few samples are reported as unsatisfactory if a liquid-based technique is used. The report next indicates whether the cellular material is normal. If other than normal, the abnormalities are further divided into squamous and glandular. The cytologist may also comment on whether there is evidence of infection, such as yeast, or changes consistent with a diagnosis of bacterial vaginosis.

ATYPICAL SQUAMOUS CELLS

The most common squamous abnormality is atypical squamous cells (ASC) of undetermined significance (ASC-US). This finding indicates that a few cells may show features associated with

Figure 28.4 Diagram of cervical epithelium showing various terminologies used to characterize progressive degrees of cervical neoplasia. *CIN*, Cervical intraepithelial neoplasia; *HPV*, human papilloma-virus; *HSIL*, high-grade squamous intraepithelial lesion; *LSIL*, low-grade squamous intraepithelial lesion.

squamous intraepithelial lesions, but there are few of these cells present or the changes are not consistent with a more precise diagnosis. ASC-US changes are reported in approximately 3% to 5% of all Pap samples. The management of ASC-US and other Pap abnormalities is based on the recommendations of the American Society of Colposcopy and Cervical Pathology (ASCCP), with the most recent guidelines published in 2012 (Solomon, 2001; Massad, 2013). Patients with ASC-US Pap result can undergo repeat cytology at 12 months or reflex HPV testing. If HPV testing is positive, colposcopy is performed. If HPV testing is negative, return to routine screening is recommended.

The second ASC abnormality is ASC-H (atypical squamous cells, cannot exclude a higher-grade lesion). Approximately 5% to 10% of ASC cases are classified at ASC-H. Women with this diagnosis should be evaluated with colposcopy because there is a higher likelihood that a significant lesion, such as CIN 2/3, is present (Massad, 2013).

LOW-GRADE SQUAMOUS INTRAEPITHELIAL LESION

Low-grade squamous intraepithelial lesion (LSIL) is often found to be consistent with histology reports of low-grade dysplasia or cervical intraepithelial neoplasia 1 (CIN 1) (Fig. 28.5, A and B). LSIL may resolve spontaneously or progress to more severe dysplasia and should be managed according to the ASCCP guidelines (Massad, 2013). If HPV testing is negative, both Pap and HPV testing should be repeated in 1 year. If no HPV testing is performed or HPV testing is positive, the patient should undergo colposcopy.

HIGH-GRADE SQUAMOUS INTRAEPITHELIAL LESION

A diagnosis of high-grade squamous intraepithelial lesion (HSIL) indicates more severe dysplasia or CIN 2/3 (Figs. 28.6 and 28.7). If unmanaged, approximately 20% of patients with HSIL will progress to cervical cancer. All patients with HSIL should be evaluated with colposcopy, according to ASCCP guidelines, and the majority treated with excision or ablation, depending on age and colposcopy and biopsy results (Massad, 2013).

ATYPICAL GLANDULAR CELLS

Atypical glandular cells (AGC) are noted in approximately 3 out of every 1000 Pap tests, and the risk of underlying invasive cancer is 3% to 17% (Zweigtig 1997; ACOG, 2013). The atypical cells can sometimes be classified by the site of origin (e.g., endometrium, endocervix, ovary); however, this is not always possible. Per the ASCCP guidelines, it is recommended that all women with AGC undergo colposcopy with endocervical sampling (Massad, 2013). Endometrial sampling should also be performed in women who are older than 35 years or at risk for endometrial cancer (unexplained vaginal bleeding, obese, conditions suggesting chronic anovulation such as infertility or polycystic ovarian syndrome, or family history suggestive of Lynch syndrome/hereditary nonpolyposis colorectal cancer [HNPCC]).

COLPOSCOPY

Colposcopy is often the first step in evaluation of women with abnormal cytology. The colposcope is a low-power binocular

Figure 28.5 **A**, Cervical intraepithelial neoplasia 1 (mild dysplasia). Atypical cells are present in the lower one third of the epithelium (H&E stain, $\times 250$). **B**, Low-grade squamous intraepithelial lesion cytology. These cells show an altered nuclear-to-cytoplasmic ratio with enlargement and have granular chromatin (Pap stain, $\times 800$).

microscope with a powerful light source that is used to carefully examine the cervix. The instrument is placed just outside the vagina after a speculum has been inserted and the cervix brought into view. After any obscuring mucus is removed with a swab, the cervix is carefully examined for the presence of lesions. Dilute acetic acid (3% to 5%) is applied to the cervix, and after 30 to 60 seconds the cervix is again examined. Acetic acid dehydrates the epithelial cells and dysplastic cells with large nuclei will reflect light and appear white. An experienced colposcopist can distinguish those tissue patterns associated with cervical dysplasia from normal epithelium (Fig. 28.8).

For a thorough and complete exam, the entire transformation zone must be assessed (“satisfactory” colposcopy). If some portions of the transformation zone cannot be visualized as they extend into the endocervical canal or for other reasons, the colposcopy is considered “unsatisfactory” as the examiner is unable to determine the presence or extent of abnormal tissue. In the case of abnormal cytology and an unsatisfactory colposcopy, it is recommended that an endocervical curettage (ECC) be performed. Cervical biopsies should be performed of any acetowhite lesions

Figure 28.6 Cervical intraepithelial neoplasia 2 (moderate dysplasia). The atypical cells extend approximately halfway through to the epithelium (H&E, $\times 300$).

noted (Fig. 28.9). It is common for a small amount of bleeding to occur after biopsy, and this can be controlled with ferric sulfate (Monsel’s solution) or silver nitrate sticks. Cervical biopsy specimens are very small and the biopsy site usually heals within a few days (Fig. 28.10).

CERVICAL DYSPLASIA IN PREGNANCY

In pregnancy, the cervix becomes larger, the blood supply to the cervix is increased, and decidual changes in the epithelium can be confused with CIN. The ASCCP provides guidelines for the management of abnormal cytology in pregnancy (Massad, 2013). Colposcopy is safe in pregnancy. However, biopsies should only be performed if there is suspicion for invasive disease. It is highly unlikely for dysplasia to progress significantly during pregnancy, and in the majority of patients further evaluation can be postponed until 6 to 8 weeks after delivery. If invasive cancer is suspected, cervical biopsies are indicated and can be performed safely during pregnancy. However, ECC should never be performed during pregnancy. If CIN2/3 is diagnosed, further evaluation and treatment can be delayed until the postpartum period. If there is significant concern for a dysplastic lesion, a follow-up with colposcopy or repeat cytology is acceptable at intervals no more frequent than every 12 weeks. If invasive cancer is diagnosed, a conization procedure under anesthesia can be performed.

NATURAL HISTORY OF CERVICAL INTRAEPITHELIAL NEOPLASIA

Cervical intraepithelial neoplasia (CIN), the precancerous lesion of the squamous epithelium of the cervix, is a histologic (versus cytologic) diagnosis based on tissue examination of a cervical biopsy specimen. CIN is graded as 1, 2, or 3 depending on the how much of the epithelial layer contains atypical cells. CIN 1, or mild dysplasia, frequently spontaneously regresses, often within weeks to months. When cellular atypia involves two thirds of the thickness of the epithelium, it is designated as CIN 2. The process still remains reversible at this stage, with approximately 40% regressing spontaneously without treatment. When the cellular atypia involves more than two thirds of the epithelium, it

Figure 28.7 **A**, Cervical intraepithelial neoplasia 3 (severe dysplasia, carcinoma in situ). There is a lack of squamous maturation throughout the thickness of the epithelium. Almost all the cells have enlarged nuclei with granular chromatin. Note that the basement membrane is intact, showing that this process is confined to the epithelial layer only. **B**, High-grade squamous intraepithelial lesion. These cells exhibit large nuclei with granular chromatin. Very little cytoplasm can be seen (Pap stain, $\times 800$). **C**, Extensive cervical intraepithelial neoplasia 3 (CIN 3) lesion covering most of the epithelium visible in this image. The predominant feature is a mosaic pattern. There is umbilication of many of the tiles with a punctate vessel, a common feature of CIN 3. Although this large lesion must be examined carefully for evidence of atypical vessels, a hallmark of invasive cancer, none are seen in this view ($\times 8$). (**C**, From Kolstad P, Stafil A. *Atlas of Colposcopy*. Baltimore: University Park Press; 1972.)

is designated as CIN 3. This term encompasses what was once called severe dysplasia and carcinoma in situ. CIN 3 is a precursor to invasive cancer, and treatment is recommended. However, approximately one third of these lesions may spontaneously disappear.

Among women screened in the United States, the incidence of CIN 1 is approximately 4% and the incidence of CIN 2/3 is approximately 5%.

MANAGEMENT OF CERVICAL DYSPLASIA

The approach to treatment of CIN lesions since the 1970s has changed and continues to evolve. Many low-grade lesions disappear spontaneously, and treatment is indicated for lesions that have demonstrated a potential for further progression. The ASCCP provides regularly updated guidelines for the management of cervical dysplasia (Massad, 2013).

CERVICAL INTRAEPITHELIAL NEOPLASIA 1

In almost all cases, CIN 1 is a manifestation of a transient HPV infection, and the regression rates are high. Patients with CIN 1 require follow-up to ensure that the lesion regresses.

Cervical Intraepithelial Neoplasia 1 with Low-Grade Squamous Intraepithelial Lesion Cytology

Given the high rates of spontaneous regression, CIN 1 with LSIL cytology is usually managed with observation. These patients should undergo co-testing with cytology and HPV testing at 12 months or repeat cytology alone at 12 months in patients 21 to 24 years old. If CIN 1 persists for more than 2 years, a definitive excisional procedure can be considered.

Cervical Intraepithelial Neoplasia 1 with High-Grade Squamous Intraepithelial Lesion Cytology

If the diagnosis of CIN 1 is preceded by cytology showing HSIL or AGC, there is a higher chance of underlying CIN

Figure 28.8 Normal cervix as seen through a colposcope at approximately 6 \times magnification. The central grapelike structures are covered with columnar epithelium. The tissue outside this area represents squamous metaplasia. There are multiple gland openings in this area, indicating that columnar epithelium is being replaced by squamous epithelium. This area between the columnar and squamous epithelia is known as the *transformation zone*. (From Coppleson M, Pixley E, Reid B. *Colposcopy: A Scientific and Practical Approach to the Cervix in Health and Disease*. Springfield, IL: Charles C. Thomas; 1971.)

Figure 28.9 Cervical biopsy instruments: biopsy (top); endocervical curette (bottom).

2/3, and more aggressive management should be considered. In patients who have completed childbearing, an excisional procedure is recommended. In women who desire future fertility, close follow-up with cytology and colposcopy at 6 months is recommended. A small percentage of CIN 1 lesions progress to CIN 2 or 3, but it is not possible to determine which lesions have this potential, so continued follow-up is recommended.

Figure 28.10 Image ($\approx \times 12$) of a cervical biopsy site 72 hours after the procedure. The eschar is already beginning to separate from the cervix.

CERVICAL INTRAEPITHELIAL NEOPLASIA 2/3

It is difficult to distinguish CIN 2 from CIN 3 pathologically, so the two diagnoses are often grouped together as CIN 2/3 and managed similarly. Approximately 40% of CIN 2 lesions and 30% of CIN 3 lesions regress spontaneously (Castle 2009). However, 22% of CIN 2 will progress to CIN 3 and 5% will progress to cancer. Furthermore, 12% to 40% of CIN 3 will progress to cancer. Most women with CIN 2/3 should be treated with an ablative or excisional procedure. Young women and those desiring future fertility may be managed with careful observation, including cytology and colposcopy initially every 6 months with long-term follow-up depending on findings. Pregnant women with CIN 2/3 and no evidence of invasion may be observed during the pregnancy, with evaluation delayed until 6 weeks postpartum. Women with a history of CIN 2/3 are more likely to develop another lesion in the future. Therefore long-term follow-up for at least 20 years is recommended, even if this extends screening past age 65 (Massad, 2013).

TREATMENT OF CERVICAL DYSPLASIA

Treatment of CIN can be accomplished by ablation or excision, with these methods having first-treatment success rates of greater than 90% in properly selected patients. (Östör, 1993; Soutter, 1997; Mitchell, 1998; Martin-Hirsch, 2013; Massad, 2013). Ablative methods include cryotherapy and CO₂ laser ablation. Excisional procedures include the loop electrosurgical excision procedure (LEEP), cold knife conization (CKC), and CO₂ laser conization. The choice of treatment modality depends on the availability of equipment and the experience and expertise of the clinician. Hysterectomy is not recommended as the initial treatment of cervical dysplasia, as it is usually unnecessary for the treatment of CIN. Furthermore, if high-grade dysplasia is present, conization must first be performed to rule out underlying invasive cancer that may require more advanced procedures such as radical hysterectomy, radical trachelectomy, and lymph node dissection.

Ablative Methods

Ablative procedures treat CIN but do not provide further diagnostic information. To qualify for ablative therapy, there should be no suspicion of glandular involvement or invasive cancer. Specific criteria for ablative therapies include the following:

- Satisfactory colposcopy with visualization of entire cervical squamocolumnar junction
- Biopsy confirming presence of CIN; abnormal cytology alone is not sufficient
- Lesion does not involve the endocervical canal and negative endocervical curettage (if available)

Cryotherapy

Cryotherapy is a commonly used treatment for CIN lesions that is safe, effective, and relatively simple to perform. However, it does not provide a specimen for pathology review and in many high-resource settings has been replaced by LEEP. Contraindications to cryotherapy include large lesions (those covering >75% of the cervix or those that cannot be covered by the cryoprobe) and lesions that extend into the endocervical canal. In addition, if the patient had an endocervical curettage performed and it shows evidence of dysplasia, cryotherapy is contraindicated.

The procedure includes performing colposcopy to confirm that the lesion is confined to the exocervix. A probe is selected that will cover the entire lesion. In most systems, N₂O is used as the refrigerant. The cervix will freeze quickly, but the probe must remain in place until the ice ball extends to at least 5 mm beyond the edge of the instrument. In most cases, this takes 3 minutes. The refrigerant is then turned off, and the probe is allowed to thaw and separate from the cervix. It is recommended that a 3-5-3 double freeze-thaw cycle is performed with 3 minutes of freezing, followed by 5 minutes of thawing and another 3 minutes of freezing. Most patients experience little discomfort during the procedure. Because the tissue that was destroyed remains on the cervix, the patient will experience vaginal discharge within a few hours. As the tissue sloughs, the amount of discharge increases and malodor is common. It may take as long as 3 weeks for the discharge to stop. The patient should be cautioned to place nothing in the vagina for at least 3 weeks after the procedure to avoid dislodgment of the eschar.

CO₂ Laser Ablation

This technique became available in the 1980s but has largely been replaced by LEEP in the United States. A focused CO₂ laser beam is directed at the cervical epithelium, where water in the tissue absorbs the laser energy and the tissue is destroyed by vaporization. The lesion is typically ablated to a depth of 5 mm. Several safety procedures must be followed, including the use of protective eyewear by all personnel in the procedure room, the use of a blackened or brushed speculum to avoid damage to surrounding tissues by misdirected laser beams, and using wet towels and cloth drapes to prevent fire. Because little devitalized tissue is left after the procedure, there is no prolonged vaginal discharge as there is with cryotherapy. The success rate is similar to that for cryotherapy and excisional procedures. The advantages of this technique are that the area of tissue destruction can be minimized and there is no prolonged vaginal discharge as there is with cryotherapy. Similar to cryotherapy, there is no specimen for pathologic evaluation. Treatment success depends on the correct choice of laser energy delivered and proper depth and extent of treatment.

Excisional Methods

Excisional procedures have the advantage over ablative procedures of providing a pathologic specimen for further diagnostic information. The specific indications for an excisional procedure over an ablative procedure include the following:

- Suspected microinvasion
- Adenocarcinoma in situ or other glandular abnormalities
- Unsatisfactory colposcopy in which the transformation zone is not fully visualized
- Lack of correlation between cytology and colposcopy/biopsies
- Unable to rule out invasive disease
- Lesion extending into the endocervical canal
- Endocervical curettage showing CIN or a glandular abnormality
- Recurrence after an ablative or previous excisional procedure

Loop Electrosurgical Excision

The loop electrosurgical excision procedure (LEEP), also called *large loop excision of the transformation zone (LLETZ)*, is currently the most common method for the treatment of CIN 2/3 in the United States. It involves the removal of the transformation zone of the cervix under local anesthesia and can be performed safely in the office. The cervix is infiltrated with an anesthetic/vasoconstrictor solution, and a cone-shaped piece of the cervix inclusive of the transformation zone is removed (Martin-Hirsch, 2013). The LEEP procedure utilizes a thin wire in the shape of a loop and an electrosurgical generator, providing a cutting current to remove the tissue. The loops are available in a variety of shapes and sizes, allowing selection of a loop best fit to the patient's lesion (Fig. 28.11). Bleeding areas can be cauterized with a ball electrode attached to the current generator set to cautery.

The removed tissue is examined histologically for diagnosis and evaluation of margin status. Management guidelines for positive margins are provided by the ASCCP and include reexcision versus follow-up cytology and endocervical sampling, depending on pathology results, patient age, and the desire for future fertility.²⁵ Hysterectomy is rarely indicated for the treatment of CIN, unless a repeat diagnostic procedure is recommended but not feasible due to minimal remaining cervix.

Cold Knife Conization

Cold knife conization (CKC) is an excisional procedure similar to a LEEP but is performed with a scalpel under anesthesia in the operating room. For the evaluation of squamous lesions, CKC offers little advantage over LEEP. However, CKC is advantageous in patients with glandular abnormalities or suspicion of invasive cancer, as CKC uses a scalpel and avoids the thermal artifact sometimes seen at the margins of specimens obtained by LEEP. Once the specimen is removed, bleeding can be controlled with cauterization and the application of ferrous subsulfate (Monsel's solution). Sutures to control bleeding are rarely necessary.

FOLLOW-UP AFTER TREATMENT OF CERVICAL DYSPLASIA

The rate of recurrent or persistent disease following excisional or ablative treatment for CIN 2/3 is 5% to 17%, with no significant differences in outcomes between the different treatment

Figure 28.11 Electrodes (Utah Medical) used for a loop electroexcision procedure. The width of the excised tissue specimens can range from 1 to 2 cm, and the specimen depth can be adjusted by sliding the guard attached to the electrode shaft. Following excision, the base of the cervix is often gently cauterized with a ball electrode. (Courtesy of Dr. Steven E. Waggoner, University of Chicago, Chicago, IL.)

modalities. Factors associated with recurrent/persistent disease include the following:

- Large lesion size
- Endocervical gland involvement
- Positive margins

The current ASCCP recommendations for surveillance following excision of CIN 2/3 with negative margins consist of co-testing with cervical cytology and HPV at 12 and 24 months. If both co-tests are negative, the woman can return to routine screening (Massad, 2013). If any test is abnormal, colposcopy with endocervical sampling is recommended.

CERVICAL CANCER PREVENTION IN LOW- AND MIDDLE-INCOME COUNTRIES

Although the screening and diagnosis algorithms described earlier are effective, they are expensive and require high-level infrastructure and well-trained personnel. In addition, they require three separate patient visits with communication of test results between visits. There is therefore a significant need for alternative solutions, particularly in low-resource settings in the United States and in low- and middle-income countries (LMICs) where there is often a lack of trained personnel, infrastructure, and pathology services.

One commonly used approach in low-resource settings is visual inspection with acetic acid (VIA), in which acetic acid is applied to the cervix and, if there is whitening of the epithelium indicating a precancerous lesion, immediate treatment with cryotherapy is performed (See & Treat). VIA and cryotherapy can be performed by nonphysicians, such as community health workers. Such a program using VIA has been shown to decrease cervical cancer mortality by more than 30% in unscreened communities in India (Shastri, 2014). Several additional low-cost innovative screening options are also under development for LMICs.

VAGINAL INTRAEPITHELIAL NEOPLASIA

Vaginal intraepithelial neoplasia (VaIN) is similar to CIN and is defined as squamous atypia without invasion. The true incidence of vaginal intraepithelial neoplasia (VaIN) is unknown but is estimated to be approximately 0.2/100,000 in the United States. It is most commonly diagnosed in women between 43 to 60 years of age. Classification is similar to CIN and reflects the depth of involvement of the epithelial layer (VaIN 1, 2, and 3). Risk factors for VaIN include current or previous neoplasia elsewhere in lower genital tract (cervix, vulva) and persistent HPV infection. Previous studies have shown 50% to 90% of patients with VaIN had prior or concurrent intraepithelial neoplasia or carcinoma of the cervix or vulva (Aho, 1991; Sillman, 1997; Cheng, 1999). Most cases of VaIN are discovered incidentally during colposcopy due to abnormal cytology. Presenting symptoms of postcoital discharge or spotting are rare. Suspicious lesions should be biopsied to confirm the diagnosis. The upper third of the vagina is the most common site of VaIN (Boonlikit, 2010).

Patients with VaIN 1 are followed with surveillance similar to patients with CIN 1 due to the low risk of progression to invasive cancer. However, it is recommended that patients with VaIN 2 or VaIN 3 undergo treatment, as the risk of progression to vaginal cancer is estimated to be 2% to 5%. Treatment options include excision, ablation, and topical therapy with 5-fluorouracil or imiquimod (Audet-Lapointe, 1990; Cardosi, 2001). There is a high recurrence rate of 20% to 30% regardless of the treatment modality used, and these patients should be carefully followed long term. There are no standard guidelines for the follow-up of patients with VaIN 2/3, but it is reasonable to perform cytology and colposcopy every 6 to 12 months for 2 years (Zeligis 2013). The role of HPV testing in patients with VaIN is still unknown.

VULVAR INTRAEPITHELIAL NEOPLASIA

Vulvar intraepithelial neoplasia (VIN) is defined as squamous atypia of the vulva (Fig. 28.12). The incidence of VIN 3 is approximately 2.86 per 100,000 women in the United States (Judson, 2006). VIN is classified as (1) VIN, usual type, or (2) VIN, differentiated type (Sideri, 2005; ACOG, 2011). VIN, usual type, is the most common form of VIN and is an HPV-associated condition. It occurs in younger women, may be multifocal, and is associated with cervical and vaginal dysplasia. VIN, differentiated type, is less common and unrelated to HPV infection, but it is associated with chronic inflammatory conditions such as lichen sclerosus and lichen planus. Symptoms of VIN include pruritus, pain, and burning; however, many patients

Figure 28.12 Vulvar intraepithelial neoplasia (VIN) 3 lesion as seen through a colposcope after the application of acetic acid. A second lesion is out of focus but can be seen in the background. VIN is often multifocal.

are asymptomatic and VIN is incidentally discovered during a thorough pelvic exam. Punch biopsies should be performed of any lesions noted on the vulva, particularly those that persist or are not responsive to therapy for other conditions. Furthermore, colposcopy of the vulva (vulvoscopy) with biopsies of any lesions should be performed in all patients with CIN or VaIN due to the association with these other HPV-related conditions.

VIN 1 is a benign entity, and treatment for asymptomatic disease is not necessary. However, patients with VIN 2/3 should undergo treatment due to the risks of underlying cancer and progression of disease. Treatment modalities include excision, ablation, and topical therapies (Jones, 2005; ACOG, 2011). All modalities have similar effectiveness (Wallbillich 2012). The modality used depends on the risk of invasive disease, location of the lesion, and the extent of disease and symptoms. If underlying invasive disease is suspected, patients with VIN 2/3 should undergo wide local excision. Other options for diffuse disease include CO₂ laser ablation and topical therapies. The most commonly used topical therapy is imiquimod, a topical immune response modifier that is applied to vulvar lesions three times per week for 16 weeks. Small studies have shown imiquimod to be very effective with a complete response rate of 51%, a partial response rate of 25% and a recurrence rate of 16% (van Seters, 2008; Mahto, 2010). Similar to VaIN, VIN recurrence rates are high. There are no standard guidelines for the follow-up of patients with VIN 2/3, but it is reasonable to perform vulvoscopy every 6 to 12 months for 2 years. The role of HPV testing in patients with VIN is unknown.

KEY POINTS

- HPV infection is the cause of virtually all cases of cervical cancer.
- Almost all HPV infections regress spontaneously, but if the infection persists, dysplasia and cancer may develop.

- Smoking increases the likelihood that an HPV infection will persist or progress.
- Vaccines are available that prevent HPV infection and the development of dysplasia and cancer.
- When Pap testing is used widely, it decreases the incidence of cervical cancer by approximately 70%.
- The Bethesda System (TBS) terminology is used for the reporting of cervical cytology specimens.
- The colposcope is used to evaluate women with abnormal Pap tests.
- In some cases, an HPV infection can lead to a pre-cancer of the cervix, called CIN. CIN is graded as 1, 2, or 3, depending on the depth of the epithelial thickness involved.
- CIN 1 should be observed rather than treated because it usually regresses spontaneously.
- CIN 2/3 can be treated by ablation with cryotherapy or excision with LEEP or cold knife conization.

Malignant Diseases of the Cervix Microinvasive and Invasive Carcinoma: Diagnosis and Management

Anuja Jhingran, Larissa A. Meyer

The majority of cervical malignancies are carcinomas; a summary of the more common histologic types is shown in [Box 29.1](#). Approximately 80% to 85% of these tumors are squamous cell carcinomas, and 15% to 20% are adenocarcinomas. The incidence of adenocarcinomas has increased in most developing countries, particularly among younger women. Carcinoma of the cervix is closely associated with early and frequent sexual contact and cervical viral infection, particularly human papillomavirus (HPV) as detailed in [Chapter 28](#). According to the American Cancer Society, the frequency of cervical cancer has been steadily decreasing, in part because of the effect of widespread screening for premalignant cervical changes by cervical cytology (Pap smear). In the United States, there will be an estimated 12,900 new cases of invasive cervical cancer diagnosed in 2015 with 4100 related deaths ([Siegel, 2015](#)). The incidence of cervical carcinoma in the United States is higher among the Hispanic population (10.5%) compared with whites (7.1%) and African Americans (10.2%) ([Siegel, 2015](#)). However, the mortality rate from cervical cancer is the highest among African Americans compared with other races, partly because African Americans tend to be diagnosed at a later stage. Invasive cervical cancers are diagnosed at a localized stage in 51% of white women and 43% of African American women. This chapter details the various types of cervical carcinoma and considers the natural history, methods of diagnosis and evaluation, and details of therapy. Primary sarcomas and melanomas of the cervix are extremely rare and are not considered separately ([Fig. 29.1](#)).

HISTOLOGIC TYPES

Varieties of squamous cell carcinoma of the cervix are illustrated in [Figure 29.2](#). An early form, microinvasive carcinoma, is considered separately in the next section. Most squamous cell carcinomas of the cervix are reported to be of the large cell, nonkeratinizing type, but some are keratinized, and squamous pearls may be seen. The degree of differentiation of the tumors is usually designated by three grades: G1, well differentiated; G2, intermediate; and G3, undifferentiated. However, there is

no consensus on the value of tumor grade as a major prognostic factor for squamous cell carcinoma of the cervix.

A rare variety of squamous cell carcinoma is the so-called verrucous carcinoma, which is morphologically similar to that found in the vulva (see [Chapter 30](#)). These warty tumors appear as large bulbous masses ([Fig. 29.3](#)). They rarely metastasize but unfortunately may be admixed with the more virulent, typical squamous cell carcinomas, in which case metastatic spread is more likely.

Adenocarcinomas may have a number of histologic varieties. The typical variant often contains intracytoplasmic mucin and is related to the mucinous cells of the endocervix (endocervical pattern; [Fig. 29.4](#)). However, on occasion, the cells contain little or no mucin, and then the tumor may resemble an endometrial carcinoma (endometrioid pattern). It may be difficult histologically to ascertain whether these carcinomas arise in the cervix or endometrium. Although not independently diagnostic, the immunohistochemical panel that is recommended to assist in differentiating endocervical from endometrial primary malignancies includes estrogen receptor (ER), vimentin, monoclonal carcinoembryonic antigen (CEA), and p16. Typically, an

Box 29.1 Summary of Major Categories of Cervical Carcinoma

Squamous Cell Carcinomas

Large cell (keratinizing or nonkeratinizing)
Small cell
Verrucous

Adenocarcinomas

Typical (endocervical)
Endometrioid
Clear cell
Adenoid cystic (basaloid cylindroma)
Adenoma malignum (minimal deviation adenocarcinoma)

Mixed Carcinomas

Adenosquamous
Glassy cell carcinoma

Figure 29.1 Incidence rates of invasive carcinoma. (From Ries ALG, Miller BA, Hankey BF, et al. *SEER Cancer Statistics Review, 1973-1991* [NIH Publ. No. 94-2789]. Bethesda, MD: National Institutes of Health; 1994:136-144.)

endocervical carcinoma will stain diffusely positive for p16 and CEA and will be negative for ER and vimentin.

A rare but important virulent variety of adenocarcinoma is adenoma malignum. These microscopically innocuous-appearing tumors consist of well-differentiated mucinous glands (Fig. 29.5) that vary in size and shape and infiltrate the stroma. Despite their bland histologic appearance, they tend to be deeply invasive and metastasize early. The term *minimal deviation adenocarcinoma* is applied to these tumors.

Clear cell adenocarcinomas of the cervix are histologically identical to those of the ovary (see Chapter 33) and vagina (see Chapter 31). They are uncommon in the cervix and can be associated with intrauterine diethylstilbestrol exposure, although they also may develop spontaneously in the absence of diethylstilbestrol exposure.

Adenoid cystic carcinomas are rare. Berchuk and Mullin have summarized 88 cases reported in the literature (Berchuk, 1985). These tumors are aggressive and may resemble cylindromas of salivary gland or breast origin and histologically may resemble

Figure 29.2 **A**, Large-cell, nonkeratinizing squamous cell carcinoma. Discrete islands of uniform, large cells with abundant cytoplasm are separated by fibrous stroma ($\times 160$). **B**, Keratinizing squamous cell carcinoma. Irregular nests of squamous cells forming several pearls are separated by fibrous stroma. The nests have pointed projections ($\times 160$). **C**, Small cell neuroendocrine carcinoma of the cervix (arrow) infiltrating between normal endocervical glands (H&E, $\times 240$). (**A** and **B**, From Clement PB, Scully RE. Carcinoma of the cervix: histologic types. *Semin Oncol.* 1982;9:251-264; **C**, Courtesy of Dr. Anthony Montag, Department of Pathology, University of Chicago, Chicago.)

Figure 29.3 Verrucous carcinoma. Downgrowths of papillae have broad bases. Tumor cells are well differentiated ($\times 34$). (From Clement PB, Scully RE. Carcinoma of the cervix: histologic types. *Semin Oncol.* 1982;9:251-264.)

Figure 29.5 Adenoma malignum. Glands are mostly well differentiated, appearing normal except for their irregular shapes. A few obviously malignant glands are also present ($\times 160$). (From Clement PB, Scully RE. Carcinoma of the cervix: histologic types. *Semin Oncol.* 1982;9:251-264.)

Figure 29.4 Typical adenocarcinoma. Irregular glands are lined by stratified mucin-containing epithelium. Mitotic figures are numerous ($\times 160$). (From Clement PB, Scully RE. Carcinoma of the cervix: histologic types. *Semin Oncol.* 1982;9:251-264.)

Figure 29.6 Well-differentiated adenosquamous carcinoma. Glandular structure lies adjacent to a nest of nonkeratinizing large squamous cells ($\times 400$). (From Clement PB, Scully RE. Carcinoma of the cervix: histologic types. *Semin Oncol.* 1982;9:251-264.)

basal cell carcinomas of the skin (adenoid basal, or basaloid, carcinomas). Most patients with these tumors are older than 60 years. The basaloid variety appears to be less aggressive.

Adenosquamous carcinomas, as the name implies, consist of squamous carcinoma and adenocarcinoma elements in varying proportions (Fig. 29.6). They occur frequently in pregnant women. A particularly virulent variety is termed *glassy cell carcinoma* (Fig. 29.7). This is an undifferentiated tumor consisting of large cells containing cytoplasm, with a ground-glass appearance. Glassy cell carcinomas tend to metastasize early to lymph nodes as well as to distant sites and usually have a fatal outcome.

Small cell carcinoma of the cervix is rare, comprising less than 5% of all carcinomas of the cervix. Women with small cell carcinoma

are likely to be 10 years younger than those with squamous cell carcinoma. The cells are small anaplastic cells with scant cytoplasm. They behave aggressively and are frequently associated with widespread metastasis to multiple sites, including bone, liver, skin, and brain. Efforts to treat these cancers with approaches typically used for small cell carcinoma of the lung have had mixed results.

Another variant that is not in the World Health Organization (WHO) classification is non-small cell neuroendocrine tumors. These tumors contain intermediate to large cells, high-grade nuclei, and eosinophilic cytoplasmic granules of the type seen in neuroendocrine cells. Reported survival rates for patients with these aggressive carcinomas are similar to those of patients with small cell tumors, and optimal therapy has yet to be established.

Figure 29.7 Glassy cell carcinoma. Cells have sharp borders, ground-glass-type cytoplasm, and nuclei containing prominent nucleoli ($\times 1000$). (From Clement PB, Scully RE. Carcinoma of the cervix: histologic types. *Semin Oncol.* 1982;9:251-264.)

CARCINOMA OF THE CERVIX

CLINICAL CONSIDERATIONS

Patients with carcinoma of the cervix characteristically present with abnormal bleeding or brownish discharge, frequently noted following douching or intercourse and also occurring spontaneously between menstrual periods. These patients often have a history of not having had a cytologic (Pap) smear for many years. Other symptoms, such as back pain, loss of appetite, and weight loss, are late manifestations and occur when there is extensive spread of cervical carcinoma. The patients tend to be in their 40s to 60s, with a median age of 52 years. Preinvasive intraepithelial carcinoma of the cervix (see [Chapter 28](#)) occurs primarily in women in their 20s and 30s and has become more common in those in their 20s, leading to a gradual increase in the incidence of invasive carcinoma in younger patients.

The diagnosis is established by biopsy of the tumor; a specimen can easily be obtained during an office examination. A Kevorkian, Eppendorf, Tischler, or similar punch biopsy instrument is convenient to use. Occasionally, it is necessary to biopsy nodularity or indurations in the vagina near the cervix to ascertain the limit of tumor spread and define a correct tumor stage. If the woman's cytologic smear suggests invasive carcinoma, with no gross lesion visible, and endocervical curettage does not demonstrate carcinoma, or if an adequate biopsy specimen to establish carcinoma cannot be obtained, cervical conization should be performed.

STAGING

The staging of carcinoma of the cervix depends primarily on the pelvic examination; the designation may be modified by general physical examination, chest radiographic examination, intravenous pyelography (IVP), or computed tomography (CT) and is not changed based on operative findings. [Table 29.1](#) describes the four stages of cervical carcinoma according to the International Federation of Gynecology and Obstetrics (FIGO; revised in 2009) ([Pecorelli, 2009](#)). The types of tumor distribution that may be observed in the various stages are illustrated in [Figure 29.10](#).

Table 29.1 Clinical Stages of Carcinoma of the Cervix Uteri

Stage	Characteristics
I	Carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)
IA	Invasive cancer that can be diagnosed only by microscopy, with deepest invasion ≤ 5 mm and largest extension ≥ 7 mm (Fig. 29.8)
IA1	Measured stromal invasion ≤ 3 mm in depth and extension of ≤ 7 mm (Fig. 29.9)
IA2	Measured stromal invasion of >3 mm and not >5 mm, with an extension of not >7 mm
IB	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than IA*
IB1	Clinically visible lesion ≤ 4 cm in greatest dimension
IB2	Clinically visible lesion >4 cm in greatest dimension
II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or lower third of vagina
IIA	No obvious parametrial involvement
IIA1	Clinically visible lesion ≤ 4 cm in greatest dimension
IIA2	Clinically visible lesion >4 cm in greatest dimension
IIB	Obvious parametrial involvement
III	The tumor extends to the pelvic wall or involves lower third of the vagina or causes hydronephrosis or nonfunctioning kidney†
IIIA	Tumor involves lower third of the vagina, with no extension to the pelvic wall
IIIB	Extension to the pelvic wall or hydronephrosis or a nonfunctioning kidney
IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy-proven) mucosa of the bladder or rectum; a bullous edema, as such, does not permit a case to be allotted to stage IV
IVA	Spread of growth to adjacent pelvic organs
IVB	Spread to distant organs

Modified from Pecorelli S. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynaecol Obstet.* 2009;105:103.

All cases with hydronephrosis or a nonfunctioning kidney are included, unless they are known to be from another cause.

*All macroscopically visible lesions, even with superficial invasion, are allotted to stage IB carcinomas. Invasion is limited to a measured stromal invasion, with a maximum depth of 5 mm and a horizontal extension of not >7 mm. Depth of invasion should not be >5 mm taken from the base of the epithelium of the original tissue, superficial or glandular. The depth of invasion should always be reported in millimeters, even in those cases with early (minimal) stromal invasion (minus 1 mm). The involvement of vascular or lymphatic spaces should not change the stage allotment.

†On rectal examination, there is no cancer-free space between the tumor and the pelvic wall.

NATURAL HISTORY AND SPREAD

Carcinoma of the cervix is initially a locally infiltrating cancer that spreads from the cervix to the vagina and paracervical and parametrial areas. Grossly, the tumors may be ulcerated ([Fig. 29.11](#)), similar to carcinomas occurring elsewhere in the female genital tract, and may have an exophytic growth pattern or cauliflower-like appearance extruding from the cervix. Alternatively, they may be endophytic, in which case they are asymptomatic, particularly in the early stage of development, and tend to be deeply invasive when diagnosed. These usually start initially from an endocervical location and often fill the cervix and lower uterine segment, resulting in a barrel-shaped cervix. The latter tumors tend to metastasize to regional pelvic nodes and, because of the tendency of late diagnosis, are often more advanced than the exophytic variety. The primary

Figure 29.8 A, Tumor with only 0.5 mm of invasion ($\times 40$). B, Example of so-called *spray pattern* with multiple invasive nodules in stroma. Invasion is only 1 mm ($\times 50$). (From Creasman WT, Fetter BF, Clarke-Pearson DL, et al. Management of stage IA carcinoma of the cervix. *Am J Obstet Gynecol*. 1985;153:164-172.)

path for distant spread is through lymphatics to the regional pelvic nodes. Bloodborne metastases from cervical carcinomas do occur but are less frequent and are usually seen late in the course of the disease.

Initially, cervical carcinoma spreads to the primary pelvic nodes, which include the pericervical node; presacral, hypogastric (internal iliac), and external iliac nodes; and nodes in the obturator fossa near the vessels and nerve. From this primary

group, tumor spread proceeds secondarily to the common iliac and paraaortic nodes. Rarely, the inguinal nodes are involved; however, if the lower third of the vagina is involved, the median inguinal nodes should be considered a primary node. The distribution of lymph node involvement in 26 cases of untreated carcinoma of the cervix was studied in detail by Henriksen (Fig. 29.12) (Henriksen, 1949). A series studying the incidence and distribution pattern of retroperitoneal lymph node metastases in 208 patients with stages IB, IIA, and IIB cervical carcinomas who underwent radical hysterectomy and systemic pelvic node dissection reported that 53 patients (25%) had node metastasis. The obturator lymph nodes were the most frequently involved, with a rate of 19% (39 of 208), and the authors proposed them as sentinel nodes for cervical cancers. An important distal node that becomes involved after the paraaortic group is the left scalene node—that is, the left supraclavicular node. A biopsy of this node may be performed in the assessment of advanced cervical carcinoma to clarify whether the tumor has spread outside the abdomen. In addition to nodal spread, hematogenous spread of cervical carcinoma occurs primarily to the lung, liver and, less frequently, bone (see [Recurrence](#) later in the chapter).

PROGNOSTIC FACTORS

FIGO stage is the most important determinant of prognosis for carcinoma of the cervix (Table 29.2); however, there are other factors, including tumor and patient characteristics that are prognostic and are not included in the FIGO staging system. One of the most important predictors is tumor size for local recurrence and death for patients treated with surgery or radiation therapy (Eifel, 1994). The FIGO staging classification for stage I disease has been modified to include tumor diameter (i.e., ≤ 4 cm, stage IB1; >4 cm, stage IB2). Another important prognostic factor is involvement of lymph nodes, which also is not part of the clinical staging system. In several surgical series, after a radical hysterectomy, patients with positive pelvic lymph nodes had a 35% to 40% lower 5-year survival rate than patients with negative nodes. Patients with positive paraaortic nodes have a survival rate that is approximately 50% that of patients

with similar stage disease and negative paraaortic nodes. With extended-field radiation therapy, patients with positive paraaortic nodes have approximately a 40% to 50% 5-year survival rate. There is a strong correlation between positive nodes and positive lymph–vascular space invasion (LVSI) in the tumor specimen in patients with cervical carcinoma. However, LVSI may be an independent predictor of prognosis as shown in a number of larger surgical series.

In patients who have had a radical hysterectomy, histologic evidence of extracervical spread (≥ 10 mm), deep stromal invasion ($>70\%$ invasion), and LVSI are associated with a poorer prognosis. A randomized trial from the Gynecologic Oncology Group (GOG) compared observation versus adjuvant radiation therapy in patients after radical hysterectomy with a combination of two of the factors mentioned earlier; patients who received radiation therapy had better local control as well as improved overall survival (Sedlis, 1999). Involvement of the parametrium in the hysterectomy specimen has been correlated with higher rates of lymph node involvement, local recurrence, and death from cancer. Uterine body involvement is associated with an increased rate of distant metastases in patients treated with radiation or surgery.

Patients with adenocarcinomas of the cervix have a poorer prognosis than patients with squamous cell carcinomas of the cervix. Investigators have found that among patients treated surgically, patients with adenocarcinomas have high relapse rates compared with rates in patients with squamous cell carcinomas. In an analysis of 1767 patients treated with radiation for FIGO stage IB disease, Eifel and associates found that independent of age, tumor size, and tumor morphology, patients with adenocarcinomas had the same pelvic control rate but twice as high a rate of distant metastasis as patients with squamous cell carcinomas of the cervix (Eifel, 1994). Although the prognostic significance of histologic grade for squamous carcinomas has been disputed, there is a clear correlation between the degree of differentiation and the clinical behavior of adenocarcinomas.

There has been a great interest in molecular markers regarding prognosis and treatment in carcinoma of the cervix. One of the most studied markers is the serum squamous cell carcinoma antigen. Studies have shown that pretreatment levels of this antigen correlate well with stage of disease, tumor histology, grade, type of tumor (exophytic vs. infiltrative), microscopic depth of invasion, and risk of lymph node metastases in patients with early stage disease. Possible clinical applications of this antigen may be to predict clinical outcome as well as a marker for monitoring the course of disease and response to treatment in patients with cervical cancer. Several investigators have reported significantly lower survival rates in patients with elevated values compared with patients with normal baseline levels, independent of stage. For detection of tumor recurrence, serial squamous cell carcinoma antigen testing has proved to be more specific than sensitive, with specificities ranging from 90% to 100% and sensitivities ranging from 60% to 90%. Further investigation is needed in these areas. Some investigators have found a higher rate of recurrence in patients with HPV-positive nodes (although negative for malignancies) and poor prognosis with the presence of HPV mRNA in the peripheral blood of cervical cancer patients. Other markers that have been investigated include epidermal growth factor receptor, cyclooxygenase-2, DNA-ploidy, tumor vascularity, and S-phase fraction.

TREATMENT

Pretherapy Evaluation

Once a woman has been diagnosed as having an invasive carcinoma, a pretreatment evaluation is conducted to determine the extent of disease, arrive at an accurate clinical staging, and plan the program of therapy. The usual evaluation consists of

a thorough history and physical examination, routine blood studies, IVP or CT, and chest radiography. Demonstration of an obstructed ureter or nonfunctioning kidney caused by tumor automatically assigns the case at least to stage III (see Table 29.1). A barium enema test or flexible sigmoidoscopy, as well as a cystoscopy, is sometimes performed in the case of large tumors or for patients who will be receiving radiation treatment.

The best radiographic imaging technique for detecting lymph node metastases is unclear. CT and magnetic resonance imaging (MRI) are good for identifying enlarged nodes; however, the accuracy of these techniques in the detection of positive nodes is compromised by their failure to detect small metastases, and many enlarged nodes are caused not by metastases but by inflammation associated with advanced disease. The accuracy of MRI in the detection of lymph node metastases (72% to 93%) is similar to that of CT but better than CT and physical examination for the evaluation of tumor location, tumor size, depth of stromal invasion, vaginal extension, and parametrial extension of cervical cancer. However, with regard to detecting lymph node metastases or other distant disease, positron emission tomography (PET) shows promise. Several studies from a single institution have shown that ^{18}F -fluorodeoxyglucose PET (FDG-PET) detects abnormal lymph nodes more often than CT, and those findings with PET are a better predictor of survival than those with CT or MRI in patients with carcinoma of the cervix. Medicare has approved PET/CT as part of the initial staging evaluation for patients with cervical carcinoma, and most insurance companies approve PET/CT for a 3-month follow-up.

Surgical sampling of lymph nodes is the most sensitive method of evaluating whether regional lymph nodes contain metastases; however, it is invasive, expensive, and delays treatment to the primary lesions. Laparoscopic lymph node dissection may decrease the time between surgery and the start of treatment and may be associated with less late radiation-related morbidity than open transperitoneal staging. Laparoscopic extraperitoneal paraaortic lymphadenectomy has also been described and may further decrease radiation-related bowel morbidity by avoiding entrance into the peritoneal cavity. In a study by Ramirez and colleagues, 22% of patients who had positive pelvic but negative paraaortic nodes on PET/CT had histopathologically positive paraaortic nodes (Ramirez, 2011).

Treatment for Stage I

Stage IA

The term *microinvasion* has been used for years to describe patients with minimally invasive cervical cancer, but this term is not part of the FIGO staging system. Microinvasion was used to describe patients with 3-mm invasion or less and essentially no risk of metastatic spread. Several investigators went a step further to measure not only the depth of invasion but also tumor volume by measuring lateral spread. Volumetric measurements are generally more difficult and have not been embraced by pathologists (at least not in North America). Nevertheless, volumetric measurements are used in the FIGO staging scheme. There is ample evidence that patients with small-volume tumors measured only by depth of invasion or by two-dimensional measurement have a low risk of relapse and death with radical surgery or more conservative surgical approaches.

The diagnosis of microinvasive tumor cannot be made based on a biopsy specimen alone; a cervical conization must be

performed. If the margin of the cervical cone specimen contains neoplastic epithelium, the risk of invasive tumor in the remaining uterus is increased. Decisions on treatment should be based on an adequate cone biopsy specimen. If a woman has positive margins, the cone can be repeated. Sometimes, deeper invasion will be uncovered and more radical treatment will be required. In some patients, conization alone is adequate.

Stage IA1 tumors measured stromal invasion is 3 mm or less, with lateral extension of 7 mm or less. These measurements are determined on a cone biopsy, which also determines other prognostic factors (e.g., lymph vascular space involvement, histologic subtype, grade). These factors do not alter the stage assignment, in spite of their adverse prognostic significance. In the absence of LVSI or high-risk histologic subtypes, the risk of lymph node metastases is remote and nonradical surgery is adequate. This may include cone biopsy, simple trachelectomy, or simple hysterectomy, depending on the circumstances and patient preference.

Patients with stage IA2 tumors have a measured stromal invasion of 5 mm or less. Patients in this category, even without LVSI, are at a low risk of nodal involvement. Thus radical or modified radical approaches are usually recommended, which include modified radical hysterectomy or trachelectomy and pelvic lymph adenectomy. Stage IA1 patients who have LVSI are treated in the same manner as stage IA2 patients.

There continues to be interest in determining the necessity of treating the parametrium in patients with low-stage cervical cancer. Several investigators have noted that the risk of parametrial involvement is 1% or less in patients undergoing radical hysterectomy in low-risk situations. Parametrial resection contributes significant short-term and long-term morbidity to surgery. Lymphatic mapping techniques suggest that parametrial sentinel lymph nodes can be identified and resected without a radical dissection. In the future, we expect that the indications for surgery that omits the parametrial resection will grow.

Stage IB

Stage IB encompasses tumors that are larger than stage IA, meaning 5 mm or larger in measured stromal invasion or more than 7-mm lateral spread. Stage IB also includes all visible lesions, even if the invasion is superficial (<5 mm). Clinicians should be aware of low-grade squamous cancers that can be easily visualized without magnification and have very superficial invasion. In our judgment, these patients should be treated similarly to stage IA patients.

Stage IB1 patients have tumor limited to the cervix that is 4 cm or less in diameter. These patients have equally good outcomes with radical surgery or radiotherapy. A major factor in favor of radical surgery is younger age, especially premenopausal patients for whom ovarian preservation is an option. In addition, there is now increasing availability of ovum transfer and pregnancy surrogates. Other factors favoring radical surgery are smaller size, desire to preserve fertility, and absence of other comorbidities that escalate the risk of surgery. Factors that favor radiotherapy are the presence of indicators that would result in postoperative radiotherapy if surgery were the primary therapy. These include larger size, extensive LVSI, suspicious findings on preoperative imaging, high-risk histologic subtypes, and deep stromal invasion on imaging or examination that increases the risk of close margins.

The decision regarding radical surgery or radiotherapy should be made with the active involvement of the woman, gynecologic oncologist, and radiation oncologist. Both modalities are associated with the potential for significant short- and long-term complications. Some complications such as bladder atony, food intolerance, or loss of sexual function are not easy to measure and can persist for years following treatment. Long-term survival data are similar for well-selected patient populations. Some data suggest more long-term patient satisfaction with outcomes related to surgery than radiotherapy.

Most gynecologic oncologists and radiation oncologists recommend concurrent chemoradiation for patients with stage IB2 cervical cancer. Reports demonstrate that up to 80% of stage IB2 patients who have undergone a radical hysterectomy will have clear indications for postoperative radiotherapy. Our experience is that postoperative radiotherapy results in greater toxicity than treatment with the cervix intact. The counterargument is that radical hysterectomy obviates the need for high-dose brachytherapy that is associated with the most severe and difficult to manage complications, notably pelvic fistulas. A number of innovations in treatment targeting techniques appear to be having a beneficial impact on reducing post-treatment fistula. Concurrent chemoradiation is our primary recommendation for stage IB2 patients and is discussed later in this chapter.

Operative Therapy: Radical Hysterectomy and Pelvic Node Dissection

Radical hysterectomy and bilateral pelvic lymphadenectomy are effective for the treatment of stage IB and some early stage IIA cancers. It is important that the surgery removes the same volume of tissue that has received tumoricidal doses of radiation in patients for whom radiation is the sole therapy. The amount of tissue removed, particularly in the paracervical and parametrial areas near the ureter, depends on the extent and location of the tumor. Piver and colleagues defined five classes to describe the extent of the operation (Piver, 1974). Class I guarantees the removal of the entire cervix and uterus. The ureter is not disturbed from its bed. In many cases, this is described as an extrafascial hysterectomy, the type used after preoperative radiation for treatment of a barrel-shaped cervix (discussed later). A class II operation (Fig. 29.13) removes more paracervical tissue than class I; the ureters are retracted laterally but are not dissected from their attachments distal to the uterine artery, and the uterosacral ligaments are ligated approximately halfway between the uterus and rectum. The operation is usually performed with pelvic lymphadenectomy and is often termed a *modified radical hysterectomy*. The operation is useful to treat small microscopic carcinomas of the cervix. Magrina and colleagues used modified radical hysterectomy primarily for tumors smaller than 2 cm (median, 1.1 cm), with 5-year survival of 96% (Magrina, 1999). This procedure may occasionally be used to treat small, central cervical recurrences of carcinoma that are diagnosed following radiation therapy of the primary tumor. For a class III operation, the uterine artery is ligated at its origin from the anterior division of the hypogastric artery and the uterosacrals are ligated deep in the pelvis near the rectum (see Fig. 29.12). This operation is usually termed a *radical hysterectomy* (Meigs-Wertheim hysterectomy) and is performed for stage IB and, rarely, for stage IIA carcinomas of the cervix.

Figure 29.13 Classes I and II radical hysterectomy with points of dissection shown (see text).

Class IV and V operations are infrequently performed. A class IV procedure involves a complete dissection of the ureter from its bed and sacrifice of the superior vesical artery. A class V operation involves resection of the distal ureter, bladder, or both, with reimplantation of the ureter into the bladder (ureteroneocystostomy). Both are designed to remove small, central recurrent disease and would be attempted to avoid an anterior exenteration (see later). Extensive data are not available, but the latter two procedures appear to have high complication rates.

Other classification systems for radical hysterectomy exist. Querleu and Morrow described a classification that is principally based on the lateral extent of resection (four types, A through D) with subtypes that address nerve preservation and paracervical lymphadenectomy (Querleu, 2008). Within this classification, four levels of lymph node dissection (1-4) are also defined according to arterial anatomy and overall radicality of the procedure.

Preoperative preparation for a woman who is to undergo a radical hysterectomy includes the same basic considerations for anyone undergoing a major operative procedure. Graduated compression, below-the-knee leg stockings and perioperative prophylactic doses of heparin or other low-molecular-weight heparin formulations are used to reduce the risk of thromboembolism. Prophylactic antibiotics are also frequently prescribed. During the course of the operation, care is taken not to grasp the ureters with instruments such as forceps to avoid damaging the periureteral capillary blood supply.

An important complication of pelvic lymphadenectomy is lymphocyst formation. Most gynecologic oncologists have abandoned the use of closed suction drains in radical hysterectomy patients and leave the pelvic peritoneum open to allow lymph fluid to drain internally in the peritoneal cavity.

Ovarian function may be preserved in younger patients if there is little likelihood of postoperative radiation. If intraoperative findings suggest that radiotherapy will be given postoperatively, the ovaries may be transposed superior and lateral to preserve their function. This technique has some liabilities, including early loss of ovarian function and abdominal pain from ovarian cysts.

In stage I cases treated by radical hysterectomy and node dissection, the results obtained are related primarily to the status of the pelvic nodes, as well as the surgical resection margins around the primary tumor (ideally, >1 cm). If the pelvic nodes are free of tumor, the 5-year survival rate can be expected to exceed 90%, whereas if the nodes are found to contain tumor, the 5-year survival rate drops to 45% to 50%. If the woman is found to have extensive spread of gross disease to the pelvic nodes, the studies of Potter and coworkers (Potter, 1990) have suggested that it is preferable to cease the operation and complete radiation therapy to improve pelvic control of tumor. However, Hacker and associates reported an estimated 5-year survival of 80% for 34 patients whose tumor-positive pelvic or paraaortic nodes were resected and the areas subsequently radiated (Hacker, 1995). In a GOG study, Sedlis and coworkers evaluated disease-free survival for patients treated with radical hysterectomy who have negative lymph nodes and surgical margins but with intermediate risk factors, including more than one third stromal invasion, capillary lymphatic space involvement, adenocarcinoma, and large tumor diameter by randomizing patients to pelvic radiotherapy or observation (Sedlis, 1999). Survival was improved in those who received postoperative pelvic radiation; however, there were radiation complications, including bowel obstruction and death.

Nerve-sparing radical hysterectomy is an innovation described by Hockel and others (Hockel, 2003). Bladder atony

is a difficult-to-study outcome of radical hysterectomy. The incidence of complete bladder atony requiring self-catheterization or nerve stimulators is low, but milder forms are common. The severity of bladder atony is directly related to the trauma inflicted on the hypogastric nerves that may be traumatized during radical hysterectomy. The impact of the nerve-sparing approach on sexual function is not known.

Fertility-Sparing Surgery

Dargent developed a combined laparoscopic and vaginal technique for removal of the pelvic lymph nodes, cervix, parametrium, and upper vagina (Dargent, 1995). Dargent trained gynecologic oncologists from around the world to perform radical vaginal trachelectomy and laparoscopic pelvic lymphadenectomy (Dargent, 1995). Long-term outcomes reported by Plante, Diaz, and others have confirmed that in well-selected patients, oncologic outcomes are identical to radical hysterectomy outcomes (Plante, 2005; Diaz, 2008). First-trimester pregnancy loss rates are approximately the same for radical trachelectomy patients as for the general population. Second-trimester pregnancy loss is approximately doubled in trachelectomy patients compared with the general population presumably because of the loss of cervical stroma. Approximately two thirds of patients have a successful pregnancy following radical trachelectomy.

When fertility-sparing surgery was first described, the assumption was that it would be offered to only a small proportion of patients. Sonoda and colleagues determined from a cohort of over 400 radical hysterectomy patients that approximately 50% of those younger than 40 years have low-risk histologic types and tumor size smaller than 2 cm, making them candidates for radical trachelectomy (Sonoda, 2004).

In spite of the contribution of radical vaginal surgery to fertility preservation, the technique has been difficult for gynecologic oncologists in the United States to master. Vaginal surgical skills are diminishing and there are no other indications for radical vaginal surgery. American gynecologic oncologists, unlike their counterparts in Canada and Europe, appear to have been discouraged by the long learning curve and have not invested the time to master the approach. Gynecologic oncologists in the United States have described abdominal radical trachelectomy as an alternative to the vaginal approach. Although smaller numbers have been published, it is anticipated that oncologic and fertility outcomes will be similar to the laparoscopic-vaginal approach. In addition, performance of robotic radical trachelectomy continues to rise and we anticipate will further advance use of the abdominal approach.

Patient selection is important when considering fertility-sparing surgery. Preoperative pelvic MRI is recommended for all patients with a visible lesion. Patients should have a desire to preserve fertility, no evidence of metastatic disease to lymph nodes or distant metastases, age <45, stage IAI with LVSI or IA2 or IB1 disease, and lesion size less than or equal to 2 cm with limited endocervical extension assessed by colposcopy and MRI.

Minimally Invasive Surgery

Minimally invasive techniques for treatment of cervical cancer are attractive for several reasons. The tumor itself can be removed through the vagina, so an abdominal incision is not needed for this purpose. Lymph nodes can be removed safely through laparoscopic ports, especially if removed in a protective bag prior

to pulling through the port. Minimally invasive surgery reduces postoperative adhesions. This is important, because these adhesions play a role in the severity of bowel complications if postoperative radiotherapy is given. Minimally invasive surgery is associated with shorter length of stay, less pain, few postoperative infections, fewer thromboembolic complications, and reduced blood loss compared with abdominal procedures.

Laparoscopic radical surgery has become more popular in North America because of faculty in major training programs who have embraced the concept and trained their associates. For gynecologic oncologists in practice, the long learning curve associated with laparoscopy has been an impediment to advancement. The most recent minimally invasive technique, robotic laparoscopic surgery, offers new advantages. The robot more closely replicates the wristed motions that surgeons use during open cases, offers three-dimensional imaging, and completely eliminates the tremor of the surgeon and the assistant holding the camera. Many gynecologic oncologists who have not had the time or inclination to master traditional laparoscopic surgery can master robotics relatively quickly. Radical pelvic surgery (e.g., radical prostatectomy, hysterectomy) is an ideal application for robotic surgery and will continue to become increasingly available in the United States.

Sentinel Node Biopsy

Cervical cancer, like most solid tumors, spreads primarily by lymphatic spread. Surgical management of solid tumors, as pioneered more than 100 years ago by Halsted, is based on the resection of all regional lymph nodes and lymphatic channels connecting the lymph nodes to the primary tumor. Implicit in this approach is that all regional lymph nodes have the same risk of containing metastatic disease. Morton, working in patients with cutaneous melanoma, has demonstrated that there are sentinel lymph nodes that are the first nodes to receive lymphatic drainage from the primary tumor and are therefore the first site of metastases (Morton, 2001). Experience with thousands of melanoma and breast cancer patients has validated this concept, which has been successfully extended to other disease sites, notably vulvar cancer.

Cervical cancer is an excellent target for the sentinel lymph node concept because the tumor is easy to inject and the regional lymph nodes can be reached through an incision. Lymphatic drainage of the cervix is complex; however, most sentinel lymph nodes of the cervix are found along the external iliac artery or vein, obturator space, or parametrium. A number of investigators have reported their experience with sentinel lymph node biopsy in radical hysterectomy patients. So far, the procedure has shown great promise; however, the false-negative rates have been higher for cervical cancer patients than for those with, for example, vulvar cancer. Improving techniques and patient selection should correct this problem. It is likely that sentinel lymph node biopsy will ultimately be incorporated into the surgical management of cervical cancer.

Surgical Complications

Following radical hysterectomy, many patients experience long-term complications. Montz and associates noted a 5% frequency of small bowel obstruction, which increases to 20% if radiation is used postoperatively (Montz, 1994). Fistulas from the urinary tract, particularly ureterovaginal fistulas, have been reported

to occur in approximately 1% of cases. The low rate appears to result from the administration of antibiotics, prevention of retroperitoneal serosanguineous collections, and avoidance of direct manipulation of the ureter to avoid injury to the periureteral blood supply. Most gynecologic oncologists do not reoperitonealize the pelvis, which allows direct drainage of lymphatic fluid to the peritoneal cavity, where it is reabsorbed.

Many women suffer postoperative bladder dysfunction. In part, this appears to be caused by disruption of the sympathetic nerve supply to the bladder. However, the dysfunction may be temporary. Low and associates noted an increase in bladder pressure with a decrease in urethral pressure following radical hysterectomy (Low, 1981). There was reduced bladder compliance with detrusor instability. The bladder can develop hypotonicity, and overdistention can then become a problem. If overdistention of the bladder and infection are avoided, progressive improvement of bladder function usually occurs. Forney correlated the degree of bladder dysfunction after radical hysterectomy with the extent of resection of the cardinal ligament (Forney, 1980). Those who had a complete resection of cardinal ligaments could void satisfactorily at an average of 51 days compared with 20 days for those with only partial resection of the ligaments. All patients experienced a decrease in bladder sensation. In a few patients, the decrease in bladder sensation can be permanent. For patients in whom it is temporary, recovery usually occurs after continuous drainage of the bladder with an indwelling catheter. Westby and Asmussen observed that by 1 year after surgery, a slight decrease in urethral pressure persists but that the decrease is not as great as that noted immediately after the operation (Westby, 1985). After 1 year, the postoperative changes and bladder function usually recover. Newer nerve-sparing surgical techniques where the uterosacral ligament is transected after separation of the hypogastric nerve and preservation of the bladder branches of the pelvic plexus have been associated with improved bladder function without compromising oncologic outcomes and survival.

In a 1999 study from Sweden, Bergmark and coworkers noted compromised sexual activity, decreased lubrication, and shortened vagina in women treated for cervical cancer by surgery or radiation (Bergmark, 1999). During the consent process, patients should be informed regarding the potential impact of radical hysterectomy on their sexual function.

Lymphedema is another complication of radical pelvic surgery that can affect quality of life. The areas most affected are the mons, lower abdomen, and upper thighs. Lymphedema massage may help reduce this problem, but treatment options are limited and of only modest effectiveness.

Outcomes After Surgical Treatment

Reported 5-year survival rates for women with stage IB cervical cancer treated with radical hysterectomy and pelvic lymphadenectomy are approximately 80% to 90%. Patients with positive or close margins or positive lymph nodes have the highest risk of recurrence and poor outcome. In large prospective studies, 3-year disease-specific survival rates of 85.6% in patients with negative nodes and 50% to 74% in patients with positive nodes were reported. A randomized study has shown that postoperative chemoradiation improves survival in patients with positive lymph nodes and positive surgical margins (Peters, 1999).

Radiation Treatment

Most patients with carcinoma of the cervix are treated by radiation. The principles of external megavoltage treatment (teletherapy) and local implants (brachytherapy) are reviewed in Chapter 26. External beam radiation is administered in fractions, usually 180 cGy/day, 5 days/week, to destroy the tumor without causing permanent damage to normal tissues. This delivers uniform doses to the entire pelvis, including the regional pelvic nodes. The local implant delivers its highest energy locally to the cervix, surface of the vagina, and paravaginal and paracervical tissues. The radiation from the implant diminishes according to the inverse square law. The uterus and cervix serve as a receptacle for arranging and holding the intracavitary applicator stem (tandem) and accompanying vaginal applicators (ovoids) in a fixed and optimal position for delivering the desired radiation dosimetry. Usually, the tandem and ovoids or a tandem and ring are inserted with in the woman, and a pack is placed into the vagina to stabilize the apparatus and increase the distance from the mucosa of the bladder and rectum. After the position of the applicator has been confirmed to be satisfactory by imaging, the radioactive source, such as cesium-137 or Iridium 192, is inserted (afterloading technique). Other types of applicators are available, but the principle of delivering intense radiation to the cervix and paracervical areas is the same. The goal is to increase the total dose of radiation to the maximum allowable to achieve tumor control without introducing a major risk of complications and injury to adjacent normal tissue. The specific protocols followed in various treatment centers differ; individualization for specific patients is often needed depending on the stage and size of the cervical tumor as well as the patient's local anatomy. In general, external therapy is given first to treat the regional pelvic nodes and shrink the central tumor mass, which then is more amenable for a local implant. In some patients, external therapy can lead to excessive shrinkage of the vaginal apex, making safe, effective implantation of local radiation sources difficult. This can be a problem, particularly in older or postmenopausal patients. Occasionally, in those patients, the implantation is done first, especially for smaller stage I tumors. Intraoperative ultrasounds may be helpful especially in difficult cases for optimal implant positioning. In some cases, the central pelvis is shielded during external radiation therapy to allow for subsequent higher doses from the implant. Occasionally, interstitial therapy in the form of needles implanted into the area of the tumor is needed to achieve effective local tumor control. Although criteria differ, patients with stage III disease or poor vaginal anatomy are most often considered candidates for interstitial brachytherapy.

Intracavitary radiation therapy may be delivered at either a low-dose rate or a high-dose rate. The advantage of high-dose-rate brachytherapy is that it is given on an outpatient basis and can be done with 3 to 4 hours. High-dose-rate brachytherapy and low-dose-rate brachytherapy have similar survival and toxicity and high-dose-rate brachytherapy has become the most common type of brachytherapy available throughout the world. The number of fractions varies from two to five; the most common one in the United States is 5.5 Gy to 6 Gy to point A in five fractions.

In calculating the doses of radiation, two reference points, A and B, are used (Fig. 29.14). Point A is 2 cm above the external os and 2 cm lateral to the cervical canal. Point B is 5 cm lateral to the cervical canal and 3 cm lateral to point A, which places

Figure 29.14 Points A and B with central stem (tandem) and two ovoids in place.

point B in the vicinity of the lateral pelvic wall (see Fig. 29.14). The total dose administered depends on tumor stage but, in general, at the pelvic wall, it is in the range of 50 to 65 Gy, with the higher doses used for high-stage disease. At point A, it varies, but approximately 80 Gy is given for small IB1 lesions and doses higher than 85 Gy for larger lesions. The normal cervix is particularly resistant to radiation and can tolerate doses as high as 200 to 250 Gy over 2 months, whereas the adjacent bladder and, in particular, the rectum are much more sensitive, and their exposure in general should be limited at the point of maximal radiation to 80 Gy to the bladder and 70 Gy to the rectum, with overall average doses in the range of 65 to 70 Gy. The small bowel can be damaged at doses above 45 to 50 Gy, especially if adhesions limit intestinal mobility and a large volume is treated.

There has been increased interest in the use of image-based three-dimensional treatment planning for intracavitary and interstitial brachytherapy. Among the many potential advantages of image-based planning are its ability to provide a better sense of the actual doses delivered to critical structures and possibly a more solid basis for comparisons among institutions. Studies have used CT- and MRI-based images; at present, a large multi-institutional study of image-based brachytherapy is ongoing in Europe and worldwide.

Outcomes

Radical radiation therapy achieves excellent survival and pelvic disease control rates in patients with stage IB or IIA cervical cancer. Eifel and associates reported 5-year disease-specific survival of 90%, 86%, and 67% in patients with stage IB tumors with cervical diameters less than 4 cm, 4 to 4.9 cm, and larger than 5 cm, respectively (Eifel, 1994). In 1961, a report suggested that adjuvant hysterectomy improved local control in patients with stage IB disease with tumors larger than 6 cm; however, several studies since then have shown no improvement in local control

but an increase in toxicity (Keys, 1999). One of these studies was a large GOG study in which patients were randomized to a trial of radiation, with or without extrafascial hysterectomy; results showed no difference in survival or local control but a higher complication rate (Keys, 1999). Therefore there is no clear evidence that adjuvant hysterectomy improves outcome in patients with early stage disease and large tumor size. The 5-year survival for patients with stage IIA disease is similar to that for patients with stage IB disease. For patients with more advanced disease, 5-year survival rates of 65% to 75%, 35% to 50%, and 15% to 20% have been reported for stages IIB, IIIB, and IV tumors, respectively. The addition of chemotherapy has further improved local control and survival for stage IB2 and higher (discussed later).

Chemoradiation

In 1999, prospective randomized trials involving concurrent cisplatin-containing chemotherapy to standard radiotherapy showed such improved survival that the trials were preliminarily halted to release the results, which changed clinical practice. In one of the studies by GOG, Rose and colleagues treated patients with advanced squamous cell, adenosquamous, or adenocarcinoma of the cervix (stages IIB, III, or IVA) (Rose, 1999). The patients received external radiation therapy (40.8 to 51 Gy) followed by one or two brachytherapy implants. The patients were randomized to receive one of three concomitant chemotherapy regimens: hydroxyurea; cisplatin, 5-fluorouracil, and hydroxyurea; or cisplatin alone. The best results were obtained with the cisplatin-containing regimens, with the least complications seen with weekly cisplatin (40 mg/m²) alone. Progression-free survival at 24 months was an impressive 67% for this very high-risk group of patients.

In another collaborative trial, Keys and associates studied 369 women with bulky stage IB carcinoma (>4 cm) in diameter (Keys, 1999). They were randomized to receive radiation alone or with concomitant weekly cisplatin (40 mg/m²). Adjuvant extrafascial hysterectomy was performed 3 to 6 weeks after conclusion of the chemoradiation treatments. The therapeutic results were markedly better in the chemoradiation group, with a 3-year 83% disease-free survival compared with 74% in the radiation group alone ($P = .008$), and they noted no added benefit with the addition of extrafascial hysterectomy. At the same time, the Radiation Therapy Oncology Group also conducted a trial comparing paraaortic–pelvic radiation therapy with concurrent chemotherapy and pelvic radiation in patients with stages IB to IVA tumors and also found a significant improvement in outcome for all stages of disease with concurrent chemotherapy compared with radiation therapy alone (Eifel, 2004). Another trial studied concurrent chemotherapy with radiation therapy in patients who had undergone a radical hysterectomy for cervical cancer and were found to have pelvic lymph node metastases, positive margins, or parametrial involvement. In this trial, patients who received chemoradiation had a better disease-free survival rate than patients who received radiation therapy alone (Peters, 1999).

Only one large randomized trial has failed to demonstrate a significant advantage from concurrent cisplatin-based chemotherapy in cervical cancer patients. This trial, in Canada, was the smallest of six trials of concurrent cisplatin and radiation therapy (Pearcey, 2002).

In North America, the primary focus has been on cisplatin-based chemotherapy regimens, but international trials have evaluated others. In a large trial from Thailand, patients were randomized into four arms: radiation therapy alone, radiation therapy with concurrent mitomycin and oral fluorouracil, radiation therapy with adjuvant fluorouracil, or radiation with concurrent and adjuvant chemotherapy (Lorvidhaya, 2003). Patients in the two treatment groups that included concurrent chemotherapy had higher disease-free survival rates and lower rates of local recurrence than patients in the other two groups. More recently, Dueños-Gonzales published a trial comparing cisplatin-radiation therapy to cisplatin-gemcitabine-radiation therapy followed by two courses of cisplatin-gemcitabine (Dueños-Gonzales, 2011). Patients who received gemcitabine had better overall survival and disease-free survival compared with patients who did not.

A meta-analysis review of trials that included a comparison of chemotherapy plus radiation to radiation therapy alone found a 6% improvement in 5-year survival with chemoradiotherapy (Chemoradiotherapy for Cervical Cancer Meta-Analysis Collaboration 2008). A larger survival benefit was seen for the two trials in which chemotherapy was administered after chemoradiotherapy. There was a significant survival benefit for the group of trials that used platinum-based and non-platinum-based chemoradiotherapy but no evidence of a difference in the size of the benefit by radiotherapy or chemotherapy dose or scheduling was seen. Chemoradiotherapy also reduced local and distant recurrence and progression and improved disease-free survival.

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy may be given before surgery or before radical radiation therapy. Advantages of chemotherapy before surgery include the potential for reducing tumor volume, increasing resectability, and helping to control micrometastatic disease. Neoadjuvant chemotherapy may also have the potential to provide a viable alternative when access to radiotherapy is poor or if there are unavoidable delays in delivering radiotherapeutic treatment. In one study by Sardi and coworkers, 205 patients with stage IB1 were randomized to neoadjuvant chemotherapy plus radical hysterectomy or to radical hysterectomy alone (Sardi, 1993).³² They reported that the patients who received neoadjuvant chemotherapy had more resectable tumors and better overall survival than patients who did not receive neoadjuvant chemotherapy. In the United States, the GOG closed a trial with 258 patients with stage IB2 cervical tumors who were randomized to neoadjuvant chemotherapy plus radical hysterectomy or to radical hysterectomy alone. They found no difference in the two arms in the rate of surgery performed (79% chemotherapy + surgery vs. 54% surgery) in the surgical-pathologic findings, specifically in progression-free survival (56% chemotherapy + surgery vs. 54% surgery) and overall survival (63% chemotherapy + surgery vs. 61% surgery) at 5 years. A meta-analysis of six randomized trials of neoadjuvant chemotherapy plus surgery compared with surgery alone found that although progression-free survival was improved with neoadjuvant chemotherapy, there was no significant survival benefit, and distant recurrence and rates of resection only tended to favor the neoadjuvant chemotherapy (Rydzewska, 2010). The authors observed heterogeneity in the trials but concluded that it remains unclear whether neoadjuvant chemotherapy consistently offers a benefit

over surgery alone for women with early stage or locally advanced cervical cancer. In the United States, neoadjuvant chemotherapy is rarely used; however, internationally, there is much interest in using neoadjuvant chemotherapy, especially in countries in which radiotherapy is not easily accessible.

The other use of neoadjuvant chemotherapy is prior to radiation therapy. Seven randomized trials have studied neoadjuvant chemotherapy plus radiation therapy compared with radical radiation therapy alone. Other randomized trials have studied neoadjuvant chemotherapy plus surgery compared with radical radiation therapy in locally advanced cervical cancer. A meta-analysis published in 2004 evaluated 21 of these trials (NACCCMA Collaboration, 2004); however, all the trials that were included in this analysis were carried out before 1999, when the concurrent chemotherapies were all published. Much heterogeneity was found in the trials, which made them difficult to analyze. However, it was concluded that the timing and dose intensity of cisplatin-based neoadjuvant chemotherapy appeared to have an important impact on whether it benefited women with locally advanced cervical cancer; further exploration was recommended. Presently, two trials of this issue are ongoing in Europe and India, and in both trials the standard arm is concurrent chemoradiation.

Para aortic Node Involvement

Numerous small series of patients having documented para-aortic node involvement have demonstrated that some patients have long-term disease-free survival. Patients with microscopic involvement have a better survival duration than those with gross involvement; however, even patients with gross involvement have a 15% to 20% survival rate with aggressive management. Laparoscopy and laparotomy using the extraperitoneal approach allow the removal of positive nodes and sampling of other paraaortic nodes, which may enhance control with radiation therapy and help design the treatment field.

Patients with paraaortic lymph node involvement can be treated effectively with extended-field radiation. The superior boundary of the extended field is usually placed at the T12 vertebral body to cover the paraaortic nodes. Patients are treated with a combination of external beam radiation therapy and brachytherapy. The 5-year survival rates range from 25% to 50%. At present, the standard treatment for patients with positive para-aortic nodes is extended-field radiation therapy with concurrent weekly cisplatin.

Radiation Complications

Complications following radiation therapy are related to dose, volume treated, and sensitivity of the various tissues receiving radiation. The patient's habitus and presence of diseases that affect circulation, such as diabetes and high blood pressure, increase the risk, as does previous intra-abdominal surgery. Acute minor complications, such as diarrhea and nausea, subside after radiation therapy is completed. Complications usually develop in 1 to 2 years but can occur as early as 6 months or as late as many years after radiation therapy has been completed. Scarring of normal tissues can lead to severe radiation fibrosis. The rare development of a second primary cancer after radiation for cervical cancer was reported by Kleinerman and associates from 13 population-based European registries (Kleinerman, 1995). With 30 years of survival, there was approximately a doubling of the

risk of a new primary in an irradiated pelvic organ, including the ovaries and bladder, as well as the vagina and vulva.

The treatment of radiation complications depends on the symptoms and location of the complication. Vaginal or cervical ulcerations occasionally occur, and local treatment with topical antibiotics and estrogen creams is usually satisfactory. Postradiation cystitis may manifest itself as urinary frequency or dysuria. After infection has been ruled out, symptomatic treatment is undertaken with drugs such as antispasmodics or urinary analgesics (e.g., phenazopyridine [Pyridium], 100 mg three times daily); these are prescribed until the symptoms clear. Occasionally, hemorrhagic cystitis develops, which may require hospitalization for continuous bladder irrigation or instillation of agents to control bleeding, such as silver nitrate or possibly fulguration of the bleeding points. In cases of hematuria, recurrent tumor should first be ruled out. Periureteral fibrosis can lead to ureteral obstruction and loss of kidney function. McIntyre and coworkers studied 1784 patients with stage IB carcinomas who were treated by radiation therapy and found 29 cases of ureteral stenoses, which increased from a frequency of 1% at 5 years to 2.5% at 20 years (McIntyre, 1995). Although tumor recurrence was the most common cause of early ureteral obstruction, radiation fibrosis can be a rare but occasionally fatal late complication.

Bowel complications tend to be more frequent than urinary complications. Proctosigmoiditis can lead to diarrhea, severe pain on defecation, or gastrointestinal bleeding. Conservative therapy with stool softeners and a low-roughage diet may suffice; occasionally, local corticosteroids (e.g., cortisone enema) are of assistance. Fistulas or rectal ulcerations are occasionally seen in the area adjacent to the tip of the cervix, which is also the area maximally radiated during local vaginocervical implantation. If a fistula develops, or in cases of ulceration or severe bleeding and pain, a diverting colostomy is required. Serious small bowel complications may occur, leading to obstruction, fistula formation, or necrosis. The use of parenteral nutrition and intravenous hyperalimentation are excellent measures to help deal with these problems. Follow-up studies by Klee and colleagues have shown that bladder and bowel symptoms tend to be chronic in some patients, but long-term fatigue is also reported. In most patients, it regresses in a few months (Klee, 2000).

Compromise of sexual function because of inelastic vaginal walls and decreased utilization was noted in the studies by Bergmark and associates (Bergmark, 1999). In a randomized trial of experimental psychoeducational intervention involving regular vaginal dilation, Robinson and coworkers noted a reduced fear of sexual activity posttreatment in the experimental group (Robinson, 1999).

SPECIAL CONSIDERATIONS

Cervical Stump Tumors

Some patients undergo supracervical hysterectomy for nonmalignant disease. Carcinomas that subsequently develop in the cervical stump pose special problems because of the shortness of the cervical canal and absence of the uterus, both of which curtail the effective use of brachytherapy, especially insertion of an intracervical tandem. There is also the risk that bowel adhesions to the apex of the vagina and cervix will increase the chances of radiation complications; a pretherapy barium study of the small and large bowel may be helpful to identify loops that adhere to

the cervical apex. For patients with small stage IB tumors, an operative approach similar to radical hysterectomy can be considered. However, most patients are treated with radiation. External treatment is emphasized because of the difficulty of an optimal intracavitary implant. A transvaginal cone may also be used to supplement external pelvic therapy. Effective treatment of cervical stump carcinoma can be achieved, resulting in overall 5-year survival rates ranging from 45% to 60%. However, because of the previous supracervical hysterectomy, there is an increased risk of complications compared to patients treated with a supracervical hysterectomy. Results of chemoradiation studies of these tumors are not available but, based on data already presented, radiation, combined with weekly cisplatin, appears to be optimal.

Carcinoma of the Cervix Inadvertently Removed at Simple Hysterectomy

Unfortunately, the situation occasionally arises in which a woman undergoes a simple total hysterectomy and an invasive carcinoma of the cervix is found after operation. Patients with unsuspected invasive cervical carcinoma detected after simple hysterectomy have been classified into five groups according to the amount of disease and presentation: (1) microinvasive cancer, (2) tumor confined to the cervix with negative surgical margins, (3) positive surgical margins but no gross residual tumor, (4) gross residual tumor by clinical examination documented by biopsy, and (5) patients referred for treatment more than 6 months after hysterectomy (usually for recurrent disease).

The treatment plan is based on the amount of residual disease. Sometimes, the surgeon can subsequently perform a radical operation, removing the tissues that would normally be removed at radical hysterectomy, including the regional pelvic nodes. Such an approach has been used, particularly in younger patients, especially those with small tumors. However, most women are usually treated with some sort of radiation therapy. Patients with minimal or no known residual disease at most require brachytherapy to the vaginal apex; patients with gross disease at the specimen margin require full-intensity therapy. Patients with minimal or no gross residual disease (groups 1 to 3) have excellent 5-year survival rates (59% to 79%), whereas rates for patients with gross residual disease (groups 4 and 5) are poorer (in the range of only 41%).

Carcinoma of the Cervix in Pregnancy

Rarely, an invasive carcinoma of the cervix is discovered in a pregnant woman. Within each stage, survival statistics are similar in pregnant and nonpregnant women. A concern has been that the delivery of a fetus through a cervix replaced by carcinoma might worsen the prognosis because of tumor dissemination, but there is no clear evidence to indicate that the birth process causes tumor dissemination. However, tumor recurrence in episiotomy sites following vaginal delivery has been reported in some studies. The major risk to the patient of delivery through a cervix containing invasive carcinoma is that of hemorrhage as a result of tearing of the tumor during cervical dilation and delivery.

A problem arising in pregnancy is whether a woman with an abnormal cytologic smear has intraepithelial neoplasia or invasive cancer. In general, if the cytologic and histologic findings of colposcopically directed biopsies are comparable and suggest intraepithelial neoplasia or carcinoma in situ, the woman

is observed and delivered, with final evaluation and therapy completed approximately 6 weeks after delivery. Even if there is a question of microinvasion, a woman so diagnosed in the last trimester of pregnancy is usually followed and evaluated further after delivery. Cervical conization during pregnancy can lead to severe complications, particularly hemorrhage and loss of the fetus. If it is necessary to perform a conization or preferably a wedge resection of the cervix during pregnancy, it is probably best to perform this procedure during the second trimester, when the risks of fetal loss and hemorrhage are minimal. For patients in whom invasive cancer is diagnosed, a therapeutic plan must be developed to deliver appropriate care, with regard also for the outcome of the pregnancy.

The therapy of carcinoma during pregnancy is influenced by the stage of the disease, time in pregnancy when the cancer is diagnosed, and beliefs and desires of the woman in terms of initiating therapy that can terminate the pregnancy, as opposed to postponing therapy until fetal viability is achieved. If carcinoma is diagnosed in the first trimester or early in the second trimester (before 20 weeks), treatment may be undertaken immediately because of the concern that a delay could lead to tumor progression or spread. If the woman has resectable tumor (stage IB or early IIA), effective treatment consists of radical hysterectomy and node dissection (class III). This procedure can usually be carried out without difficulty on a pregnant woman. Increased uterine motility and edema of the pelvic tissue planes help simplify the procedure for the experienced surgeon, but pregnancy does increase the risk of blood loss. For higher-stage tumors, therapy begins with external beam radiation (teletherapy) and, usually in 4 to 6 weeks, this leads to spontaneous abortion. The dose of external therapy prescribed varies depending on the stage of the tumor, but approximately 40 to 50 Gy is given. Although the results of a published series are not available, it would appear preferable to augment the radiation with weekly cisplatin because the pregnancy in this case would be terminated. Following abortion, the uterus involutes and an implant (brachytherapy) is placed. If the pregnancy does not spontaneously abort, dilation and curettage, prostaglandin-assisted delivery or, rarely, hysterotomy may be necessary to empty the uterus before brachytherapy. Alternatively, if the initial tumor was small and has completely regressed, an extrafascial hysterectomy or modified radical hysterectomy may be performed.

For patients beyond the 20th week of gestation, therapy is often delayed until fetal viability. The health and maturity of the fetus are determined by appropriate ultrasound studies and amniotic fluid analysis to ensure fetal lung maturity. Delivery is usually accomplished by cesarean section; after this, therapy is completed by surgery or radiation with the usual considerations of tumor stage and size. Overall, treatment results in pregnant patients are similar to those in nonpregnant patients, stage for stage. It should be noted that many published studies dealing with carcinoma of the cervix in pregnancy include cases treated as long as 1 year postpartum, which assumes that the carcinoma was present during pregnancy. Hacker and coworkers summarized the results of 1249 cases reported in various series in the literature (Hacker, 1982). Overall, a 5-year survival rate of 49.2% was recorded for pregnant patients compared with 51% for nonpregnant patients treated during the same period. Their statistics included not only patients treated during pregnancy, but also those treated up to 6 months after delivery, and the

postpartum group had the poorest survival statistics. Survival was most closely related to stage, as expected, and those diagnosed during the first trimester had a better prognosis than those diagnosed during the third trimester.

RECURRENCE

Approximately one third of patients treated for cancer of the cervix will experience tumor recurrence, which is defined as the reappearance of tumor 6 months or more after therapy. Metastases can occur anywhere, but most are in the pelvis—centrally in the vagina or cervix, or laterally near the pelvic walls—or, less frequently, distally in the periaortic nodes, lung, liver, or bone. It should be noted that liver, lung, and distal bone metastases outside the pelvis likely result from hematogenous tumor spread.

The symptoms caused by recurrence depend on the site and extent of metastatic disease. Vaginal discharge and abnormal bleeding are often symptoms of an early central pelvic recurrence. Malaise, loss of appetite, and general symptoms associated with widespread metastatic disease are late manifestations of recurrence. Lateral pelvic recurrences often have a retroperitoneal component, which can lead to sciatic nerve irritation and cause severe pain around the distribution of the sciatic nerve in back of the leg, as well as loss of muscle strength, causing the woman to walk with a limp. Unilateral leg edema frequently accompanies such metastases, or leg swelling may occur from fibrosis of lymphatics following surgery or radiation. In addition, tumor recurrence can also cause ureteral obstruction, leading to unilateral or bilateral compromise of kidney function. Low back pain frequently occurs.

Patients treated for carcinoma of the cervix are examined according to the same schedule as patients with other malignancies—every 3 months the first 2 years, every 6 months from years 3 to 5, and yearly thereafter. More frequent examinations are done if abnormal symptoms or signs develop. Examination consists of physical and pelvic examination at every visit and Pap smear annually unless an abnormality is detected on the Pap smear. Generally, a PET/CT is repeated at the 3 to 6 months post chemoradiation therapy and chest x-rays are done annually. Other imaging tests are only ordered if the patient has symptoms or there are other indications. Renal function tests may be indicated because ureteral fibrosis can occur more than 5 years after the completion of radiation therapy. Once recurrent disease is suspected, verification is usually obtained by biopsy of an accessible mass or CT-directed thin-needle aspiration, depending on the location of the tumor recurrence.

PELVIC RECURRENCE

Approximately 50% of recurrences will develop in the pelvis. In addition to clinical assessment and CT, a vaginal ultrasound scan is often useful to document pelvic recurrence. Recurrences of adenocarcinoma are less frequent in the pelvis and are more likely to be at distant sites, such as the lung or supraclavicular areas. For patients who were initially treated by surgery, radiation is usually prescribed for pelvic recurrences; approximately 45- to 50-Gy whole-pelvis irradiation is given. Supplemental interstitial or intracavitary radiation is also prescribed, depending on the size and location of recurrence in the pelvis. As noted,

chemoradiation is preferable. Patients who have isolated central recurrences without pelvic wall fixation or regional metastasis can be cured in as many as 60% to 70% of cases. The prognosis is much poorer when the pelvic wall is involved; usually, 10% to 20% of patients survive 5 years after radiation therapy. For patients who were initially treated with radiation who have developed a localized pelvic recurrence, surgical eradication of the tumor should be considered because further effective radiation is not possible and limited surgical resection of the pelvic recurrence may not lead to a cure but will often cause severe complications of wound healing and intestinal and urinary fistulas. However, in rare, carefully selected patients initially treated with primary radiation therapy, radical hysterectomy may be a feasible alternative to exenterative surgery. Coleman and associates reported on 50 patients who underwent a radical hysterectomy for persistent or recurrent disease and found 5- and 10-year survival rates of 72% and 60%, respectively, with complication rates of 64% for severe complications and 42% for permanent complications (Coleman, 1994). The authors concluded that a radical hysterectomy was an alternative to exenteration in patients with small, centrally recurrent cervical cancer, but that it should be used only in carefully selected patients. If neither surgery nor radiation is a feasible alternative, palliative chemotherapy is considered.

Pelvic Exenteration

Exenterative therapy for central pelvic tumor recurrence is an extensive operative procedure used only if the preoperative evaluation suggests that the patient's condition has the potential be cured by this procedure. Exenteration is not performed for palliation. Three types of procedures may be used. Anterior pelvic exenteration is removal of the bladder, uterus, cervix, and all or part of the vagina. Posterior pelvic exenteration is removal of the anus and rectum and resection of the uterus, cervix, and all or part of the vagina. Total exenteration removes all the pelvic contents. Shepherd and coworkers noted that patients older than 69 years, those who had a recurrence within 3 years, or those who had persistent disease or positive resection margins had a poorer prognosis for the procedure (Shepherd, 1994). Rarely, select patients with recurrence involving the sidewall that would not be standard candidates for total pelvic exenteration secondary to concern for a positive surgical margin may be considered for an extended pelvic resection, or the laterally extended endopelvic resection (LEER procedure) (Hockel, 2003, 2008). This procedure requires multidisciplinary advanced surgical support and carries high risk of surgical morbidity, but it may be contemplated as a possible curative option for very select patients.

Before an exenterative operation is undertaken, the patient is thoroughly evaluated for any evidence of disease spread outside the pelvis. At operation, abdominal exploration is carried out to ensure that the tumor is resectable. Biopsy specimens of any enlarged lymph nodes or suspicious areas outside the pelvis are taken, and frozen-section studies are performed, including evaluation of the operative margins. Usually, total exenteration is performed.

Several surgical innovations have expanded the reconstruction options. The introduction of continent urinary diversion provides an alternative incontinent urinary conduit. Generally, the urinary stoma is located in the abdomen on the right side and the intestinal stoma on the left side. The use of intestinal

stapling devices sometimes allows preservation of the rectal sphincter and anal function and avoids a permanent colostomy. Long-term complications are usually ureteral stricture or difficulty catheterizing the intestinal reservoir.

Continent conduits require the woman to catheterize the pouch every 4 hours, but no external appliance is required. Goldberg and colleagues reported long-term dissatisfaction among women with continent conduits and, in our practice, we have been doing an increasing number of incontinent diversions (Goldberg, 2006).

Transverse rectus abdominis myocutaneous (TRAM) flaps have provided a welcomed alternative to gracilis flaps. TRAM flaps, even small ones, as described by Sood and associates, are reliable and provide patients with the option of intercourse (Sood, 2005).

Severe postoperative and intraoperative complications can occur with this extensive procedure and perioperative mortalities as high as 10% to 20% have been reported in the past. Infection and bowel obstruction are the major risks. However, current surgical techniques of preoperative bowel preparation, use of antibiotics, careful intraoperative fluid and volume monitoring, and use of parenteral nutrition have reduced the immediate postoperative mortality to less than 5%. The use of a peritoneal graft or an omental flap, created from the right or left side of the omentum and placed in the pelvis to protect the denuded pelvic floor, can help avoid bowel obstruction and reduce postoperative morbidity. Occasionally, gracilis myocutaneous grafts are used to create a new vagina and bring a new blood supply to the previously irradiated pelvis, which aids in wound healing. Morley and associates reported on a 5-year survival rate of 61% in 100 patients aged 21 to 74 years (Morley, 1989). No patients with positive nodes in the operative specimen survived.

NONPELVIC RECURRENCE

Recurrences outside of the pelvis can be treated with radiation, surgery, or chemotherapy. Localized recurrences in areas not previously irradiated are occasionally treated by radiation. Resection of the metastasis is rarely done; it is usually restricted to a localized lesion that occurs 3 to 4 years after primary therapy on the assumption that such a solitary metastasis can be effectively treated with local resection. However, in general, distant metastases are usually manifestations of systemic disease and are not cured with local therapy.

CHEMOTHERAPY AS TREATMENT FOR RECURRENCE

Patients with advanced, recurrent, or persistent cervical cancer are the most difficult to treat and, for this patient population, chemotherapy offers the best hope. Cisplatin is the single most active drug in the treatment of cervical cancer. Several phase II studies have evaluated novel single agents or the combination of cisplatin with other agents, including mitolactol, ifosfamide, gemcitabine, topotecan, paclitaxel, and vinorelbine, and all have shown promising results. This has led to several phase III studies evaluating chemotherapy in patients with recurrent, advanced, or persistent cervical cancer.

The GOG has published results from four randomized phase III trials (protocols 110, 149, 169, and 179) trying to find the

optimal platinum doublet to treat women with metastatic disease. The first of these trials to be published was GOG protocol 110, which compared single-agent cisplatin with cisplatin-mitolactol and cisplatin-ifosfamide (Omura, 1997). Despite the fact that overall response rates were 17.8% in the cisplatin-only arm, 21.1% in the cisplatin-mitolactol, and 31.1% in the cisplatin-ifosfamide arm ($P = .004$), there was no significant difference in overall survival and greater toxicity with the cisplatin-ifosfamide regimen. GOG protocol 149 demonstrated that the addition of bleomycin did not enhance the activity of the cisplatin-ifosfamide doublet (Bloss, 2002), and GOG protocol 169 showed that the addition of paclitaxel to cisplatin or increasing the dose of cisplatin only improved response rate and prolonged progression-free survival but not overall survival (Moore, 2004).

GOG protocol 179 was a notable trial that demonstrated a significant improvement in overall survival (Long, 2005). In this trial, patients were randomized to single-agent cisplatin versus cisplatin and topotecan. There was a 2.9-month improvement in median survival in patients receiving the combination of cisplatin-topotecan versus cisplatin alone with no increase in toxicity. The result of this trial led to GOG protocol 204, which compared cisplatin-paclitaxel with cisplatin-topotecan, cisplatin-gemcitabine, and cisplatin-vinorelbine in patients with advanced, recurrent, or persistent disease in an attempt to find the optimal platinum doublet (Monk, 2009). The trial was closed early due to futility; however, in 513 patients, there was no difference in overall

survival among the four arms but there was a trend in response rate, progression-free survival, and overall survival that favored the cisplatin-paclitaxel arm, and the conclusion of the study was that cisplatin-paclitaxel should be considered the standard treatment for patients with stage IVB or metastatic cervix cancer.

There has been a major step forward in the treatment of patients with recurrent or metastatic cervix with the addition of targeted therapy. In GOG 240, patients were randomized to treatment with one of two chemotherapy regimens (cisplatin plus paclitaxel vs. paclitaxel plus topotecan) and to bevacizumab versus no bevacizumab (Tewari, 2014). There was no difference in outcomes between the two chemotherapy regimens; however, the addition of bevacizumab significantly improved overall survival (17 months vs. 13.3), progression-free survival (8.2 months versus 5.9 months), and response rate (48% vs. 36%) compared to chemotherapy alone. Cisplatin-paclitaxel-bevacizumab triplet has been listed as category 2A in the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines for cervical cancer (NCCN, 2014).

Despite the results of 240, the prognosis of patients with stage IVB or recurrent disease cervical cancer remains poor and represents an urgent unmet need worldwide. In addition to more robust prevention and screening strategies, better therapeutic strategies must be explored, including determining prognostic factors, the administration of novel agents that may improve the therapeutic index of definitive chemoradiation, and various immunotherapeutic approaches.

KEY POINTS

- Carcinomas of the cervix are predominantly squamous cell carcinomas (85% to 90%), and approximately 10% to 15% are adenocarcinomas.
- Squamous cell carcinomas appear to have a viral and venereal association, particularly with HPV. In the United States, squamous cell carcinoma is more frequent in blacks than in whites.
- Cervical carcinoma is the third most frequent malignancy of the lower female genital tract, after endometrial and ovarian cancer, and the second most frequent cause of death, after ovarian cancer.
- Definitive diagnosis of microinvasive carcinoma is established only by means of cervical conization, not biopsy. The margins of the cone should be free of neoplastic epithelium before conservative therapy is undertaken.
- Microinvasive carcinoma of the cervix can be effectively treated by total hysterectomy, with a 5-year survival rate of almost 100%, but recurrent neoplasia can develop after 5 years. However, a precise and reliable definition of microinvasion is controversial.
- Prognosis in squamous cell cancer of the cervix is related to tumor stage and lesion volume (size), depth of invasion, and spread to lymph nodes.
- The prognosis of adenocarcinoma of the cervix is related to tumor stage, size, grade, and depth of invasion. Large adenocarcinomas tend to be poorly differentiated.
- Metastases to regional pelvic nodes in stage I squamous carcinomas correlate with lesion size, depth of invasion, and the presence of capillary lymphatic space involvement, and correlate inversely with patient age.
- Cervical carcinomas are locally invasive tumors that spread primarily to the pelvic tissues and then to the pelvic and paraaortic lymph nodes. Less frequently, hematogenous spread to the liver, lung, and bone occurs.
- The risk of the spread of cervical carcinoma to pelvic nodes is approximately 15% for stage I, 29% for stage II, and 47% for stage III. For the paraaortic nodes, the figures are 6% for stage I, 19% for stage II, and 33% for stage III.
- Stage IB carcinomas of the cervix may be treated equally effectively by radical hysterectomy and pelvic node dissection or radiation. The 5-year survival rate is approximately 80%. If lymph nodes are free of tumor, the 5-year survival rate is approximately 90%; if the nodes contain metastatic tumor, the rate is 50%. Improved overall survival rates have been reported for patients with tumors smaller than 4 cm in diameter treated by preliminary brachytherapy followed by radical hysterectomy.
- Surgery is often used for treating stage IB and early stage IIA carcinomas of the cervix, particularly for smaller tumors and for younger patients to preserve their ovarian function. Surgery produces less scarring and vaginal fibrosis than radiation and is preferred for women with a pelvic mass, pelvic infection, or history of conditions such as inflammatory bowel disease, which increase the risk for radiation complications.

KEY POINTS—cont'd

- High-stage tumors are treated by chemoradiation. Current programs usually use cisplatin, 40 mg/m² weekly, during external treatment and with brachytherapy.
- Most cancers of the cervix are treated by radiation therapy (teletherapy and brachytherapy). Radiation doses vary with tumor size and stage but are approximately 50 to 65 Gy at point B and 80 to 85 Gy at point A. Current practice is to combine radiation with simultaneous chemotherapy to optimize the results.
- Improved cure rates of cervical cancers are obtained with increased doses, which also lead to an increased frequency of complications. Large increments in dose may increase complications without increasing cure rates.
- Complications following radiation are related to dose and volume of tissue treated; these include radiation inflammation of the bladder or bowel, which may lead to pain, bleeding, or, infrequently, fistula formation. The normal cervix is resistant to radiation, and the dose can be as high as 200 to 250 Gy over 2 months. The rectum should be limited to doses of 70 Gy or less and the bladder to doses of 80 Gy or less. Overall, the rate of moderate to severe radiation complications for treatment of all stages is approximately 10%.
- Worldwide 5-year survival rates reported for patients with carcinomas of the cervix are as follows: stage IA, 95%; stage IB, 80%; stage II, 70%; stage III, 50%; and stage IV, 20% with radiation therapy alone.
- Pregnancy does not adversely affect the survival rate for women with carcinoma of the cervix, stage for stage.
- Approximately one third of patients treated for cervical carcinoma develop tumor recurrence, and approximately 50% of these recurrences are located in the pelvis; most occur within 2 years.
- Patients whose recurrences occur more than 3 years after primary therapy have a better prognosis than those with earlier recurrence.
- Pelvic exenteration in carefully selected patients with central pelvic recurrence can lead to a 5-year survival rate of 50% or better.
- Chemotherapy of recurrent squamous cell carcinoma of the cervix does not produce long-term cures, but recent results suggest that cisplatin-paclitaxel-bevacizumab should be considered the standard treatment for patients with stage IVB recurrent or metastatic cervix cancer.
- Leg pain following the distribution of the sciatic nerve or unilateral leg swelling is often an indication of pelvic recurrence of carcinoma of the cervix.

Neoplastic Diseases of the Vulva Lichen Sclerosus, Intraepithelial Neoplasia, Paget Disease, and Carcinoma

Michael Frumovitz, Diane C. Bodurka

Cancer of the vulva accounts for approximately 5% of malignancies of the lower female genital tract, ranking it fourth in frequency after cancers of the endometrium, ovary, and cervix. Well-defined predisposing factors for the development of vulvar carcinoma have not been identified. In general, premalignant and malignant changes frequently arise at multifocal points on the vulva. Human papillomavirus (HPV) has been noted in almost 70% of patients with carcinoma of the vulva (Saraiya, 2015), and invasive carcinoma may arise from areas of carcinoma in situ, similar to the mechanism in cervical squamous cell carcinoma (see Chapter 29). However, some cases of squamous cell carcinoma of the vulva appear to develop in the absence of HPV or premalignant changes in the vulvar epithelium. Other factors, such as granulomatous disease of the vulva, diabetes, hypertension, smoking, and obesity, have all been suggested as causative factors, but data do not provide consistent evidence regarding their association with vulvar carcinoma. Carcinoma of the vulva occurs with increasing frequency in those who have been treated for squamous cell carcinoma of the cervix or vagina, presumably as a result of the increased risk of carcinogenesis in the squamous epithelium of the lower genital tract in these patients. It appears that HPV DNA is involved in the development of a subset of vulvar carcinomas that tend to occur in younger patients, as noted by Crum (Crum, 1987). Monk and colleagues demonstrated that not only were the HPV DNA-associated carcinomas found in younger patients but also that HPV-negative patients appear to have had a poorer prognosis with tumors that were more likely to recur and lead to patient death (Monk, 1995). As demonstrated by Hording and coworkers, HPV-positive tumors tend to have a warty or basaloid appearance, whereas HPV-negative tumors tend to be keratinized (Hording, 1994). The former tend to be associated with premalignant vulvar changes (vulvar intraepithelial neoplasia [VIN]). The incidence of vulvar carcinoma in situ has increased by over 400% since the 1980s, with most of the cases occurring in women under 50 years old (Judson, 2006).

Most vulvar malignancies are squamous cell carcinomas and most occur in women over 50 years old. In fact, although over 80% of patients with vulvar carcinoma in situ are under 50 years old, less than 20% of women with invasive carcinoma are under 50. The age-specific incidence of vulvar cancer increases with

each decade of life but overall has remained relatively stable since the 1980s (Fig. 30.1). Although most patients with carcinoma of the vulva are older than 60, those with carcinoma in situ of the vulva are usually 10 to 15 years younger—that is, 40 to 55 years of age. Premalignant changes of the vulva have been seen with increasing frequency among younger patients, often in their 20s and 30s, possibly as a result of an increasing rate of multiple sexual contacts and increased exposure to venereal infections, particularly HPV, in this population. Carter and colleagues reported a link between immunosuppression and invasive squamous cell carcinoma of the vulva in women younger than 40 years (Carter, 1993). Similar to cervical cancer, HPV-related infections would presumably progress through dysplasia to invasive cancer in these immunocompromised women. This chapter reviews the clinical and pathologic aspects of premalignant vulvar lesions and vulvar atypias (Box 30.1). This is followed by consideration of the diagnosis, natural history, and management of invasive cancers of the vulva, which includes not only the squamous cell carcinomas but also the rarer melanomas and sarcomas.

VULVAR ATYPIAS

SPECIFIC CONDITIONS

Vulvar Atypias: Intraepithelial Neoplasia

Lichen sclerosus (Fig. 30.2) is a change in the vulvar skin that often appears whitish. Microscopically, the epithelium becomes markedly thinned, with a loss or blunting of the rete ridges. In some cases, there is also a thickening or hyperkeratosis of the surface layers (Fig. 30.3). Inflammation is usually present. Hart and associates studied 107 patients with lichen sclerosus, and only one followed for 12 years eventually developed vulvar carcinoma (Hart, 1975). Five patients had vulvar carcinoma when lichen sclerosus was diagnosed. Twelve other patients subsequently developed malignancies at other sites, such as the cervix, colon, breast, ovary, and endometrium. In the past, patients with lichen sclerosus were thought not to be at increased risk for the development of vulvar carcinoma. A study by Carlson and colleagues has supported a small premalignant potential of lichen sclerosus (Carlson, 1998). Their study, and a literature review, showed

Figure 30.1 Incidence of invasive vulvar cancer by age and diagnosis year. (Modified from Judson PL, Habermann EB, Baxter NN, et al. Trends in the incidence of invasive and in situ vulvar carcinoma. *Obstet Gynecol.* 2006;107[5]:1018-1022.)

Box 30.1 Classification of Vulvar Atypias

Squamous cell hyperplasia (formerly hyperplastic dystrophy)
 Lichen sclerosus
 Intraepithelial neoplasia
 VIN I: Mild dysplasia
 VIN II: Moderate dysplasia
 VIN III: Severe dysplasia–carcinoma in situ
 Others
 Paget disease
 Melanoma in situ (level 1)

VIN, Vulvar intraepithelial neoplasia.

Figure 30.2 Lichen sclerosus et atrophicus. Homogeneous collagen in the papillary dermis is accompanied by a scattered lymphocytic infiltrate and atrophy of the epithelium (H&E, $\times 80$). (Courtesy of Dr. Anthony Montag, Department of Pathology, University of Chicago, Chicago.)

Figure 30.3 Lichen sclerosus. Hyperkeratosis is occasionally present. (From Friedrich EG, Wilkinson EJ. The vulva. In: Blaustein A, ed. *Pathology of the Female Genital Tract*. New York: Springer-Verlag; 1982.)

Figure 30.4 Squamous hyperplasia (formerly hyperplastic dystrophy), benign. Hyperkeratosis, acanthosis, and mild inflammation are present. (From Friedrich EG, Wilkinson EJ. The vulva. In: Blaustein A, ed. *Pathology of the Female Genital Tract*. New York: Springer-Verlag; 1982.)

that a risk of lichen sclerosus and squamous cell carcinoma was 4.5%, with an average of 4 years latency between symptomatic lichen sclerosus and squamous cell carcinoma. The tumors that developed tended to be clitoral in location. For women who are compliant with topical corticosteroid therapy, the risk of developing vulvar dysplasia or carcinoma approaches 0% compared with noncompliant women, whose risk is 4.7% (Lee, 2015). Squamous hyperplasia (formerly, hyperplastic dystrophy) involves the elongation and widening of the rete ridges, which may be confluent (Fig. 30.4). There may also be hyperkeratotic surface layers, and the tissue grossly is often whitish or reddish.

Atypical changes may appear in the vulvar epithelium. These are usually marked by a loss of the maturation process usually seen in squamous epithelium, as well as an increase in mitotic activity and nuclear/cytoplasmic ratio (Fig. 30.5). Mild dysplasia (atypia) is diagnosed if these changes involve the lower third of the epithelium, moderate dysplasia (atypia) if half to two-thirds of the epithelium is involved, and severe dysplasia (atypia) if more than two-thirds of the epithelium is affected. Carcinoma in situ involves the full thickness of the epithelium. The term *VIN I* is used for mild atypia, *VIN II* for moderate atypia, and *VIN III* for severe atypia and carcinoma in situ. It is sometimes difficult to distinguish between squamous hyperplasia and intraepithelial neoplasia. Crum has suggested that VIN usually contains nuclei that are fourfold or greater different in size, whereas differences in the size of nuclei in condyloma or nonneoplastic epithelia are threefold or less (Crum, 1987). Furthermore, abnormal mitoses are usually observed in VIN.

Carcinoma in Situ (Vulvar Intraepithelial Neoplasia III)

Carcinoma in situ is diagnosed if the full thickness of the epithelium is abnormal (Fig. 30.6, A). Occasionally, the process may histologically resemble carcinoma in situ of the cervix and, in many lesions, there are multinucleated cells, abnormal mitoses, an increased density in cells, and an increase in the nuclear-to-cytoplasmic ratio.

Paget Disease

Paget disease is a rare intraepithelial disorder that occurs in the vulvar skin and histologically resembles Paget disease in the breast. Paget cells are large pale cells (Fig. 30.7). The cells often occur in nests and infiltrate upward through the epithelium. Frequently, histologic abnormalities of the apocrine glands of the skin may be noted in these lesions. There has been an increased association of Paget disease of the vulva with underlying invasive adenocarcinoma of the vulva, vagina, and anus, as well as distant sites, including the bladder, cervix, colon, stomach, and breast. Paget disease of the vulva tends to spread, often in an occult fashion, and recurrences are frequent after treatment.

DIAGNOSIS

Clinical Presentation

Atypias of the vulva present with a variety of symptoms and signs. Irritation or itching is common, although some patients do not report these symptoms. The vulva often has a whitish change because of a thickened keratin layer. In the past, the term *leukoplakia* was used. This term has been discarded, in part because abnormal lesions of the vulva require biopsy to establish a correct diagnosis. When lichen sclerosus is present, there is usually a diffuse whitish change to the vulvar skin (Fig. 30.8). The vulvar skin often appears thin and there may be scarring and contracture. In addition, fissuring of the skin is often present, accompanied by excoriation secondary to itching. Areas of squamous hyperplasias (formerly called *hyperplastic dystrophy without atypia*) also appear as whitish lesions in general, but the tissues of the vulva usually appear thickened and the process tends to be more focal or multifocal than diffuse (Fig. 30.9).

Abnormal areas of vulvar atypia or VIN may also appear as white, red, or pigmented areas on the vulva. However, the clinical appearance of VIN is variable. Friedrich and colleagues estimated that approximately one-third of patients with carcinoma in situ will present with pigmented lesions, emphasizing the importance of a biopsy to establish the diagnosis (Friedrich, 1980). The lesions tend to be discrete and multifocal and occur more frequently in those who have had squamous cell neoplasia of the cervix. In addition, reddish nodules may also be foci of Paget disease as well as of carcinoma in situ. Paget disease often has a reddish eczematoid appearance. It should be reemphasized that these conditions cannot be accurately diagnosed from their clinical appearance, and biopsies are needed.

Diagnostic Methods

In general, cytologic evaluation (Pap smear) of the vulva has not proved helpful, in part because the vulvar skin is thick and keratinized and does not shed cells as readily as the epithelium of the vagina and cervix. However, in some cases, particularly if there

Figure 30.5 **A**, Vulvar intraepithelial neoplasia from which human papillomavirus type 16 was isolated. Characteristic features displayed here include abnormal mitoses (a two-group metaphase is denoted by the *arrowhead*), a full-thickness population of abnormal cells, and abnormal differentiation. Superficial cells contain perinuclear halos, which in contrast to condylomata are small and concentric. **B**, The higher power photomicrograph of vulvar intraepithelial neoplasia illustrates the marked variability in nuclear size and staining, with both enlarged nuclei and multinucleated cells. Coarsely clumped mitoses (*small arrowheads*) and a three-group metaphase (*large arrowhead*) are present. (From Crum CP. *Pathology of the Vulva and Vagina*. New York: Churchill Livingstone; 1987.)

is ulceration of the vulva, a cytologic smear can be helpful diagnostically (see Fig. 32-6, *B*). A tongue depressor moistened with normal saline or tap water is scraped over the surface portion of the vulva to be sampled, and the specimen is placed on a glass slide and then fixed.

The toluidine blue test (1% toluidine blue applied for 1 minute, followed by 1% acetic acid) with biopsy of the retained blue-staining areas has generally been discarded because it appears to be very nonspecific.

Colposcopy of the vulva is difficult because the characteristic changes in vascular appearance and tissue patterns that are seen in the cervix are not present (see [Chapter 28](#)). Nevertheless, the magnification of the colposcope may be used to help follow patients with VIN as well as identify the discrete whitish or pigmented areas that warrant biopsy. The colposcope is not used for routine vulvar examination but is primarily used for those who are being evaluated or followed for vulvar atypia or VIN. The addition of 3% acetic acid highlights whitish areas for biopsy.

Biopsy of the vulva can be conveniently accomplished with a Keyes dermal punch biopsy ([Fig. 30.10](#)). Usually, a 3- to 5-mm diameter punch is used. Each area in which a biopsy sample is to be obtained is usually infiltrated with local anesthesia using a fine 25-gauge needle. The punch is then rotated and downward pressure applied so that a disk of tissue is circumscribed.

When the entire thickness of the skin has been incised, the specimen is elevated with forceps and removed with a sharp scissors. Occasionally, a larger biopsy is needed, in which case a larger field is anesthetized and a small scalpel or cervical punch biopsy (see [Fig. 30-14](#) later in the chapter) is used to obtain the specimen. Usually, little bleeding is encountered and it can generally be controlled by applying silver nitrate or ferrous subsulfate (Monse's solution). Depending on the size of the atypical area and the variety of atypical-appearing areas, one or multiple biopsies may be needed.

TREATMENT

Vulvar Atypias

Most vulvar atypias have pruritus as the major symptom, so the relief of itching is often the woman's main concern. Once the correct diagnosis has been established by biopsy, appropriate therapy can be undertaken. Most whitish lesions will be benign, as lichen sclerosus is the most common condition encountered.

Topical steroids can be used for atrophic conditions of the vulva, particularly lichen sclerosus. The most commonly used option for the treatment of lichen sclerosus is 0.05% clobetasol propionate ointment. This can be used anywhere from nightly to twice weekly for up to 12 weeks and then used to re-treat,

Figure 30.6 **A**, Carcinoma in situ, histology. The full thickness of the epithelium is replaced by hyperchromatic cells with poorly defined cellular borders ($\times 80$). **B**, Carcinoma in situ, cytology. Cells derived from carcinoma in situ of the vulva may exhibit varying sizes and shapes, as depicted in this photomicrograph. Note variation in nuclear pattern from one nucleus to another. Degenerated polymorphonuclear leukocytes are present in the background ($\times 800$). **C**, Invasive squamous carcinoma, histology. Tumor nests and cords infiltrate stroma. The squamous nature of the tumor is more apparent on surface (*left*), where cells have abundant dense cytoplasm. Keratin is also seen ($\times 80$).

Figure 30.7 Vulvar epidermis with Paget disease. Malignant cells (*arrows*) are seen infiltrating the epidermis and spreading along the dermal-epidermal junction (H&E, $\times 160$). (Courtesy of Anthony Montag, MD, Department of Pathology, The University of Chicago.)

Figure 30.8 Vulva, lichen sclerosus. The tissue of the labia minora and perineum have a white, brittle, cigarette paper appearance. (From Kaufman RH, Gardner HL, Merrill JA. Diseases of the vulva and vagina. In: Romney SL, Gray MJ, Little AB, et al, eds. *Gynecology and Obstetrics*. New York: McGraw-Hill; 1980.)

Figure 30.9 Vulva, hyperplastic dystrophy. A sharply demarcated, raised, white area is noted at lower tip of white pointer. (From Kaufman RH, Gardner HL, Merrill JA. Diseases of the vulva and vagina. In: Romney SL, Gray MJ, Little AB, et al, eds. *Gynecology and Obstetrics*. New York: McGraw-Hill; 1980.)

Figure 30.10 Diagnostic Keyes punch biopsy. (From Friedrich EG. *Vulvar Disease*. 2nd ed. Philadelphia: WB Saunders; 1983.)

as necessary. Although lichen sclerosus can be associated with the development of squamous cell carcinoma as described previously, use of a potent steroid cream may offer protection from malignant evolution.

A newer class of drug, topical calcineurin inhibitors (TCIs), has been evaluated as a nonsteroidal treatment of lichen sclerosus. Both of the TCIs pimecrolimus and tacrolimus have been

compared with clobetasol. In one study, twice daily usage of pimecrolimus 1% cream was compared with once daily application of clobetasol 0.05% cream in 38 women with biopsy-proven vulvar lichen sclerosus (Goldstein, 2011). Although clobetasol was superior in improving inflammation, patients who used pimecrolimus did have some reduction in inflammation and showed equivalent improvement in pruritus and burning/pain. Another study compared nightly tacrolimus 0.1% ointment with nightly clobetasol 0.05% cream in 55 women with lichen sclerosus (Funaro, 2014). Both groups had significant improvement in disease-related symptoms, although the clobetasol group had a larger improvement. Most would agree that clobetasol should still be used as first-line therapy in the treatment of lichen sclerosus with consideration of TCIs in women who fail clobetasol or have other contraindications to topical steroid therapy.

For women who fail clobetasol and TCIs, some advocate the use of hormonal creams, although results from small clinical trials using testosterone and progesterone creams have been mixed. A preparation of 2% testosterone propionate in petrolatum can be used twice daily, with once-daily maintenance after the first week. Often, reducing the dosage of testosterone cream to twice weekly is a sufficient maintenance dose. Side effects, such as clitoral hypertrophy and increased hair growth, can occur. If there are undesirable side effects with testosterone, local progesterone cream is sometimes tried, with variable success. Those who have a beneficial response to testosterone should be continued on the medication indefinitely.

The control of local irritation of the vulva is discussed in Chapter 18 (Benign Gynecologic Lesions). In addition to local measures to diminish irritation (e.g., cotton underclothes, avoidance of strong soaps and detergents, avoidance of synthetic undergarments), topical fluorinated corticosteroids are helpful to control itching. Frequently used preparations are 0.025% or 0.1% triamcinolone acetonide (Aristocort, Kenalog), fluocinolone acetonide (Synalar), and 0.01% or 0.1% betamethasone valerate. These are usually applied twice daily to control the itching, which is often relieved in 1 to 2 weeks. Unfortunately, the prolonged use of fluorinated topical steroids can lead to vulvar atrophy and contraction. Thus once the symptoms of itching are controlled, the dose of topical corticosteroids is tapered off or, if long-term therapy is needed, a nonfluorinated compound such as 1.0% hydrocortisone is used to avoid vulvar contraction. Occasionally, 1% hydrocortisone is sufficient for initial therapy. In some cases, the corticosteroids are not successful, and numerous types of topical therapy must be tried to control symptoms. Gentle soaps are helpful. Burow's solution (5% solution of aluminum acetate) is frequently used as a wet dressing to help control irritation and itching. Doak tar, 3%, in petrolatum (USP) or in 1% hydrocortisone ointment is useful for severe cases.

In some patients with lichen sclerosus, severe contracture of the vulva, particularly in the area of the posterior fourchette, will occur with concomitant scarring and tenderness. Intercourse may then become painful for these patients. Woodruff and coworkers described a useful surgical technique to treat these vaginal outlet disorders by repair of the perineum (Woodruff, 1981). The contracted and fissured area in the posterior fourchette is excised, which results in an elliptic defect. This is then closed by undermining the distal 3 to 4 cm of the posterior vaginal mucosa and suturing the freed mucosa to the perineal skin (Fig. 30.11).

Figure 30.11 Surgical correction of perineal scars. (From Woodruff JD, Julian C. *Surgery of the vulva*. In: Ridley JH, ed. *Gynecologic Surgery: Errors, Safeguards, Salvage*. Baltimore: Williams & Wilkins; 1974.)

Vulvar Intraepithelial Neoplasia

Once the diagnosis of VIN has been established by biopsy, therapy is performed to eradicate the area containing the neoplasia. The clinician must be aware that the progress of vulvar atypia (mild dysplasia [VIN I]), to moderate dysplasia (VIN II), to severe dysplasia and carcinoma in situ (VIN III), and then to invasive carcinoma is not as well documented for vulvar neoplasia as it is for squamous cell neoplasia of the cervix. Moreover, vulvar neoplasia is frequently multifocal, requiring treatment of several areas. An additional complication is that some cases originally diagnosed as intraepithelial neoplasia have been reported to regress spontaneously.

In 1972, Friedrich reported Bowenoid atypia (histologically similar to carcinoma in situ) in a pregnant woman that regressed spontaneously postpartum (Friedrich, 1972). Others also reported spontaneous regression of this lesion. These spontaneously regressing lesions tend to be discrete elevations in young women. Some may be explained by studies of the nuclear DNA content of vulvar atypias that suggest that not all lesions with this designation are premalignant. Fu and colleagues noted that only four of eight cases of vulvar atypia had an aneuploid (neoplastic) distribution.

A polyploid distribution was noted in four of the cases, which is consistent with a benign process, whereas aneuploidy is consistent with intraepithelial neoplasia (Fu, 1981).

Although VIN has been diagnosed more commonly in younger women, the risk of progression to invasive cancer is higher for those who are older and for those who are immunosuppressed, such as women with AIDS or transplant recipients. Chafe and associates studied 69 patients with a diagnosis of VIN treated by surgical excision (Chafe 1988). Unsuspected invasion was found in 13 patients. The median age was 36 years for those without invasive carcinoma, whereas the median age was 58 years ($P = .003$) for those with invasion found in the excision specimen, emphasizing the increased risk of invasion in the older patients. Furthermore, the risk of invasion was higher in those who had raised lesions with irregular surface patterns. Thus patients who were older and those with irregular raised lesions had the greatest risk of unrecognized invasive carcinoma. A study by Modesitt and colleagues of 73 women, with a mean age of 45 years, found an invasive carcinoma in 22% of VIN III excision specimens (Modesitt, 1998). Not surprisingly, the risk of recurrence was almost 50% if the margins were positive, and only 17% if they

were negative. The risk of progression from intraepithelial disease to invasive carcinoma appears to be less for vulvar cases than for cervical disease (see [Chapter 28](#)).

Women with HIV-AIDS are also more likely to develop vulvar carcinoma in situ and invasive cancer than the general population. In a large population-based study, Chaturvedi and colleagues found a relative risk (RR) of 1.59 for developing VIN III in the 28 to 60 months after the onset of AIDS and an RR of 4.91 for developing invasive carcinoma in this group ([Chaturvedi, 2009](#)).

Studies have suggested that the potential of VIN to develop into invasive cancer is low. Buscema and coworkers followed 102 patients with vulvar carcinoma in situ for 1 to 15 years without treatment; 4 patients developed invasive disease, 2 of whom were immunosuppressed ([Buscema, 1980](#)). Unfortunately, current techniques do not allow precise prediction of which lesions of VIN are at the greatest risk of progression to invasive disease. A population-based study from Norway has confirmed an increasing frequency of VIN III that nearly tripled from the mid-1970s to 1988 to 1991 but, during the same period, the age-adjusted frequency of invasive vulvar carcinomas remained almost constant ([Iversen, 1998](#)). Iversen and Tretli further noted an estimated conversion rate of VIN III to invasive carcinoma of approximately 3.4% for these in situ lesions ([Iversen, 1998](#)).

HPV types 6 and 11 have generally been recognized as being found most often in benign vulvar warts, whereas primarily HPV types 16, 18, 31, 33, and 35 are more frequently associated with intraepithelial neoplasia or invasive carcinoma (see [Chapter 28](#)). The Centers for Disease Control and Prevention (CDC) has estimated that 80% of women aged 50 will have acquired a genital HPV infection at some point in their lives. Beutner and associates have predicted that as many as 1 million new cases of perineal warts will occur annually in the United States ([Beutner, 1998](#)). An additional complication is that HPV type 16 infection is not always accompanied by histologic evidence of VIN. Moreover, HPV types 6, 11, and 16 can be recovered from a single site, including those that show only condyloma as well as those that show carcinoma. Thus a unique role for HPV types in VIN has not been elucidated. With current data, therapy should be based on histologic findings and not on the presence or absence of HPV infection or specific HPV types. Studies by Buscema and associates have suggested that HPV type 16 is frequently found in vulvar neoplasia and, as noted, HPV 16 has been frequently associated with some vulvar carcinomas ([Buscema, 1980](#)).

Human Papillomavirus Therapy

The problem of the management of vulvar HPV infection is particularly complicated because it is extremely prevalent and the risk of progression from HPV infection to VIN is small. Planner and Hobbs evaluated 148 women with cytologic evidence of vulvar HPV infection and found that two-thirds of them had pruritus and dyspareunia ([Planner, 1988](#)). Results of the biopsy revealed that only 11 of the 148 women had VIN. Follow-up showed spontaneous regression of HPV infection in 56 patients, whereas VIN III developed in 2 and invasive cancer eventually developed in 1. It appears that the best approach is to restrict therapy to those with clinically bothersome symptoms such as warts or to eradicate lesions with VIN, particularly VIN II and III. Cytologic or histologic evidence of an asymptomatic HPV

infection, such as koilocytosis, is not an indication for therapy. Riva and colleagues treated lower genital tract HPV infection with laser to include the cervix, vagina, and vulva; 25 patients had proved subclinical HPV infection, and their male partners were also evaluated and treated ([Riva, 1989](#)). All 25 patients suffered severe pain and many required hospitalization. At 3 months after therapy, 24 of 25 again had evidence of subclinical HPV infection and 22 had persistent histologic evidence of koilocytosis, indicating the futility of trying to eradicate HPV infection by this method.

Many VIN lesions tend to be posterior, predominantly in the perineal area. Surgical removal has been effectively used, but the type of operation has been changing. In the past, simple vulvectomy was widely practiced to treat carcinoma in situ of the vulva, but this disfiguring operation is now infrequently used, particularly because the disease is occurring in younger women. To improve the cosmetic result and sexual function, Rutledge and Sinclair introduced the method of skinning vulvectomy ([Rutledge, 1968](#)). This removes the superficial vulvar skin, preserving the clitoris, and replaces the removed skin with a split-thickness vulvar graft. In many cases, however, such extensive surgery is not needed. Often, the abnormal area of the vulva can be removed only with wide local excision. Of the patients in the series reported by Buscema and coworkers, 62 were treated with local excision; 68% showed no recurrence ([Buscema, 1980](#)). For comparison, in 28 patients treated by vulvectomy, 70% showed no recurrence. The risk of recurrence is higher if neoplastic epithelium is found at the resection margin. Friedrich has noted a 10% risk of recurrence if the surgical margins are free of disease compared with a 50% risk if the surgical margins are involved with neoplasia ([Friedrich, 1980](#)). However, because recurrence may develop even if the resection margins are negative, long-term follow-up is mandatory.

The carbon dioxide laser has been used to treat VIN, usually to a depth of 1 to 3 mm, with a deeper depth being used for areas that contain hair. This results in eradication of the abnormal vulvar tissue and healing without scarring. Most patients require a single treatment but some require more, particularly those with large or multiple lesions. Usually, patients can be treated on an outpatient basis with local, regional, or general anesthesia. The laser is particularly useful for younger patients. It is essential to be certain that the woman does not have invasive disease before using the laser, so a biopsy of any suspicious lesions should be performed before laser ablation. The surgeon should be experienced in the diagnosis and treatment of vulvar disease before using laser ablation. Older patients or those with raised lesions should be treated by surgical excision. Treatment is usually carried out to a depth of 3 to 4 mm, and healing is usually complete within 2 to 3 weeks. Leuchter and associates treated 142 patients with carcinoma in situ of the vulva ([Leuchter, 1982](#)). Of the 42 treated by laser, 17% had recurrence; 4 of the 16 treated with vulvectomy (25%) and 15 of 45 treated by local excision (33%) also had recurrence. In view of the risk of unsuspected carcinoma in older patients, as noted by the studies of Chafe and colleagues (1988), those older than 45 years and those with raised or irregular lesions should have an excision performed and the entire tissue submitted for histologic evaluation. Posterior lesions near the anus require particular attention because the anal canal is often involved and this abnormal tissue also should be removed.

5-Fluorouracil (5-FU) cream has been tried to treat carcinoma in situ of the vulva, but it causes severe burning and is generally not used. Investigators have explored using 5% imiquimod cream as primary treatment for VIN III, with promising results. Van Seters and coworkers performed a randomized control study of 5% imiquimod topical cream versus placebo in 52 women with VIN II and III ([van Seters, 2008](#)). Most women included in the study (96%) were positive for HPV prior to initiation of therapy. In the treatment group, 81% had at least a reduction in the size of the primary lesion by over 25% at 20 weeks, and 35% had a complete response. In the placebo group, there were no patients with partial or complete responses. At 12 months after enrollment, 3 patients (6%), however, had progressed to microinvasive vulvar carcinoma (1 in treatment group, 2 in placebo group).

Therapeutic vaccines using HPV peptides have also been explored for the treatment of VIN III. Kenter and colleagues combined long peptides from the E6 and E7 oncoproteins of HPV 16 into a vaccine and immunized 20 women with HPV 16–positive VIN III ([Kenter, 2009](#)). At 12 months after last vaccination, 79% had a clinical response, with 47% achieving complete response. Of note, all the women who had a complete response by 12 months also remained disease free at 24 months.

Paget Disease of the Vulva

Paget disease is generally seen in postmenopausal women and typically appears grossly as a diffuse erythematous eczematoid lesion that has usually been present for a prolonged time. Itching is a common problem. The disease is primarily seen in white women and the average age is approximately 65 years. The major importance of Paget disease of the vulva is the frequent association with other invasive carcinomas. Squamous cell carcinoma of the vulva or cervix or an adenocarcinoma of the sweat glands of the vulva or Bartholin gland carcinoma may be present. Cases of adenocarcinoma of the gastrointestinal (GI) tract and breast accompanying Paget disease have also been reported. Once a diagnosis of Paget disease of the vulva is made, it is important for the gynecologist to rule out the presence of breast and GI malignancy. In a review by Fanning and associates, 20% of patients with vulvar Paget had nonvulvar malignancies including cancers of the breast, uterus, pancreas, lung, stomach, thyroid, and skin. In addition, 12% had invasive Paget disease of the vulva and 4% had invasive adenocarcinoma of the vulva ([Fanning, 1999](#)).

If no local or distant primary malignancy is uncovered, a wide excision of the affected area can be performed. It is important to remove the full thickness of the skin to the subcutaneous fat to ensure that all the skin adnexal structures are excised, because they may have a subclinical malignancy. Bergen and coworkers evaluated 14 patients with Paget disease of the vulva treated by surgery, usually vulvectomy, skinning vulvectomy with graft, or hemivulvectomy ([Bergen, 1989](#)). With a median follow-up of 50 months, all patients were free of disease, although 2 with positive margins and 1 with negative margins required treatment for recurrence. Fishman and colleagues studied 14 patients treated by various surgical procedures for Paget disease ([Fishman, 1995](#)). Frozen-section or gross visual inspection was used to judge the operative margins. In this series, visual estimation was as useful as frozen section insofar as the error rate for judging margins by the final pathology report was approximately 35%. In addition, 2 of 5 patients with positive margins had a recurrence after the initial

operation compared with 3 of 9 with negative margins. This small series therefore suggests that gross visual inspection may be as useful as frozen section when judging the extent of surgical operation. Other small series evaluating Mohs micrographic surgery for treating vulvar extramammary disease have failed to reduce recurrence significantly. A conservative approach involving removal of gross Paget disease with approximately a 1-cm margin appears to be the most appropriate, with the understanding that reexcision may be required for recurrence in the future. The full thickness of the vulvar skin to the adipose layer should be removed.

Even if resection margins are free of Paget disease at the time of surgical excision, local recurrence remains a risk. Women who have been treated for Paget disease of the vulva should have as part of their routine follow-up an annual examination of the breast, cytologic evaluation of the cervix and vulva, and screening for GI disease, at least by testing for occult blood in the stool. Progression of Paget disease of the vulva to invasive adenocarcinoma has been rarely reported.

Investigators have also explored using topical imiquimod cream as a nonsurgical therapy for extramammary Paget disease of the vulva. In one retrospective study, 21 women with Paget disease were treated with imiquimod cream and 11 (52%) had a complete response to therapy, whereas an additional 6 (29%) had a partial response with no cases of progressive disease ([Luyten, 2014](#)). As treatment of Paget disease not associated with underlying malignancies is largely for symptom control, trial of imiquimod may be a reasonable approach for patients who do not desire surgery or are not surgical candidates. In addition, as achieving negative margins with surgical resection is rare, some may consider using a course of imiquimod adjuvantly after surgical resection in an effort to reduce recurrence.

MALIGNANT CONDITIONS

SQUAMOUS CELL CARCINOMA

Squamous cell carcinomas comprise approximately 90% of primary vulvar malignancies, but a variety of other vulvar cancers are encountered; the major types are listed in [Box 30.2](#). Melanomas account for approximately 4% to 5%, and the other types make up the remainder.

Morphology and Staging

Grossly, vulvar carcinomas usually appear as raised, flat, ulcerated, plaquelike, or polypoid masses on the vulva ([Fig. 30.12, A](#)). Biopsy sample of the lesion reveals the characteristic histologic appearance of squamous cell carcinoma (see [Fig. 30.6, C](#)).

Four clinical stages are defined for carcinoma of the vulva according to the International Federation of Gynecology and Obstetrics (FIGO), similar to the system used for other gynecologic malignancies. In addition, many centers use the TNM

Box 30.2 Primary Vulvar Malignancies

- Squamous cell carcinoma

system (tumor, nodes, metastases) for classification; *T* denotes the size and extent of the tumor, *N* the clinical status of the nodes, and *M* the presence or absence of metastatic disease.

In the clinical staging system, lymph node status was assessed clinically and incorporated into the stage. Enlarged or clinically suspicious lymph nodes were assigned a higher stage, regardless of disease status documented at surgery. Clinically negative nodes were assigned an earlier stage, which was upheld even if they were found to harbor metastasis after surgical removal and pathologic examination. Therefore in 1988, the FIGO staging was modified to a surgical staging of vulvar cancer system to reflect lymph node status more accurately. In addition, a location on the perineum is no longer assigned to stage III. This system, with the modifications introduced in 2009 for new definitions of stages I to III, is shown in [Box 30.3](#).

Natural History, Spread, and Prognostic Factors

The vulvar area is rich in lymphatics, with numerous cross connections. The main lymphatic pathways are illustrated in [Figure 30.13](#). Tumors located in the middle of either labium tend to drain initially to the ipsilateral inguinofemoral nodes, whereas perineal tumors can spread to the left or right side. Tumors in the clitoral or urethral areas can also spread to either side. From the inguinofemoral nodes, the lymphatic spread of tumor is cephalad to the deep pelvic iliac and obturator nodes. Although

Box 30.3 TNM and Staging Classifications of Carcinoma of the Vulva

TNM

T: Primary tumor

Tis: Preinvasive carcinoma (carcinoma in situ)

T1: Tumor confined to the vulva or perineum, ≤ 2 cm in diameter

T2: Tumor confined to the vulva or perineum, > 2 cm in diameter

T3: Tumor of any size with adjacent spread to the urethra, vagina, anus, or all of these

T4: Tumor of any size infiltrating the bladder mucosa, rectal mucosa, or both, including the upper part of the urethral mucosa or fixed to the anus

N: Regional lymph nodes

N0: No nodes palpable

N1: Unilateral regional lymph node metastases

N2: Bilateral regional lymph node metastases

M: Distant metastases

M0: No clinical metastases

M1: Distant metastases (including pelvic lymph node metastases)

Staging (FIGO), Modified 2009

Stage I—T1/2, N0, M0: Tumor confined to vulva or perineum

IA: Lesions ≤ 2 cm in size, confined to the vulva or perineum and with stromal invasion ≤ 1 mm; no nodal metastasis

IB: Lesions > 2 cm in size or with stromal invasion > 1.0 mm, confined to the vulva or perineum, with negative nodes

Stage II—T3, N0, M0: Tumor of any size with extension to adjacent perineal structures (one third lower urethra, one third lower vagina, anus) with negative nodes

Stage III—T1-3, N1/2, M0: Tumor of any size with or without extension to adjacent perineal structures (one third lower urethra, one third lower vagina, anus), with positive inguinofemoral lymph nodes

IIIA: (i) With one lymph node metastasis (≥ 5 mm) or (ii) one or two lymph node metastasis(es) (< 5 mm)

IIIB: (i) With two or more lymph node metastases (≥ 5 mm) or (ii) three or more lymph node metastases (< 5 mm)

IIIC: With positive nodes with extracapsular spread

Stage IV—any T, any N, M1: Tumor invades other regional (two thirds upper urethra, two thirds upper vagina) or distant structures

IVA: Tumor invades any of the following: (i) upper urethral or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone; or (ii) fixed or ulcerated inguinofemoral lymph nodes

IVB: Any distant metastasis including pelvic lymph nodes

FIGO, International Federation of Gynecology and Obstetrics; TNM, tumor-node-metastasis.

there has been concern in the past that tumors in the clitoral-urethral area would spread directly to the deep pelvic nodes, this rarely, if ever, occurs. The characteristics of lymph drainage of the vulva have been evaluated by Iversen and Aas, who injected technetium-99 m colloid subcutaneously into the anterior and posterior labia majora, anterior and posterior labia minora, clitoral area, and perineum (Iversen, 1983). They then measured the radioactivity in the pelvic lymph nodes, which were surgically removed 5 hours later. More than 98% of the radioactivity was found in the ipsilateral node and less than 2% on the contralateral side. The anterior labial injections resulted in a 92% concentration of radioactivity in the ipsilateral side, with 8% on the

Figure 30.13 Vulvar lymph drainage is shown in this general schematic representation of major drainage channels of vulva.

contralateral side. The clitoral and perineal injections developed a bilateral nodal distribution of radioactivity in all the patients. It is of interest that two-thirds of the patients with labial injections had a small amount of detectable radioactivity in the contralateral nodes. Thus anastomoses of the lymphatics do exist, but a direct connection from the clitoris to the deep nodes was not demonstrated.

The prognosis of a woman with vulvar carcinoma is related to the stage of the disease (Fig. 30.14), lesion size, and the presence or absence of cancer in regional nodes.

The status of the regional lymph nodes is the most important factor prognostically and therapeutically. Numerous studies, including a multicenter collaborative investigation from the Gynecologic Oncology Group (GOG), have indicated that tumor stage, location on the vulva, microscopic differentiation, presence or absence of vascular space involvement, and tumor thickness are all important prognostic factors. In a GOG study of 588 patients reported by Homesley and colleagues, the risk of lymph node metastases was related to lesion size (19% for <2 cm and 42% for >2 cm) (Homesley, 1991). Additional independent predictors of positive nodes were as follows: (1) tumor grade; (2) suspicious, fixed, or ulcerated lymph nodes; (3) lymphovascular

Strata	Patients (N)	Mean age (years)	1 year	Overall survival at				Hazards ratio ^a

Milan, Italy: International Federation of Gynecology and Obstetrics; 1998.)

space involvement; (4) older age of the woman; and (5) tumor thickness. [Table 30.1](#) summarizes these factors.

Lymphovascular space invasion also appears to be a prognostic factor in vulvar tumors, as it is in cervical carcinoma (see [Chapter 28](#)). In a small study of 22 patients, Rowley and associates noted no metastases in 20 patients without lymphovascular space invasion and in 2 patients with lymphovascular space invasion ([Rowley, 1988](#)).

Stage IA: Carcinoma of the Vulva
(Early or Microinvasive Carcinoma)

Definition and Clinicopathologic Relationships

The term *microinvasive carcinoma of the vulva* typically refers to a lesion considered to be stage IA definition—that is, smaller than

2 cm, with less than 1 mm invasion—and is used to identify early tumors unlikely to spread to regional nodes. However, varying clinicopathologic results are reported when this definition is used.

Part of the confusion is because of different reference points from which the depth of invasion is measured—that is, from the surface or basement membrane. Dvoretzky and coworkers carefully analyzed the microscopic aspects of 36 cases of superficial vulvar carcinoma ([Dvoretzky, 1984](#)). Tumor penetration into the stroma was measured from the surface of the squamous epithelium (neoplastic thickness; [Fig. 30.15, A](#)) and also from the tip of the adjacent epithelial ridge (stromal invasion; see [Fig. 30.15, B](#)). Six of the 36 cases had spread to regional nodes, and all had invaded more than 3 mm from the surface. Yoder and associates found that

Table 30.1 Factors Related to Positive Inguinal Nodes (588 Cases)

GOG Grade	% Positive Nodes	Tumor Thickness (mm)	% Positive Nodes	Age (yr)	% Positive Nodes	LVSI	% Positive Nodes
1	2.8	≤1	2.6	<55	25.2	+	75

Figure 30.15 **A**, Measurement of neoplastic thickness in squamous cell carcinoma (×35). **B**, Superficially invasive squamous cell carcinoma. The reference point used to measure the depth of stromal invasion is demonstrated by line b. Note the striking variation in the measurement of stromal invasion, depending on which reference point is chosen (line a, b, or c; ×35). (From Dvoretzky PM, Bonfiglio TA, Helkamp BF, et al. The pathology of superficially invasive thin vulva squamous cell carcinoma. *Int J Gynecol Pathol.* 1984;3:331.)

no women with squamous cell carcinoma of the vulva invading <1 mm had nodal disease. For women with lesions invading 1 to 3 mm, the risk of nodal spread was 6% and for those with lesions invading 3 to 5 mm, the risk of nodal spread increased to 20%. Furthermore, none of the patients with tumors invading <1 mm had local recurrence at 258 months' follow-up (Yoder, 2008).

The presence of carcinoma in situ in the primary lesion decreases the risk of node involvement in these cases. Ross and Ehrman have noted that only 1 of 35 patients with adjacent carcinoma in situ had nodal metastases, and this tumor penetrated the stroma 1.7 mm (Ross, 1987). In contrast, 5 of 27 superficial stage I patients (2.1 to 5.0 mm penetration) without adjacent carcinoma in situ had positive nodes. Thus spread to regional lymph nodes in stage IA carcinoma of the vulva is unlikely, particularly if the tumor is well differentiated (grade 1), invades less than 3 mm measured from the surface, or has a depth of invasion measured from the adjacent rete pegs of less than 1 mm and is without vascular space involvement. The presence of carcinoma in situ is a favorable factor. Less well-differentiated tumors or those with vascular involvement or confluence and with greater depths of invasion have an increased risk of lymph node involvement by cancer.

Treatment

Based on available evidence, it would appear prudent that most patients with stage IA carcinoma of the vulva by the criteria described earlier should be treated at least with a wide excision to give a margin of 1 to 2 cm. Depending on the location of the tumor, a hemivulvectomy may be needed. The lymph node dissection may be omitted or deferred, depending on the final pathologic evaluation of the tumor in the surgical specimen. For younger patients, especially with tumors that involve the labia or perineum at a distance from the clitoris, an operation that spares the clitoris should be used. Even if the criteria for stage IA are rigorously applied, a rare nodal metastasis may occur, as reported by Van der Velden and associates (Van der Velden, 1992). However, a report by Magrina and coworkers on 40 patients with T1 lesions (less than 2 cm in diameter) and less than 1 mm invasion indicated that they could be effectively treated with wide excision (Magrina, 2000). No nodal metastases were noted in this small group, and excision appeared to be as effective as a more radical operation in preventing recurrent disease.

INVASIVE CARCINOMA OF THE VULVA

Figure 30.12, A, shows a typical carcinoma of the vulva, which usually appears as a polypoid mass. The woman frequently reports a sore that has not healed. She may also report bleeding, but this does not usually occur early in the course of the disease. Unfortunately, the delay in diagnosis is common because older patients frequently fail to seek prompt medical attention and, often when they do, a biopsy is not initially performed. For example, some patients with symptoms of irritation or itching are treated with various medications to eradicate the symptoms. It is vital that a biopsy sample be taken of any vulvar lesion before undertaking therapy, as was emphasized earlier. A biopsy of a tumor such as that shown in Figure 30.12, A, can easily be obtained on an outpatient basis using local anesthesia and biopsy forceps such as a Kevorkian punch as illustrated in Chapter 28, Intraepithelial Neoplasia of the Lower Genital Tract.

Effective therapy of clinical stage I or II and early stage III vulvar carcinoma can be accomplished with a wide radical excision and

inguinofemoral node dissection. Lesions located more than 2 cm from the midline typically need only an ipsilateral inguinofemoral lymphadenectomy, whereas midline lesions necessitate bilateral groin dissections. Because the deep pelvic nodes are almost never involved unless the inguinal nodes are also involved, only the inguinofemoral nodes are removed at the time of the primary operation and the deep pelvic nodes subsequently treated with external radiation if the superficial nodes are involved with tumor. The inguinofemoral node dissection is performed through separate inguinal incisions followed by the vulvectomy portion. Figure 30.12, A, shows the type of specimen that can be obtained through separate groin incisions. The operative incisions are shown in Figure 30.12, B. It appears that an adequate surgical dissection with decreased wound complications can be accomplished by this technique. It is advisable to use suction drainage in the inguinal area until all drainage is complete, which usually takes 7 to 10 days, and drains are also frequently used in the vulvar area. It is important that an adequate margin, usually 1 to 2 cm, be obtained around the primary tumor at the time of surgery. Grimshaw and colleagues reported on 100 cases operated on through separate incisions and noted superb results with a corrected 5-year survival rate in stage I of 96.7% and stage II of 85% (Grimshaw, 1993). Similar excellent results for separate skin incisions were reported by Farias-Eisner and associates on 74 patients, with 5-year survival rates of 97% and 90% for stages I and II, respectively (Farias-Eisner, 1994). Tumor recurrence has occurred rarely in the skin bridge over the symphysis when separate groin incisions are used, without an en bloc dissection of the vulva and intervening lymph tissue.

In treating clinical stage I and stage II tumors of the vulva, the results of histologic evaluation of the inguinofemoral nodes are important. Many initially treat the superficial nodes above the cribriform fascia (Fig. 30.16). If these nodes are negative, the deep nodes are spared. The procedure can usually be accomplished with preservation of the saphenous vein, which was traditionally sacrificed. These modifications reduce the risk of leg edema. If the lymph nodes, particularly the upper femoral group, are involved with tumor, the deep pelvic nodes require treatment. Homesley and coworkers reported improved survival for those who received radiation (4500 to 5000 rad) to the deep pelvic nodes in comparison with those who had a pelvic node dissection (Homesley, 1986).

The results of therapy in clinical stages I and II disease relate not only to the stage of the disease but also to the status of the regional pelvic nodes. If the nodes do not contain metastatic tumor and the woman can be successfully treated by radical vulvectomy and bilateral node dissection, 5-year survival rates of approximately 95% have been reported. Iversen and associates, in a series of 424 patients, noted lymph node metastasis in 10.5% of clinical stage I cases, 30% of clinical stage II, 66% of clinical stage III, and 100% of clinical stage IV (Iversen, 1980). The number of positive nodes in the radical vulvectomy specimen correlates with the size of the primary tumor and also with the woman's survival. In a study of T1 and T2 tumors, Andrews and coworkers noted that only unilateral inguinal node metastases occurred and, furthermore, the deep nodes were involved only if the superficial nodes were positive (Andrews, 1994). However, there was a small (2% to 3%) risk of contralateral node involvement of the larger T2 lesions. In a study of 113 patients, Hacker and colleagues noted an actuarial 5-year survival rate of 96% for those with negative nodes, but there was a progressive decrease in the survival rate to 94% for those having one positive node, 80% for two positive nodes, and 12% for three or

Figure 30.16 A and B, Injection of blue dye into vulvar lesion and identification of sentinel node in inguofemoral triangle.

more positive nodes (Hacker, 1983). In the various cases that have been studied, the deep pelvic nodes do not contain tumor unless the upper inguofemoral nodes contain metastatic disease. The number of nodes involved and the size of the metastasis are both important. Hoffman and associates noted that 14 of 15 patients with inguinal lymph node metastases smaller than 36 mm² survived free of disease at 5 years compared with 12 of 29 whose lymph node metastases measured more than 100 mm² (Hoffman, 1985). These results should be taken into consideration when planning additional therapy for patients with positive nodes.

If tumor spread to the regional inguofemoral nodes is identified, further treatment should be considered. If only one node is microscopically involved with tumor and the woman has undergone a complete lymph node dissection of the groin, no further therapy is usually needed, particularly if only a small volume is present. However, if one node is microscopically positive and the woman has undergone a superficial inguofemoral lymph node dissection, many clinicians would be uncomfortable not treating the groin with adjuvant radiation therapy. If three or more nodes are involved, pelvic radiation as outlined is usually prescribed. For patients with only two nodes involved, the decision for further therapy will depend on the location of the nodes, extent of groin dissection performed, and size of the metastatic deposit of tumor, although most clinicians would opt for radiotherapy in such cases.

ADVANCED VULVAR TUMORS

Large tumors of the vulva, particularly those that encroach on the anal-rectal area or urethra, may require more extensive treatment than radical vulvectomy to achieve effective tumor control. In such cases, it may be necessary to remove the anus or urethra as part of a primary operative procedure, in which case diversion

of the urinary or fecal stream is required (see the discussion of exenterative surgery for carcinoma of the cervix in Chapter 29, Malignant Diseases of the Cervix).

For tumors that encroach on the urethra or anus, making procurement of negative margins improbable, multidisciplinary organ-sparing approaches may be used in an effort to reduce the morbidity of exenterative procedures. A useful therapeutic approach has been to treat large vulvar tumors with external radiation and then, after the tumor has been reduced in size, to remove the residual tumor surgically, usually by radical vulvectomy. External radiation is used to deliver approximately 4000 cGy to the tumor and 4500 cGy to the pelvis and inguinal nodes. The operation is usually performed approximately 5 weeks after the completion of radiation therapy. Although a large series of patients have not been treated by this technique, a sufficient number have been treated to demonstrate that marked tumor regression does occur. The primary cancer can be eradicated by a procedure that does not require diversion of the urine or feces. Boronow and associates initially summarized the treatment of 26 patients with primary carcinoma of the vaginal vulvar area with this technique and noted a 5-year survival rate of 80% (Boronow, 1987). Rotmensch and colleagues reported on 16 patients, 13 stage III and 3 stage IV, and achieved an overall 5-year survival rate of 45% with this technique, somewhat better than might be expected with stages III and IV (see Fig. 30.14) (Rotmensch, 1990). Recurrences are more likely if the resection margins were within 1 cm of the tumor.

Chemotherapy with radiation appears to offer a therapeutic advantage. Koh and coworkers studied 20 patients with stages III and IV disease and 3 with recurrence, using 5-FU with radiation (Koh, 1993). In addition, some patients also received cisplatin with concurrent radiotherapy. Actuarial 3- and 5-year survival rates in this small group were 59% and 49%, respectively. Similar results

with 5-FU and radiation, occasionally with the addition of cisplatin, were also reported by Russell and associates in 25 patients (Russell, 1992). Moore and colleagues reported on a phase II GOG study and noted the need for a less extensive operation when chemotherapy with cisplatin and 5-FU were combined with preoperative radiation (Moore, 1998). Multiple chemoradiation programs are available, but a convenient outpatient regimen consists of weekly intravenous (IV) cisplatin with radiation, usually to 4500 cGy. Other complications reported include stenosis of the introitus, urethral stenosis, and rectovaginal fistula, but this technique is an effective alternative to primary exenteration for large vulvar vaginal carcinomas and is preferred in most treatment centers, although success with exenteration can occasionally be achieved.

Radiation Therapy and Recurrences

In a few cases, the medical condition of the woman precludes surgery, and radiation therapy may be used as the sole treatment. However, the vulvar skin is prone to radiation dermatitis, fibrosis, and ulceration, making irradiation as the sole form of therapy a less desirable treatment. Therefore irradiation is seldom used as the sole treatment of carcinoma of the vulva. To manage recurrences, reoperation is often tried. Piura and colleagues analyzed 73 patients whose disease recurred only on the vulva (Piura, 1993). Salvage was achieved with wide radical local excision, which appeared to be successful in 30 patients in whom the recurrence was only on the vulva.

As may be expected, the risk of recurring carcinoma rises as the stage of the disease increases. In an analysis of 224 patients with vulvar carcinoma, Podratz and associates noted a recurrence rate of 14% in stage I and 71% in stage IV (Podratz, 1983). Local vulvar recurrences were the most common and occurred in 40 of 74 cases of recurrence (54%). The remaining recurrences were in the groin, pelvis, or distant sites. Radiation therapy or additional operations for local vulvar recurrences usually provide effective control and yield 5-year survival rates of approximately 50%. The risk of recurrence of the disease in the vulva requires careful attention to the surgical resection margins at the time of initial operation.

Combined chemotherapy and radiation has been used for primary treatment of late-stage advanced vulvar tumors, as noted. It has also been applied to recurrences, especially those near the anus or urethra. Radiation alone may also be used for vulvar recurrences, although chemoradiation would appear to be a more effective choice.

Treatment of patients with disseminated disease requires chemotherapy but, unfortunately, no chemotherapeutic regimen has been successful for treatment of this disease. Squamous cell carcinomas of the female genital tract have generally not been responsive to cytotoxic chemotherapy; the protocols followed are similar to those described for recurrent squamous cell carcinomas of the cervix (see Chapter 29).

Quality of Life and Vulvar Carcinoma

There have been few studies regarding quality of life in patients with vulvar cancer. Body image disturbance is significant and may account for decreased or absent sexual activity in women who have undergone vulvectomy. Interestingly, Green and colleagues noted that the extent of surgery or type of vulvectomy performed does not correlate well with the degree of sexual dysfunction (Green, 2000). They demonstrated a significant need to address sexual problems with all women undergoing any type of vulvectomy. The Functional Assessment of Cancer Therapy–Vulvar (FACT-V) is a valid and reliable instrument to assess quality of life in

women with vulvar cancer. Perhaps this tool can be used to help assess quality of life and also facilitate vital communication about quality-of-life issues in women with this disease.

Lymphatic Mapping and Sentinel Lymph Node Biopsy

As noted, regional lymph node dissections are routinely performed in the surgical treatment of vulvar cancer because the status of regional lymph nodes is essential for therapeutic planning and overall prognosis. More than 80% of women with clinical stages I and II disease, however, will have no metastatic disease found in the lymph nodes, therefore making an extensive lymphadenectomy unnecessary while increasing postoperative morbidities, such as lymphedema and lymphocyst formation. Lymphatic mapping and sentinel lymph node biopsy, as used for the treatment of patients with melanoma and breast cancer, are appealing techniques for patients with vulvar cancer. The sentinel nodes are those that directly drain the primary tumor and are thought to predict the metastatic status of the upper echelon or nonsentinel nodes in the groin. If the sentinel node is negative, in theory, all the other groin nodes would also be negative and surgeons could abandon full groin dissections, thereby greatly reducing the associated morbidities of lymphocyst, lymphedema, and wound separation (see Fig. 30.16).

Van der Zee and colleagues performed a prospective observational study in 403 women with clinical stage I squamous cell carcinoma of the vulva smaller than 4 cm (GROningen International Study on Sentinel nodes in Vulvar cancer [GROINSS-V]) (Van der Zee, 2008). Women enrolled in this study underwent a sentinel node biopsy, with omission of complete inguinofemoral lymphadenectomy if no metastatic disease was found. Patients with negative sentinel nodes were triaged to no further therapy and observed for recurrence. With a median follow-up of 35 months, only six groin recurrences (2.3%) have been noted in patients without multifocal disease. In a validation study, Levenback and colleagues set out to determine the true sensitivity and negative predictive value of the sentinel node technique in 453 women with vulvar cancer (GOG 173) (Levenback, 2012). In contrast to GROINSS-V, all women in GOG 173 underwent a sentinel node biopsy followed by a complete inguinofemoral lymphadenectomy. They found a sensitivity of 90.1% and a negative predictive value of 95.7%. Therefore if the sentinel node was negative, there was only a 4.3% chance that disease was present in that groin (false negative predictive value). In an accumulation of data from smaller studies on the subject, Frumovitz and colleagues reviewed the combined data on 279 patients with vulvar cancer who had undergone lymphatic mapping and sentinel lymph node identification (Frumovitz, 2008). They found the overall sensitivity of the sentinel node for detecting metastatic disease in patients with vulvar cancer to be 97.7% and the false-negative rate for the procedure to be 2.3%. The overall negative predictive value was 99.3%. Although these numbers are promising, at this time, lymphatic mapping and sentinel lymph node biopsy are considered experimental, with the standard of care remaining full inguinofemoral node dissection.

OTHER VULVAR MALIGNANCIES

Bartholin Gland Carcinoma

Bartholin gland carcinomas are adenocarcinomas that constitute approximately 1% to 2% of vulvar carcinomas. An enlargement of Bartholin gland in a postmenopausal woman should raise

suspicion for this malignancy. These tumors are treated similarly to primary squamous cell carcinoma of the vulva; radical vulvectomy with bilateral inguofemoral lymphadenectomy is the treatment of choice. If the regional lymph nodes are free of tumor, the prognosis is good.

Basal Cell Carcinoma

Basal cell carcinoma can arise in the vulva, as it can arise in the skin elsewhere in the body. It is rare and comprises approximately 2% of vulvar carcinomas. Therapy consists of wide local excision of the lesion, which is generally ulcerated. If the surgical resection margins are free of tumor, the disease is cured.

Verrucous Carcinoma

Verrucous carcinomas of the vulva are also rare. They are a special variant of squamous cell cancer, with distinctive histologic features. Clinically, they appear as a large condylomatous mass on the vulva. Histologically, they consist of mature squamous cells and extensive keratinization, with nests that invade the underlying vulvar tissue. It is often necessary to perform multiple biopsies of the condylomatous lesion to establish a diagnosis of malignancy. Radiation therapy is ineffective and can worsen the prognosis by causing anaplastic changes in the tumor and is therefore contraindicated. The treatment of an authentic verrucous carcinoma is wide excision.

In 24 cases of verrucous carcinoma, Japaze and coworkers noted no lymph node metastases (Japaze, 1982). Some of the primary tumors were as large as 10 cm in diameter. Recurrences developed in nine patients, five of whom had previous radiation therapy. Wide local excision is effective therapy. Depending on the size and location of the tumor, simple vulvectomy may be needed, but a radical vulvectomy or inguinal node dissection is not indicated. The 17 patients treated surgically and reported by Japaze and colleagues had a 5-year survival rate of 94%. It is important to take a large biopsy specimen to establish the diagnosis. This is particularly important when dealing with a malignant-appearing tumor from a biopsy specimen that has been reported as benign, which can lead to incorrect therapy for condyloma acuminatum. Conversely, too shallow a biopsy may fail to show areas of squamous cell carcinoma that can coexist with verrucous carcinoma, but in the presence of areas of squamous cell carcinoma, local excision is inadequate therapy. Verrucous tumors with squamous cell carcinoma elements can metastasize to regional nodes; these tumors should not be treated as true verrucous carcinomas.

Melanoma

Melanoma is the most frequent nonsquamous cell malignancy of the vulva. It comprises approximately 5% of primary cancers of this area. As is true elsewhere in the body, melanomas arise from junctional or compound nevi. Pigmented lesions of the vulva are usually junctional nevi and all such lesions should be removed by excision.

Patients with malignant melanoma of the vulva vary widely in age, from the late teens to women in their 80s. The average age is approximately 50 years. Clinically, melanomas appear as brown, black, or blue-black masses on the vulva. The lesion can be flat or ulcerated; occasionally, it is nodular, and small, darkly pigmented areas (satellite nodules) may surround the primary lesion. Some melanomas may be without pigment and can grossly resemble squamous cell carcinoma of the vulva. Most

melanomas of the vulva occur on the labia minora or the clitoris (Fig. 30.17).

Vulvar melanomas, if staged, use the same FIGO classification used for squamous carcinomas. However, staging is not as useful a prognostic indicator as is the depth of invasion. A staging system for vulvar melanoma analogous to that used by Clark for cutaneous melanomas has been adopted. Five levels (I to V) have been defined based on the Clark classification. Figure 30.18 shows the depth of invasion for each level of superficial

Figure 30.17 Nodular melanoma arising directly from glans clitoris. (Courtesy of Dr. J.M. Morris [deceased], Yale University School of Medicine, New Haven, CT.)

Figure 30.18 Level of invasion for superficial spreading melanoma and nodular melanoma. (From Podratz KC, Gaffey TA, Symmonds RE, et al. Melanoma of the vulva: an update. *Gynecol Oncol.* 1983;16:153.)

spreading melanoma and nodular melanoma, the two most common varieties of melanomas that occur on the vulva. Superficial spreading melanoma is more common and, fortunately, has a better prognosis, with a 5-year survival rate of 71% reported in the series by Podratz and associates (Podratz, 1983). The 5-year survival for nodular melanoma, which is more invasive, was only 38%. The level of invasion correlates with survival, which varies from 100% for level II, to 83% for level IV, to 28% for level V.

Tumor thickness is also useful to evaluate the tumor. Breslow has reported that overall prognosis is excellent, and spread to a regional node is not likely for melanomas whose thickness is less than 0.76 mm, measured from the surface epithelium to the deepest point of penetration (Breslow, 1970). Most of these lesions would correspond to level I or II penetration by the modified Clark system. Stefanon and coworkers, in a study of 28 patients, noted no lymph node metastasis if melanoma thickness was less than 3 mm; the 5-year survival rate in this group was 50% compared with 25% for those whose melanomas were more than 3 mm thick (Stefanon, 1987). In a comprehensive long-term study of 219 Swedish women, Ragnarsson-Olding and coworkers noted that tumor thickness and ulceration are prognostic factors (Ragnarsson-Olding, 1999). In addition, gross amelanosis and advanced age worsened the prognosis. They further noted that amelanotic tumors were seen in approximately 25% of patients and that overall the vulvar melanomas were approximately 2.5 times more frequent than cutaneous melanomas. A preexisting nevus was not necessary; *de novo* melanoma development does appear to occur on the vulva, particularly in the glabrous (hairless) skin.

The standard therapy for vulvar melanoma is a wide excision of the primary tumor. Because the tumors are rare, a large clinical experience is not available. It was believed that melanoma of the vulva could metastasize to pelvic nodes, bypassing the inguinofemoral nodes, but it is now thought that there is no pelvic node involvement without previous inguinal node involvement. A further therapeutic consideration is that patients with melanoma whose pelvic nodes are involved with tumor usually do not survive the disease.

Excision margins have been extensively studied for cutaneous melanomas. Veronesi and colleagues found that cutaneous melanomas less than 2 mm thick could be adequately treated with a 1-cm margin, which was as effective as a 3-cm margin for these thin lesions (Veronesi, 1988). Although comparable data do not exist for vulvar melanomas, evidence from studies of cutaneous

melanomas has suggested that a 1-cm margin may be used for very thin vulvar melanomas. In a report of 36 melanoma cases, Rose and associates noted that wide excision was as effective as radical vulvectomy (Rose, 1988). They found that the prognosis was improved in younger patients, presumably because most of them had superficial spreading (good prognosis) rather than nodular (poor prognosis) melanomas. Although firm recommendations from available data are not possible, a reasonable approach would be to excise a melanoma with a 2-cm margin without node dissection for tumors that are smaller than 0.76 mm thick. An excision with a 2- to 3-cm margin combined with node dissection would be carried out for more advanced melanomas.

For lesions that correspond to Clark's level 1 or 2—that is, less than 0.76 mm thick—a wide local excision results in 5-year survival rates of approximately 100%. The prognosis is poor for patients with melanomas more than 3 mm thick. If the regional nodes are negative, the survival rate is greater than 60% but decreases to less than 30% if the regional nodes are involved with tumor. Most series of malignant melanoma have reported overall survival rates of approximately 50%. Although metastases of melanoma to regional inguinal nodes are usually fatal, isolated prolonged survivals have been observed.

Distant metastases are frequently noted, and no effective program of chemotherapy has been described. Regressions (but not cures) have been reported with various multiagent cytotoxic programs. Current efforts are devoted to developing an effective program of bioimmunotherapy.

Sarcoma

Sarcomas of the vulva are extremely rare, accounting for less than 3% of vulvar cancers. Leiomyosarcomas are the most common histologic subtype found, followed by liposarcomas, neurofibrosarcomas, angiosarcomas, and epithelioid sarcomas. Surgical removal of the primary tumor is the treatment of choice. Chemotherapeutic considerations are the same as those for sarcomas of other sites in the female genital tract.

Granular Cell Myoblastomas

Granular cell myoblastoma is also an extremely rare tumor that is almost invariably benign but morphologically shows pleomorphism. Local excision is generally sufficient therapy. The tumor appears as a solitary, firm, nontender, slowly growing nodule in the subcutaneous tissue of the vulva.

KEY POINTS

- Squamous cell carcinomas constitute 90% of primary vulvar malignancies. More than 80% of patients are older than 50 years at the time of diagnosis.
- Cancer of the vulva accounts for approximately 4% of malignancies of the lower female genital tract and occurs less frequently than uterine, ovarian, and cervical cancers.
- Paget disease generally occurs in postmenopausal women and is usually treated by wide excision. Invasive carcinomas at other sites should be ruled out.
- Prolonged use of fluorinated corticosteroids to treat itching accompanying vulvar dystrophy can lead to vulvar contraction.
- Topical testosterone is sometimes beneficial to treat lichen sclerosus but is absorbed systemically and occasionally can produce masculinizing symptoms.
- Studies have indicated that symptomatic lichen sclerosus is a premalignant condition preceding carcinoma by a mean of 4 years. The tumors that develop tend to be clitoral in location and identified in patients older than age 40 years.
- HPV vulvar infection is common. Intraepithelial neoplasia occurs much less frequently.
- HPV-positive tumors tend to occur in younger patients, and these tumors tend to have a better prognosis than HPV-negative tumors.

Continued

KEY POINTS—cont'd

- A clear progression of dysplasia–carcinoma in situ (VIN I, II, and III) to invasive carcinoma in the vulva has not been clearly established. VIN may spontaneously regress. VIN III has an approximately 3.4% risk of progression to invasive carcinoma.
- Intraepithelial neoplasia of the vulva is usually treated by local excision. Laser therapy of the atypical area may be used for younger patients who do not have raised lesions.
- Vulvar carcinomas less than 2 cm in diameter and depth of invasion less than 1 mm (3-mm thickness) rarely metastasize to regional nodes.
- Unilateral vulvar tumors (>2 cm from midline) usually metastasize to ipsilateral inguinofemoral nodes only.
- Prognosis in vulvar cancer is primarily related to lesion size, lymph node status, and stage.
- The risk of lymph node groin metastases is related to tumor differentiation, lesion thickness, lymphovascular space involvement, patient age, and tumor size.
- The deep pelvic nodes do not become involved with metastatic vulvar cancer unless the inguinofemoral nodes are affected.
- The 5-year survival rate of vulvar carcinoma with negative nodes is more than 95%. With one positive node, the 5-year survival is approximately the same, 94%; with two nodes, it decreases to 80% and with three or more to 12%.
- Advanced vulvar tumors encroaching on the urethra or anus may be treated by radiation followed by wide radical excision rather than exenteration. Enhanced results have also been reported with the combined use of chemotherapy and radiation.
- Verrucous carcinomas are a variant of squamous cancer that do not metastasize to regional nodes. Radiation therapy is contraindicated, and local surgical excision is the treatment of choice.
- Melanomas constitute 5% of vulvar cancers and are the most frequent nonsquamous cell malignancies.
- The overall 5-year survival of patients with vulvar melanoma is approximately 50%.
- Superficial spreading melanomas tend to occur in younger patients and have a better prognosis than nodular melanomas.
- Prognosis of vulvar melanoma is related to tumor invasion (Clark's level) and to tumor thickness.
- Basal cell carcinoma of the vulva is treated by wide local excision.

Malignant Diseases of the Vagina Intraepithelial Neoplasia, Carcinoma, Sarcoma

Diane C. Bodurka, Michael Frumovitz

This chapter focuses on premalignant and malignant diseases of the vagina. Premalignant changes in the vagina occur less frequently than comparable lesions in the cervix and vulva. However, the histologic appearance of intraepithelial neoplasia of the vagina is similar to that described for the cervix (see [Chapter 28](#)). These changes are also similarly designated as dysplasia (mild, moderate, or severe) and carcinoma in situ. The term *VAIN* (*v*aginal *i*ntraepithelial *n*eoplasia) has been used to describe these histologic changes; the comparable categories are VAIN-1 (mild dysplasia), VAIN-2 (moderate dysplasia), and VAIN-3 (severe dysplasia to carcinoma in situ). VAIN-1 is classified as a low-grade squamous intraepithelial lesion, whereas VAIN-2 and VAIN-3 are grouped as high-grade squamous intraepithelial lesions ([Audet-Lapointe, 1990](#)). The cytologic and histologic features of these changes are illustrated in [Figure 31.1](#).

VAIN occurs more commonly in patients previously treated for cervical intraepithelial neoplasia. The frequency of vaginal premalignancy in these patients is approximately 1% to 3%. Similarly, there is an increased risk of VAIN in those previously treated for squamous cell neoplasia of the vulva. The tendency to develop premalignant changes in the lower genital tract is known as a *field defect* and denotes the increased risk of squamous cell neoplasia arising anywhere in the lower genital tract in such individuals. Most VAIN cases are related to infection with human papillomavirus (HPV). Additional risk factors include HIV infection, cigarette smoking, previous radiation therapy of the genital tract, and immunosuppressive therapy. In situ and invasive vaginal neoplasias have many of the same risk factors as cervical cancer, including a strong association with HPV infection. Women who have previously been treated for anogenital cancer, particularly for cervical cancer, have a high relative risk of being diagnosed with vaginal cancer ([Shrivastava, 2015](#)).

Primary cancer of the vagina is rare and constitutes less than 2% of gynecologic malignancies. Most vaginal malignancies are metastatic, primarily from the cervix and endometrium. Less commonly, ovarian and rectosigmoid carcinomas, as well as choriocarcinoma, metastasize to the vagina. The most common histologic type of primary vaginal cancer is squamous cell carcinoma, which is usually seen in women older than 60 years. Other types of carcinoma, including melanomas and adenocarcinomas, occur less commonly. Malignant transformation of endometriosis has been described in the vagina and rectovaginal

septum. Clear cell adenocarcinoma, historically associated with young women exposed in utero to diethylstilbestrol (DES), may also occur in unexposed women. Primary vaginal sarcomas are rare and are usually a disease of children. [Table 31.1](#) summarizes the major primary malignancies of the vagina arranged according to age at occurrence.

PREMALIGNANT DISEASE OF THE VAGINA

DETECTION AND DIAGNOSIS

Because premalignant disease of the vagina is generally asymptomatic, detection depends primarily on cytologic screening (see [Fig. 31.1, B and D](#)). Usually, the changes will be observed in patients who have undergone previous therapy for intraepithelial disease of the cervix. This fact underscores the importance of continued examinations and Pap smears for women, even after hysterectomy for dysplastic conditions. VAIN usually occurs in the upper half of the vagina or along the vaginal cuff suture line. Once an abnormal smear from vaginal epithelium is identified, a biopsy is required for histologic identification (see [Fig. 31.1, A and C](#)). A colposcopic examination is usually performed to identify the areas requiring biopsy. As in the case of cervical neoplasia, a repeat Pap smear is often taken before the colposcopic examination. Vaginal colposcopic techniques are similar to those described for the cervix. A large speculum is used to aid in visualizing the entire vaginal wall. Although the abnormal colposcopic findings resemble those of the cervix (see [Chapter 28](#)), full visualization of the entire vaginal wall is often difficult and time consuming. A useful adjunct to colposcopy for identifying an area in which to perform a biopsy is to stain the vaginal epithelium with Lugol's solution and to take a biopsy sample from the nonstaining areas. The vaginal epithelium must be adequately estrogenized so that sufficient epithelial glycogen is present for the normal tissue to stain dark brown. The more rapidly dividing dysplastic epithelium uses up its glycogen and thus does not pick up the iodine stain. Vaginal estrogen cream used for 1 to 2 weeks before examination is helpful for evaluating postmenopausal women and those with atrophic vaginitis who present with cytologic atypia. The estrogen cream will not only increase epithelial glycogen but also helps mature the squamous epithelium, reducing the number of parabasal cells at the surface. Parabasal cells,
