Gill et al. (65) compared patients undergoing laparoscopic partial nephrectomy ($n = 100$) with open nephron-sparing surgery ($n = 100$) for a solitary ≤7 cm tumor. The median tumor size was 2.8 versus 3.3 cm in the laparoscopic versus open group, respectively ($p = 0.005$). The tumor was located centrally in 35% of cases in the laparoscopic group and in 33% of cases in the open group ($p = 0.83$). Indication for partial nephrectomy was imperative in 41% versus 54% of patients, respectively ($p = 0.001$). Comparing the laparoscopic and open groups, median surgical time (3 vs. 3.9 hrs; $p < 0.001$) and blood loss (125 vs. 250 mL; $p < 0.001$) were lesser in the laparoscopic group, while warm ischemia (warm ischemia) time was longer during laparoscopic partial nephrectomy (28 vs. 18 min; $p < 0.001$). Laparoscopic patients experienced less postoperative analgesia (20.2 vs. 252.5 mg of morphine sulfate equivalents; $p < 0.001$), shorter hospital stay (2 vs. 5 days; $p < 0.001$), and quicker convalescence (4 vs. 6 weeks; $p < 0.001$). Histology revealed renal cell carcinoma in 75% of patients in the laparoscopic group and 85% in the open group ($p = 0.003$). Positive surgical margins occurred in 3% and 0%, respectively ($p = 0.11$). Intraoperative and renal/urologic complications were higher in the laparoscopic (5% and 11%, respectively) versus open (0% and 2%, respectively) group ($p = 0.02$ and 0.01, respectively). No local or port-site recurrence occurred in the laparoscopic group. Based on these data, the authors concluded that although open partial nephrectomy remained the standard nephron-sparing surgery for renal tumors, laparoscopic partial nephrectomy was emerging as an effective minimally invasive alternative. At the Cleveland Clinic, the senior author's experience with laparoscopic partial nephrectomy now exceeds 420 cases (Table 4). In the initial 300 patients (66), the indication for laparoscopic partial nephrectomy was imperative in 40% of patients, median warm ischemia time was 32 minutes, median operative time was 3.3 hours, and median hospital stay was 2.6 days. Pathology confirmed renal cell carcinoma in 71% of patients.

MULTIPLE TUMORS

Renal cell carcinoma may be multifocal at presentation in 6.5–25% of cases, and satellite tumors may be detected in 15.6% of cases (67,68). Although many consider radical nephrectomy (open or laparoscopic) as the standard of care for such cases, consensus is lacking. A recent report demonstrated the feasibility of performing minimally invasive nephron-sparing surgery in the setting of multiple renal tumors. A total of 27 multiple tumors in 13 patients were treated by a combination of minimally invasive treatments (69). The indication for nephron-sparing surgery was imperative in 92% of patients. Minimally invasive treatments performed included en bloc excision of adjacent tumors during laparoscopic partial nephrectomy (three); individual laparoscopic partial nephrectomy of discrete, distant masses (two); laparoscopic partial nephrectomy of one mass and laparoscopic cryoablation of the other (two); and laparoscopic cryoablation of all masses (six). Mean tumor size treated by laparoscopic partial nephrectomy was 2.5 cm (range, 1–4.1), mean size of masses treated by cryotherapy was 1.8 cm (range, 0.9–3.2), mean operative time was 4.3 hours, and mean blood loss was 169 mL. Mean warm ischemia time was 40 minutes in patients treated with laparoscopic partial nephrectomy for adjacent masses, and 30 minutes in patients undergoing laparoscopic partial nephrectomy and cryotherapy. No intraoperative complications occurred. Postoperative complications included pneumonia (one), deep venous thrombosis treated with systemic anticoagulation and vena cava filter (one), and sepsis (one). Pathology confirmed renal carcinoma in 83% of all excised specimens with negative margins. Core needle biopsies before cryoablation showed renal carcinoma in 54% of specimens. After a mean follow-up of 16.4 months (range, 1–54), disease did not recur either locally or systematically in any patient. A new ipsilateral, distant from cryotherapy site, tumor developed in one patient 54 months postoperatively. The authors concluded that the judicious combination of complementary minimally invasive techniques was safe and efficacious.

TABLE 4 ■ Laparoscopic Partial Nephrectomy at the Cleveland Clinic: Single-Surgeon Experience in the Initial 300 Cases

Parameter	No. (%)
Median age (years)	62

CONCOMITANT ADRENALECTOMY

Incidence of adrenal involvement from renal cell carcinoma is 1–2% (70). Candidates for nephron-sparing surgery for an upper pole tumor may present with contiguous involvement of the adrenal gland (pT$_{3a}$ tumor) or hematogenous involvement of the gland (M$_1$ tumors) (71). In such cases, partial or radical nephrectomy with concomitant adrenalectomy is indicated. Ramani et al. (72) reported concomitant ipsilateral adrenalectomy during laparoscopic partial nephrectomy in four patients with an upper pole renal tumor and suspected adrenal involvement. Preoperative three-dimensional computed tomograpgy scan revealed renal tumor abutting the adrenal gland in three patients, and a 4-cm adrenal mass in one patient. Using a transperitoneal approach, en bloc adrenalectomy was performed first, followed by laparoscopic partial nephrectomy. The adrenal gland was maintained en bloc with the partial nephrectomy specimen. No intraoperative complication occurred, and open conversion was not necessary in any patient. Urinary leak occurred in one patient. One (25%) renal tumor was confirmed renal cancer case on pathology, while all adrenals (three normal adrenal glands and one adenoma) were free from malignant involvement. The authors highlighted some caveats, including adrenalectomy before laparoscopic partial nephrectomy to respect oncologic principles, no dissection between the adrenal and the renal upper pole to prevent tumor spillage and lymphatic violation, prevention of excessive manipulation of the reconstructed kidney to maintain renal parenchymal hemostasis, and limitation of warm ischemia to laparoscopic partial nephrectomy only.

COMPLICATIONS

Numerous studies regarding open nephron-sparing surgery present data on technical and renal-related complications secondary to partial nephrectomy (Table 5) (76,77). Urinary fistula is the most frequent complication following nephron-sparing surgery. Other complications include hemorrhage, ureteral obstruction, and acute or chronic renal insufficiency. Corman et al. (78) compared complications after open radical ($n =$ 1373) and open partial ($n = 512$) nephrectomy. Analyzing surrogate-to-complication morbidities (progressive renal insufficiency, acute renal failure, UTI, prolonged ileus, postoperative transfusion requirement, and deep wound infection), no significant differences were detected ($p = 0.58$) between radical nephrectomy and nephron-sparing surgery in specific complication rates (Table 6).

The most common complications of laparoscopic partial nephrectomy include intraoperative or delayed hemorrhage, urine leak, and open conversion (Table 7). In the first 200 consecutive patients undergoing laparoscopic partial nephrectomy from August 1999 to January 2003 at the authors' institute (80), perioperative complications occurred in 66 patients (33%). Open conversion was required in two patients (1%) due to dense postsurgical adhesions (one), and persistent bleeding secondary to inadequate renal hilum clamping (one). Reoperative laparotomy was necessary in four patients (2%) for delayed hemorrhage after discharge (two), ischemia of the colon (one), and leakage from the ileoileal anastomosis in one patient undergoing laparoscopic ileal ureter for inadvertent ureteral injury during laparoscopic partial nephrectomy. Overall, hemorrhagic complications (Table 8) occurred in 19 patients (9.5%), of whom 18 required blood transfusion. Intraoperative hemorrhages ($n = 7$; 3.5%) were due to bulldog malfunction (three), Satinsky clamp malfunction (one), systemic coagulopathy (one), or inadequate control of multiple renal arteries (two). Intraoperative hemorrhage was managed with laparoscopic parenchymal suturing in five patients, laparoscopic radical nephrectomy in one patient with normal contralateral kidney, and emergent open conversion in one patient. Four patients (2%) developed postoperative bleeding from the partial nephrectomy bed at a mean interval of two days; all responded to conservative management. Delayed hemorrhagic complications after hospital discharge occurred in eight patients (4%) at a mean interval of 16 days (range, 6–30). Etiology of the delayed hemorrhage included vigorous exercise (one), accidental fall (one), coagulopathy (one), systemic heparinization (one), intraoperatively unrecognized splenic tear (one), or unknown (three). Patients with delayed hemorrhage were treated conservatively (four), or with percutaneous selective angioembolization (two); two patients underwent explorative laparotomy. Urinary leak occurred in nine patients (4.5%), eight (89%) of whom had intraoperative suture repair of pelvicalyceal entry during laparoscopic partial nephrectomy. Management included J-stenting in six patients, J-stenting and CT-guided drainage in two patients, or conservatively in one patient. Other urological complications occurred in 4.5% of patients and included transient renal

insufficiency (four), inferior epigastric artery injury (one), epididymitis (one), transient hematuria (one), and ureteral injury (one). Non-urological complication occurred in 15% of patients including pulmonary (ten), cardiovascular (nine), musculoskeletal (five), gastrointestinal (four), or septic (two).

Complications occurring after laparoscopic partial nephrectomy and laparoscopic radical nephrectomy for renal tumors ≤4.5 cm were recently assessed by Kim et al. (64). In the laparoscopic partial nephrectomy group (*n* = 79), mean operative time was 3 hours, mean warm ischemia time 26.4 minutes (range, 13–37), and mean blood loss 391.2 mL. Four patients (5.1%) had hemorrhages requiring blood transfusion, with one open conversion. Specific intraoperative complications during laparoscopic partial nephrectomy included one ureteral injury, one lumbar vein injury, and one splenic capsule injury treated laparoscopically. Two cases of postoperative urinary leak were treated conservatively with suction drains. However, comparing laparoscopic partial nephrectomy with the laparoscopic radical nephrectomy group, no significant differences were noted as regards specific complications. Positive surgical margin were detected in two laparoscopic partial nephrectomy patients (2.5%), of whom one underwent laparoscopic radical nephrectomy, while a 26-month disease-free follow-up was observed in the other patient.

HEMOSTATIC AIDS AND IMPACT OF FLOSEAL

The specific technical challenge of laparoscopic partial nephrectomy lies in achieving a bloodless operative field for precise tumor excision and pelvicalyceal repair followed by renal hemostasis in a time-sensitive manner, with the least possible compromise of renal function. Achieving prompt and durable hemostasis is of paramount importance. Several techniques of parenchymal hemostasis during laparoscopic partial nephrectomy have been reported with varying success, including cauterization of the cut surface with argon beam coagulation, electrocautery, harmonic scalpel, gelatin

sponges and fibrin glue application, microwave thermotherapy, ultrasonic surgical aspirator, laser (holmium:neodymium:YAG laser), or prior radiofrequency coagulation (62,80–86). Physical compression of the kidney using parenchymal tourniquets and cable tie devices has been described in an attempt to achieve regional vascular control during polar partial nephrectomies (48,88,89).

Gettman et al. (85) performed laparoscopic partial nephrectomy with the assistance of radiofrequency coagulation technique in 10 patients with a solid renal lesion. A spherical area of coagulation including both the lesion and a 1-cm margin (at least) of normal parenchyma was created by deploying a percutaneously positioned radiofrequency probe. After probe withdrawal, the lesion and 0.5–1 cm of normal parenchyma were excised using laparoscopic scissors or ultrasound shears. Median blood loss was 125 mL, and complete hemostasis was reported in all cases. However, insufficient deployment of the RF probe in one patient resulted in large blood loss (700 mL) due to incomplete coagulation of a margin. Thus, adjunctive agents (fibrin glue, argon beam coagulation, or oxidized cellulose) were necessary. Negative margins were confirmed by frozen section analysis of 5 mm cup biopsies from the surgical bed.

Biologic hemostatic agents have been employed to facilitate hemostasis during laparoscopic partial nephrectomy (90,91). Fibrin sealant (glutaraldehyde cross-linked fibers derived from bovine collagen) application facilitates the last step of the clotting cascade (fibrinogen to fibrin conversion). Further, cross-linking of soluble fibrin monomers creates an insoluble fibrin clot acting as a vessel sealant. The gelatin granules (500–600 μm size) swell upon contact with blood and create a composite hemostatic plug with physical bulk that mechanically controls hemorrhage independently from the natural coagulation cascade (92).

Bak et al. (93) used gelatin matrix thrombin tissue sealant for achieving effective hemostasis during laparoscopic partial nephrectomy in six patients. Their technique consisted of thrombin gel slurry application to the cut parenchymal surface after tumor

resection, followed by a 1–2 minutes compression of the resected surface with a sponge stick. After releasing the previously positioned hilar clamp, hemostasis was obtained within 5–10 minutes. No bleeding occurred after clamp removal, and no blood transfusions were required. The collecting system was not entered in any patient. Median operative time was 3.2 hours (range, 1.5–3.9), median warm ischemia time was 13 minutes (range, 10–14), and median blood loss was 200 mL (range, 50–350). Although the use of this bioadhesive was reserved for selected, small, exophytic, superficial tumors not requiring pelvicalyceal entry, the results of this study, particularly as regards shortened warm ischemia time, were encouraging.

The capability of the biologic hemostatic sealant Floseal[®b] in facilitating hemostasis during laparoscopic partial nephrectomy was recently evaluated at the authors' institute (94). After completing the initial 224 laparoscopic partial nephrectomies, from patient number 225 onwards the author's laparoscopic partial nephrectomy technique (51) was modified to incorporate topical application of the gelatin matrix thrombin sealant (Floseal) to cover the partial nephrectomy bed prior to sutured renorrhaphy over a bolster. The prepackaged hemostatic sealant comprised $1.5 \, cm^3$ of dry bovine-derived gelatin matrix provided in one syringe, and 5000 U.S. units of bovine-derived thrombin provided in a vial, which was drawn up in a second syringe. The two were admixed, thereby creating $4 \, cm^3$ of gelatin matrix thrombin slurry in a single syringe. This syringe was connected by luer lock to a 14Fr, 30 cm long reusable metal delivery cannula introduced into the abdomen through a 5 or 10/12 mm laparoscopic port. The slurry was layered directly onto the renal surface, covering the entire partial nephrectomy bed. Surgical bolster was then positioned and renorrhaphy sutures secured prior to hilar unclamping. Usually, two vials of Floseal were employed per patient. The gelatin matrix and thrombin slurry were used within 2–3 minutes of being admixed (if allowed to stand for a longer duration of time, the slurry becomes more viscid, making it difficult to inject through the metal cannula). Postoperative strict bed rest for 24–48 hours, followed by restricted activity for two weeks, was prescribed. The impact of Floseal on reducing hemorrhagic complications was evaluated by comparing two sequential groups of patients: group I = no Floseal ($n = 68$), and group II = with Floseal ($n = 63$). Group I (no Floseal) and group II (with Floseal) were comparable as regards tumor size, number of central tumors, and performance of pelvicalyceal suture repair (84% vs. 92%; $p = 0.16$). Intraoperative variables were also comparable as regards mean warm ischemia time (36.1 vs. 37.2 minutes; $p = 0.55$), blood loss (150 vs. $106 \, cm^3$; $p = 0.36$), operative time, and hospital stay. Compared to the no Floseal group, the Floseal group had significantly decreased overall complications (37% vs. 16%; $p = 0.008$), and tended towards a lower rate of hemorrhagic complications (12% vs. 3%), although this did not achieve statistical significance ($p = 0.08$). In the authors' experience, adjunctive use of gelatin matrix thrombin sealant substantially enhanced parenchymal hemostasis and decreased procedural and hemorrhagic complications to levels comparable with contemporary open partial nephrectomy series. As such, this gelatin matrix–thrombin tissue sealant has become a routine part of laparoscopic partial nephrectomy at our institution. However, we emphasize that ready facility with laparoscopic suturing is important to manage persistent hemorrhage occurring despite the use of gelatin matrix thrombin sealant.

Urena et al. (95) reported their initial experience with a monopolar radio frequency device[c] to perform laparoscopic partial nephrectomy without clamping the renal vasculature. A monopolar device that uses radio frequency energy with low-volume saline irrigation (4–$6 \, cm^3$/min) was employed for simultaneous blunt dissection, hemostasis, and coagulation (coagulation power of 80 W on a regular electrosurgical generator) of the renal parenchyma. Technical characteristics of this technology included precoagulation of soft tissue with simultaneous sealing of small-sized blood vessels, parenchymal thermal coagulation depth directly proportional to the type and duration of contact between the device and the parenchyma, and saline-facilitated energy transfer at the tissue–device interface preventing tissue desiccation and smoke production. The study was conducted on 10 patients with a mean tumor size of 3.9 cm (range, 2.1–8). Mean operative time was 3.9 hours (range, 2.4–4.7), and mean blood loss was 352 mL (range, 20–1000). Technical difficulties due to posterior tumor location led to open conversion in a morbidly obese patient. Blood transfusion was required in one case, and mean hospital stay was 1.7 days (range, 1–5). Postoperative complications included urinary leak managed by ureteral stenting in one patient. Pathology confirmed renal cancer case in

80% of patients, with negative margins in all cases; no interference with pathological evaluation of surgical margins due to tissue charring were reported.

IMPACT OF WARM ISCHEMIA

Hemostasis remains a primarily task during laparoscopic partial nephrectomy. Temporary en bloc renal hilar clamping allows a bloodless field with enhanced visualization during tumor excision and renal repair. Supported by experimental and clinical data, several modalities of hilar control during laparoscopic partial nephrectomy have been advocated, including the clamping of the renal artery alone, both renal artery and vein, and intermittent occlusion (96–98). Advantages and disadvantages of these means are still debated (99,100), yet conclusive data are not available. Critical renal ischemia time has generally been considered to be a 30-minute cutoff (101). In this setting, eventual recovery requires three days. laparoscopic partial nephrectomy may require somewhat longer ischemic times compared to open nephron-sparing surgery (65). Nevertheless, complete recovery of renal function after 60 minutes of warm ischemia has been reported (102,103).

Shekarriz et al. (104) prospectively evaluated the impact of warm ischemia on postoperative renal function in 17 patients undergoing transperitoneal laparoscopic partial nephrectomy with hilar clamping for exophytic tumors. Preoperative and postoperative differential glomerular filtration rate and renal function was evaluated in all patients by technetium-99-labeled diethylenetetraminepenta-acetic acid renal scans performed one month before and three months after laparoscopic partial nephrectomy. Mean operative time was 3.1 hours (range, 1.5–4.8), mean warm ischemia time 22.5 minutes (range, 10–44), mean blood loss 305 cm^3 (range, 50–1000), and mean hospital stay 2.15 days (range, 1–3). Postoperative complications included pulmonary edema in one patient, and arteriocalyceal fistula in one patient. Preoperatively, mean creatinine was 0.89 mg/dL (range, 0.7–2), mean glomerular filtration rate in the target kidney was 75.56 mL/min (range, 39.4–105), and mean differential renal function of the target kidney was 50.2% (range, 43–58%). On postoperative evaluation at three months mean serum creatinine was 0.96 mg/dL (range, 0.7–1.9), mean glomerular filtration rate in the operated kidney was 72.03 mL/min (range, 31–101), and mean differential renal function in operative kidney was 48.07% (range, 39–63%). Hilar clamp time did not significantly correlate with change in renal function, or change in glomerular filtration rate. The authors concluded that temporary hilar clamping during laparoscopic partial nephrectomy with a mean warm ischemia time of 22.5 minutes was safe in patients with functioning contralateral kidney.

We evaluated the impact of renal hilar clamping-induced warm ischemia on renal function in 179 patients undergoing laparoscopic partial nephrectomy for tumor at our center (105). Attention was focused on 15 patients undergoing laparoscopic partial nephrectomy for tumor in a solitary kidney, and on 12 patients with both functioning kidneys who had objectively documented differential renal function (preoperative and one-month postoperative serum creatinine levels and radionuclide renal scans) undergoing unilateral laparoscopic partial nephrectomy. Overall mean warm ischemia time was 31 ± 10 minutes (range, 4–55). For further analysis, the entire study population was stratified according to (i) warm ischemia time (warm ischemia ≤ 30 minutes; warm ischemia ≥ 30 minutes); (ii) warm ischemia and age (≥ warm ischemia < 30 minutes; warm ischemia > 30 minutes; age < 70 years; age (70 years); and (iii) warm ischemia and baseline serum creatinine (≥ warm ischemia < 30 minutes; warm ischemia > 30 minutes; serum creatinine < 1.5 mg/dL; serum creatinine (1.5 mg/dL). In this study, no kidney was lost due to ischemic sequelae. The nadir postoperative serum creatinine in patients with a solitary kidney was commensurate with the approximate amount of renal parenchyma resected. Temporary postoperative hemodialysis was required after 60% laparoscopic heminephrectomy in one patient with a 6.5 cm tumor in a solitary kidney. Comparing preoperative and one-month postoperative renal scans in the 12 patients with both functioning kidneys, calculated reduction of function from baseline in the operated kidney was 29%. Expectedly, unilateral laparoscopic partial nephrectomy in the setting of bilateral functioning kidneys did not show significant impact on serum creatinine. The authors concluded that a warm ischemia time of approximately 30 minutes leads to minimal clinical sequelae.

LAPAROSCOPIC RENAL HYPOTHERMIA

Warm ischemia dramatically limits the time available to perform tumor resection and collecting system and parenchymal repair during laparoscopic partial nephrectomy,

forcing the surgeon to operate "under the gun" in a race against time. As such, techniques to achieve viable renal hypothermia by minimally invasive methods have been described. The initial described technique of laparoscopic renal hypothermia was reported by Gill et al. (106) first described the technique of laparoscopic renal hypothermia. Intracorporeal surface contact renal hypothermia was performed in 12 patients. After complete mobilization, the kidney was entrapped in an Endocatch-II bag[d], whose drawstring was cinched around the intact hilum. The renal hilum was then occluded with a Satinsky clamp; the bottom of the bag was retrieved through a 12 mm port site, opened, and 600–750 mL of ice-slush delivered into the bag with 30 mL syringes within a period of 4–7 minutes. Needle thermocouples confirmed achievement of protective levels of hypothermia, with core renal temperatures in the 5–19°C range.

Janetschek (107) achieved kidney cooling by continuous perfusion of 1000 mL of cold (4°C; perfusion rate = 50 mL/min) Ringer's lactate through an angiocatheter placed into the clamped renal artery in 15 patients undergoing laparoscopic partial nephrectomy for renal cell carcinoma. At a parenchymal temperature of 25°C, a steady state was maintained by reducing the perfusion rate to 25–33 mL/min. Tumor excision was performed in a bloodless field. Mean ischemia time was 40 minutes (range, 27–103). Increased blood loss was noted in two initial patients: in one due to inadequate intraluminal balloon occlusion and in the other due to perfusion pump malfunction causing venous backflow from the injured renal vein. Blood transfusion was necessary in another patient. Reoperative laparoscopy was performed in one patient for postoperative hemorrhage. The feasibility and safety of cold ischemia via arterial perfusion during laparoscopic partial nephrectomy was demonstrated. However, since optimal hypothermic renoprotection from ischemia occurs with temperatures <15°C, these techniques need further refinement to deliver adequate levels of hypothermia.

Renal hypothermia has also been achieved by retrograde pelvicalyceal cold saline perfusion via a ureteral access sheath. Clinical application of this technique was described in a patient undergoing open radical nephrectomy. Cortical and medullary temperatures obtained were 24°C and 21°C, respectively, which are somewhat higher than optimal hypothermia temperature of 15°C (108).

ONCOLOGIC OUTCOMES

Tumor cell seeding is a major concern in laparoscopic surgery. The first reported cases of tumor seeding in urologic laparoscopy were noted after lymphadenectomy or node biopsies for bladder and prostate cancer in four and one patients, respectively. However, a specimen entrapment sac was not used in any of these initial cases (109). One of the most common sites of tumor seeding is the port where the specimen is retrieved. To date, a few cases of tumor seeding after laparoscopic renal surgery have been reported: three cases occurring after laparoscopic radical nephrectomy, and four cases after laparoscopic nephroureterectomy (61,110). Theoretically, tumor seeding during laparoscopic partial nephrectomy may occur due to high risk of tumor perforation or tumor cell spillage by contaminated instruments. In a recent survey undertaken by Micali et al. (111), 18,750 urologic laparoscopic procedures performed between 1990 and 2003 were considered, of which 10,912 were for tumor, and 555 were laparoscopic partial nephrectomies. Although the overall incidence of tumor seeding was 0.1% (13 of 10,912), no cases of tumor seeding after laparoscopic partial nephrectomy were noted in this study.

In order to become a standard procedure for the treatment of small renal tumors, long-term follow-up tumor-free survival rates of laparoscopic partial nephrectomy should approach those of open partial nephrectomy. However, results regarding local and distant cancer control have been excellent over the short- and intermediate-term follow-up available to date. Rassweiler et al. (61) reported no evidence of recurrent disease in 100% of 37 patients undergoing laparoscopic partial nephrectomy for stage T_1 renal cancer case at a mean follow-up of two years. Allaf et al. (112) evaluated oncological outcome of laparoscopic partial nephrectomy in 48 patients with pT_1 (42 patients, 87.5%) or pT_{3a} (six patients, 12.5%) renal carcinoma. Positive surgical margin rate was 2.1%. Histology demonstrated clear cell in 32 patients (67%), and papillary in 10 (21%). Laparoscopic extraction of a morcellated specimen was performed in 22.9% of cases. At a mean follow-up of 37.7 months (range, 22–84), no recurrences were noted

---

in 95.8% of patients. Local recurrence occurred at 18 months in a patient with von Hippel-Lindau disease, and at four years in the ipsilateral kidney of a patient who underwent laparoscopic partial nephrectomy with specimen morcellation for a pT_1 (2 cm) Fuhrman grade II clear cell tumor. From the oncological standpoint, these data are comparable with those after open nephron-sparing surgery.

IMPACT OF PELVICALYCEAL SUTURE REPAIR

Precise entry into the collecting system is often necessary to provide a safe margin of resection during laparoscopic excision of intraparenchymal, deeply infiltrating tumors. Desai et al. (47) compared the perioperative data of 27 patients undergoing laparoscopic partial nephrectomy with pelvicalyceal entry (group I) with 37 patients undergoing laparoscopic partial nephrectomy with no pelvicalyceal entry (group II). Mean depth of parenchymal tumor invasion was 1.5 ± 0.8 cm in group I and 0.9 ± 0.3 cm in group II. Precise intraoperative localization of collecting system entry during laparoscopic partial nephrectomy was obtained by retrograde injection of dilute indigo carmine through a previously placed ureteral catheter. Mean warm ischemia time was longer in group I versus group II (30.2 vs. 19.4 minutes; $p < 0.0001$). Pelvicalyceal suture repair was associated with longer hospital stay (3 vs. 1.8 days; $p = 0.003$). No patient undergoing pelvicalyceal entry and suture repair developed urinary leak. The authors concluded that, although laparoscopic partial nephrectomy for a tumor extending up to the collecting involves freehand laparoscopic suturing, resulting in somewhat longer, although acceptable, warm ischemia time good outcomes can be expected with a low incidence of urinary leakage.

Recently, Bove et al. (99) specifically evaluated the necessity of ureteral stenting for decreasing urinary leak after laparoscopic partial nephrectomy for single, localized, unilateral, sporadic, ≤ 4.5 cm renal tumors. Patients undergoing 5Fr open-ended ureteral catheter placement prior to laparoscopic partial nephrectomy (group I, $n = 54$) were compared with patients without ureteral catheter placement (group II, $n = 49$). Postoperative urinary leak (drain urinary output $> 50\ cm^3$ per 24 hours) occurred in one patient in each group. In both these patients, the pelvicalyceal system had been suture-repaired intraoperatively during laparoscopic partial nephrectomy. Both urinary leaks were successfully managed conservatively with suction drains. The authors concluded that preoperative placement of a ureteral catheter for retrograde injection to identify collecting system entry was not routinely necessary (62). However, at the Cleveland Clinic, we continue to routinely employ a ureteral catheter because of the following reasons: (i) it is the only way to precisely identify the location of pelvicalyceal entry, (ii) occasionally, pelvicalyceal entry can occur at two different locations, which would be difficult to locate precisely without retrograde injection after one entry site has been repaired, and (iii) retrograde injection allows testing the water-tightness of pelvicalyceal suture repair.

Alternative techniques of pelvicalyceal repair were proposed by other investigators, including sealing of the laparoscopic partial nephrectomy bed using oxidized regenerated cellulose mesh impregnated with gelatin resorcinol formaldehyde glue, and fibrin-impregnated hemostatic gauze or heat-activated tissue adhesive (54,61). In the former experience, postoperative urinoma occurred despite an indwelling double-J stent in 14% of patients; in the latter (a multi-institutional experience on 53 patients), 10% of patients who underwent laparoscopic partial nephrectomy required reintervention (nephrectomy, percutaneous drainage, or ureteral stenting) for postoperative urinoma formation (113).

LAPAROSCOPIC HEMINEPHRECTOMY

Our careful expansion of laparoscopic partial nephrectomy indications included select patients with more complex tumors such as upper pole tumor with concomitant adrenalectomy, tumor invading deeply into the parenchyma up to the collecting system or renal sinus, tumor abutting the renal hilum, tumor in a solitary kidney, and more recently, a tumor substantial enough to require heminephrectomy (47,72). Finelli et al. (114) evaluated technical efficacy and outcomes of laparoscopic heminephrectomy for large and/or deeply infiltrating tumors requiring a substantial resection (defined herein as >30%) resection of the renal parenchyma. Since August 1999, 41 patients were deemed to have undergone laparoscopic heminephrectomy (group I). A contemporary group of 41 consecutive patients who underwent laparoscopic partial nephrectomy

(<30% resection) were retrospectively identified for comparison (group II). Preoperative patient demographics were similar, except for a higher BMI ($p = 0.02$) in group I. Group I had larger tumors (3.7 vs. 2.3 cm, $p < 0.001$), which were more commonly central (41% vs. 9.8%, $p = 0.001$) and more deeply infiltrating ($p < 0.001$) compared to group II. Group I underwent larger parenchymal resections ($p < 0.001$) and routine pelvicalyceal suture repair ($p = 0.002$). Warm ischemia time was longer in group I (39 vs. 33 minutes, $p = 0.02$); however, blood loss (150 vs. 100 mL, $p = 0.28$) and total operative time (3.7 vs. 3.2 hours, $p = 0.09$) were comparable between the groups. Analgesic requirements, hospital stay, overall complications, and postoperative serum creatinine were comparable between the groups. On histopathology, all 82 surgical margins were negative. The authors concluded that although laparoscopic heminephrectomy is an advanced procedure, it can be performed efficaciously with equivalent outcomes to outcomes equivalent to those of less substantial resections.

CENTRAL VS. PERIPHERAL TUMOR

Centrally located tumors typically require precise intracorporeal suturing and complex reconstruction. As such, in the past they have not been approached laparoscopically due to the added time constraints imposed by renal ischemia. Only a limited experience in eight patients with central tumors using a hand-assisted technique has been reported (115). Open partial nephrectomy remains the gold standard for the treatment of centrally located tumors (116,117). Frank et al. (118) specifically addressed the outcomes of pure laparoscopic partial nephrectomy for central tumors and compared with peripherally located tumors. In 363 patients undergoing laparoscopic partial nephrectomy, tumors were located centrally in 154 patients, and peripherally in 209. Central tumors were defined as tumors touching, abutting, or directly invading the collecting system on the preoperative three-dimensional computed tomography. Lesions with no contact with the pelvicalyceal system were classified as peripheral. Preoperative, intraoperative, postoperative, and pathologic data were compared. Central tumors were larger in size on preoperative imaging (median 3.0 vs. 2.4 cm, $p < 0.001$) and had larger specimens at surgery (median 43 vs. 22 g, $p < 0.001$) than peripheral tumors. Although blood loss was similar (150 cm^3), central tumors required longer operative times (3.5 vs. 3 hours, $p = 0.008$), warm ischemia times (33.5 vs. 30.0 minutes, $p < 0.001$), and hospital stay (67 vs. 60 hours, $p < 0.001$). The incidence of margin positivity was 0.8% versus 1.7% ($p = 0.502$) for the central and peripheral groups. The median postoperative creatinine was 1.2 and 1.1 mg/dL for central and peripheral lesions, respectively. Intraoperative and late postoperative complications were comparable. However, there were more early postoperative complications in the central group (6% vs. 2%, $p = 0.05$).

HILAR CLAMPING VS. NON-CLAMPING

Guilloneau et al. (119) compared 12 patients undergoing laparoscopic partial nephrectomy with renal hilar clamping versus 16 patients undergoing laparoscopic partial nephrectomy without hilar control. The non-clamping group experienced significantly greater blood loss (708 vs. 270 mL; $p = 0.014$) and longer operative time (3 vs. 2 hours; $p = 0.004$) compared to laparoscopic partial nephrectomy with hilar clamping. Postoperative serum creatinine levels were not significantly different (1.3 vs. 1.45 mg/dL, respectively; $p = 0.08$) between groups. In another study, Kane et al. (120) compared 15 patients undergoing laparoscopic partial nephrectomy with arterial occlusion with 12 patients undergoing laparoscopic partial nephrectomy without arterial occlusion. A nonsignificant 10% postoperative increase of serum creatinine from preoperative baseline levels was observed in each group. Postoperative renal failure did not develop in any patient, and hemodialysis was not required. In nine patients, postoperative technetium-99 mercaptoacetyl triglycine renal scan revealed near equal split (49% vs. 51%) of postoperative renal function reflecting minimal impact of mean warm ischemia time of 43 minutes (range, 25–65). The authors concluded that temporary artery occlusion had no measurable negative effect on renal function.

EFFECT OF TUMOR SIZE

Steinberg et al. (Steinberg AP, Matin SF, Gill IS. Effect of tumor size on laparoscopic partial nephrectomy. Personal communication) evaluated the effect of tumor size by

retrospectively dividing 100 patients undergoing laparoscopic partial nephrectomy into three groups: patients with a tumor <2 cm in size (group I, $n = 15$); patients with a tumor size of 2–4 cm (group II, $n = 76$); and patients with a tumor size >4 cm (group III, $n = 9$). Comparing groups I, II, and III, increasing tumor size associated with significantly longer operative time (2.9 vs. 3.1 vs. 3.9 hours, respectively; $p = 0.03$), greater blood loss (75 vs. 150 vs. 200 mL, respectively; $p = 0.001$), more frequent need of collecting system entry and suture repair (47% vs. 64% vs. 89%, respectively; $p = 0.004$), and higher incidence of complications (13% vs. 25% vs. 33%, respectively; $p = 0.02$). No differences were noted in terms of warm ischemia time ($p = 0.65$) and hospital stay ($p = 0.16$). Pathology showed renal cancer case in 53%, 74%, and 67% of patients in group I, II, and III, respectively ($p = 0.33$). The authors concluded that laparoscopic partial nephrectomy could be performed safely and effectively for select patients with a tumor larger than 2 cm in size.

LAPAROSCOPIC PARTIAL NEPHRECTOMY FOR CYSTIC MASSES

Scant data are available as regards laparoscopic nephron-sparing surgery for cystic lesions. Many centers employ laparoscopic techniques for the management of symptomatic renal cysts. However, the risk of potential seeding of cells due to inadvertent tumor spillage during laparoscopic cyst manipulation remains a concern in laparoscopic partial nephrectomy for indeterminate renal cysts. Thirty-five patients with a complex renal cyst were evaluated laparoscopically by Santiago et al. (121). No local or distant recurrence was noted in all five patients (14%) with cystic renal cancer case after a mean follow-up of 20.2 months. The authors recently updated this experience and presented long-term follow-up results in 57 patients with indeterminate Bosniak II and III cystic lesions. None of the 11 patients (19%) found to have cystic renal cancer case had evidence of laparoscopic port site, renal fossa, local or distant recurrence at a mean follow-up of 40 months (122).

Spaliviero et al. (123) recently reported their experience with laparoscopic partial nephrectomy in 50 patients with a cystic renal lesion. Of 284 patients undergoing laparoscopic partial nephrectomy at the Cleveland Clinic since August 1999, 50 (19%) patients presented with a suspicious Bosniak $\geq$ II cystic lesion on preoperative computed tomograpgy scan (group I). Outcome data were retrospectively compared with 50 consecutive patients undergoing laparoscopic partial nephrectomy for a solid renal mass (group II). Mean tumor size was 3 cm in group I and 2.6 cm in group II ($p = 0.07$). Perioperative parameters were comparable in groups I and II. Final histopathology revealed renal cancer case in 20%, 25%, 46%, and 90% of patients with Bosniak II ($n = 10$), II ($n = 4$), III ($n = 13$), and IV ($n = 20$) cysts, respectively. All patients had negative surgical margin. Inadvertent intraoperative puncture/spillage of the cystic tumor did not occur in any instance in patients in group I. Mean follow-up was 14 months (range, 1 month to three years). The solitary recurrence in the entire series of 284 laparoscopic partial nephrectomy cases occurred in group I at one year in a patient who, despite negative surgical margins during initial laparoscopic partial nephrectomy, developed retroperitoneal recurrent disease that was resected open surgically at one year. The authors concluded that although laparoscopic partial nephrectomy nephrectomy for a suspicious cystic mass was feasible and efficacious, extreme caution and refined laparoscopic technique had to be exercised to prevent cyst rupture and local spillage.

LAPAROSCOPIC PARTIAL NEPHRECTOMY FOR HILAR TUMORS

Partial nephrectomy for hilar tumor represents a technical challenge not only for laparoscopic but also for open surgeons. Tumors located in the region of the renal hilum, in actual physical contact with the main renal vessels, have been considered by many to be beyond the scope of laparoscopic techniques. Further, the application of probe-ablative therapies such as cryoablation and radio frequency ablation for hilar tumors have the real potential of causing thermal injury to the renal vascular endothelium, resulting in thrombosis.

Gill et al. (124) recently reported the technical feasibility and perioperative outcomes of laparoscopic partial nephrectomy for hilar tumors. In 362 patients undergoing laparoscopic partial nephrectomy for tumor by a single surgeon between 01/2001 and 09/2004, 25 (6.9%) had a hilar tumor. Hilar tumor was defined as a tumor located in the renal hilum and demonstrated to be in physical contact with the renal artery and/or renal vein on preoperative three-dimensional computed tomography. En bloc hilar clamping with cold excision of tumor, including its delicate mobilization from the

renal vessels, followed by sutured renal reconstruction was performed routinely. Laparoscopic surgery was successful in all cases, without any open conversion or operative reintervention. Mean tumor size was 3.7 cm (range, 1–10.3); four patients (16%) had a solitary kidney, and indication for laparoscopic partial nephrectomy was imperative in 10 (40%). Pelvicalyceal repair was performed in 22 patients (88%): mean warm ischemia time was 36.4 minutes (range, 27–48), blood loss was 231 cm^3 (range, 50–900), total operative time was 3.6 hours (range, 2–5), and hospital stay was 3.5 days (range, 1.5–6.7). Histopathology confirmed renal cancer case in 17 patients (68%), all with negative margins. Hemorrhagic complications occurred in three patients (12%), all in 2002 or prior. No kidney was lost for technical reasons. The authors offered five specific caveats for performing laparoscopic partial nephrectomy in the setting of a hilar tumor: (i) preoperative three-dimensional computed tomograpgy scan with 3 mm cuts and video rendering to accurately assess (a) laparoscopic resectability as regards anatomic characteristics of the tumor and (b) the individual surgeon's comfort level in performing laparoscopic partial nephrectomy for that particular tumor; (ii) considerable dissection of the renal artery and/or vein towards the renal sinus to dissect the tumor off the renal vessels prior to hilar clamping; (iii) tumor excision to be performed in a preplanned manner from a lateral to medial direction to allow safer initial renal parenchymal and subsequent tumor retraction out of the partial nephrectomy bed (on occasion, direct feeding blood vessels entering the tumor directly from the main renal artery and/or vein can be identified, clipped, and divided); (iv) dedicated inspection to identify any arteriotomy, venotomy, or pelvicalyceal entry, and its precise suture repair, with routine use of Floseal as a hemostatic adjunct, as needed; (v) extreme care during sutured renal reconstruction not to compromise the main arterial blood supply and venous drainage of the renal remnant.

LAPAROSCOPIC PARTIAL NEPHRECTOMY IN THE SOLITARY KIDNEY

A patient with a renal tumor in a solitary kidney has an absolute indication for nephron-sparing surgery. Scant data are available in this regard. Gill et al. (65), measuring serum creatinine results in a cohort of eight patients with a solitary kidney who underwent laparoscopic partial nephrectomy for renal tumor, examined the effects of laparoscopic partial nephrectomy on renal function. Analysis of serum creatinine on postoperative day 1 and the repeat serum creatinine value within 30 days showed a mean change of 0.07 mg/dL after 30 days, which was comparable to open surgery.

Bhayani et al. (125) reported laparoscopic partial nephrectomy in four patients with a tumor in a solitary kidney. All four patients had undergone prior contralateral radical nephrectomy for renal cell carcinoma. Mean tumor size was 2.2 cm (range, 1.8–2.8). A transperitoneal approach was employed in all instances. Mean operative time was 4.2 hours, mean warm ischemia time 15 minutes (range, 7–28), mean blood loss 395 mL (range, 100–800), and mean hospital stay three days (range, 2–4). No perioperative complications occurred. Pathology confirmed renal cancer case in 75% of cases, all with negative margins. No evidence of disease had been detected at a mean follow-up of 17 months (range, 3–35). The mean preoperative baseline serum creatinine was 1.5 mg/dL (range, 1.0–1.8). Postoperative return to baseline creatinine required three days in three patients, and longer in one patient (six postoperative weeks). As previously assessed (9), none of the patients presented long-term change in renal function.

TRANSPERITONEAL VS. RETROPERITONEAL LAPAROSCOPIC PARTIAL NEPHRECTOMY

Ng et al. (126) has been recently retrospectively compared the outcomes of 100 transperitoneal and 63 retroperitoneal laparoscopic approach to partial nephrectomy for tumor. Choice of laparoscopic approach was dictated primarily by tumor location: transperitoneal laparoscopic partial nephrectomy for anterior or lateral lesions and retroperitoneal laparoscopic partial nephrectomy for posterior or posterolateral lesions. The approaches differed primarily by technique of hilar control since en bloc hilar control was achieved with a Satinsky clamp during transperitoneal laparoscopic partial nephrectomy, while during retroperitoneal laparoscopic partial nephrectomy individual control of renal artery and vein was obtained with two bulldog clamps. retroperitoneal laparoscopic partial nephrectomy was employed to manage 77% of posterior tumors,

whereas 97% of anterior tumors were managed with transperitoneal laparoscopic partial nephrectomy. Transperitoneal laparoscopic partial nephrectomy was associated with significantly larger tumors (3.2 vs. 2.5 cm, $p < 0.001$), more calyceal suture repairs (79% vs. 57%; $p = 0.004$), longer ischemia time (31 vs. 28 minutes; $p = 0.04$), longer operative time (3.5 vs. 2.9 hours; $p < 0.001$), and longer hospital stay (2.9 vs. 2.2 days; $p < 0.01$) compared to retroperitoneal laparoscopic partial nephrectomy. Blood loss, perioperative complications, postoperative serum creatinine, analgesic requirements, and histologic outcomes were comparable between the groups. The authors concluded that limited retroperitoneal space makes retroperitoneal laparoscopic partial nephrectomy technically more challenging but provides superior access to posterior, particularly posteromedial, lesions. However, whenever feasible, they preferred the transperitoneal approach for laparoscopic partial nephrectomy because of its larger working area for intracorporeal renal reconstruction. Also, transperitoneal laparoscopic partial nephrectomy was the preferred approach for all anterior or lateral tumors, as well as large or deeply infiltrating posterior tumors that required substantive guillotine resection (heminephrectomy).

FINANCIAL ANALYSIS

Data comparing cost effectiveness of laparoscopic versus open approach to renal tumor resection are scant. During laparoscopic partial nephrectomy, increased costs due to longer operating room time and more expensive equipment may be balanced by shorter length of hospital stay and shorter convalescence time. Retrospective case-matched studies comparing open radical nephrectomy versus open partial nephrectomy costs have shown comparable hospital costs ($p = 0.81$) (77).

Steinberg et al. (127) from Cleveland performed a preliminary, retrospective comparison of the financial data of 15 patients undergoing laparoscopic partial nephrectomy versus 15 patients undergoing open partial nephrectomy. All patients in the two groups had a normal contralateral kidney, comparable tumor size (2.4 cm in the laparoscopic partial nephrectomy group vs. 2.5 cm in the open group, $p = 0.50$), and uncomplicated perioperative course. When compared to the open group, the laparoscopic partial nephrectomy group was associated with 20.1% greater intraoperative costs ($p < 0.001$) and 55% lesser postoperative costs ($p < 0.001$). Overall, hospital costs for laparoscopic partial nephrectomy were 15.6% lesser than open surgery ($p = 0.002$).

HAND-ASSISTED LAPAROSCOPIC PARTIAL NEPHRECTOMY

In order to simplify and increase viability of laparoscopic partial nephrectomy, some surgeons have employed a hand-assisted laparoscopic approach of nephron-sparing surgery surgery. Stifelman and colleagues (128) reported their experience with hand-assisted laparoscopic partial nephrectomy (without hilar clamping) in 11 patients. Direct parenchymal compression through the hand port, argon-beam coagulator, and adjunctive agents (e.g., oxidized cellulose) were employed to control hemostasis. Mean operative time was 4.5 hours, mean blood loss 319 mL, and mean hospital stay 3.3 days. One patient required open conversion.

Comparing 10 LPNs (hand-assisted in eight patients) with a matched group of open partial nephrectomies, Wolf et al. (81) reported longer operative times (+24%) and increased blood loss in the hand-assisted group. However, pain medication requirements (−62%), hospital stay (−43%), and convalescence (−64%) were lesser in the hand-assisted group. In another study, Brown et al. (115) reviewed their initial series of 30 hand-assisted laparoscopic partial nephrectomy, comparing the results of central (<5 mm from the collecting system or hilum; $n = 8$) versus peripheral ($n = 22$) lesions. After tumor excision using endoscopic cold scissors, argon beam coagulation followed by fibrinogen-soaked sponge application (subsequently activated with thrombin) was employed to control hemostasis. No hilar clamping was performed. As regards the entire series, mean tumor size was 2.6 cm (range, 1–4.7), mean blood loss 415 mL (range, 50–2100), and mean operative time 3.6 hours (range, 90–332). When compared with peripheral lesions, centrally located lesions were associated with greater blood loss (240 ± 113 vs. 894 ± 552 cm^3, respectively), and higher rate of blood transfusion (9.1% vs. 50%, respectively) due to intraoperative or delayed hemorrhage, or symptomatic anemia. Resection of the laparoscopic partial nephrectomy bed was necessary in five

cases due to positive initial resection margin on frozen section (100% negative margin after re-resection). Considering the 3–4-fold increase in blood loss, transfusion rate, and a urinary leak associated with laparoscopic partial nephrectomy for central lesion, the authors suggested the utility of hilar clamping in this setting.

FOLLOW-UP

Patients undergoing laparoscopic nephron-sparing surgery for renal cancer case are advised to return for initial follow-up four weeks postoperatively. At that time, physical examination to exclude surgical complications, serum hemoglobin and hematocrit to assess recovery of perioperative blood loss, serum creatinine measurement, and a MAG-3 radionuclide renal scan are obtained to document renal function and anatomy. In patients with impaired overall renal function, a renal ultrasound or a magnetic resonance imaging is performed instead of the renal scan.

Hafez et al. (129) developed guidelines for long-term surveillance after nephron-sparing surgery for renal cancer case. Tumor recurrence patterns after nephron-sparing surgery for sporadic localized renal cancer case were analyzed in 327 patients. renal cancer case recurred postoperatively in 11.7% of patients. According to initial pathologic tumor stage, they reported the incidence of postoperative local tumor recurrence and metastatic disease as follows: 0% and 4% for T_1 renal cancer case, 2% and 5.3% for T_2 renal cancer case, 8.2% and 11.5% for T_{3a} renal cancer case, and 10.6% and 14.9% for T_{3b} renal cancer case. They recommended a surveillance scheme including annual evaluation of medical history, physical examination, and selected blood studies (serum calcium, alkaline phosphatase, liver function tests, blood urea nitrogen, serum creatinine, and electrolytes). A 24-hour urinary protein measurement should be obtained in patients with a solitary remnant kidney to screen for hyperfiltration nephropathy. Patients who undergo nephron-sparing surgery for pT_1 renal cancer case do not require radiographic imaging postoperatively. A yearly chest radiograph is recommended after nephron-sparing surgery for pT_2 or pT_3 renal cancer case. Abdominal computed tomograpgy scanning is indicated every two years in patients with pT_2 renal cancer case, and every six months for two years, then every two years in patients with pT_3 renal cancer case.

FUTURE DIRECTIONS: HYDRO-JET TECHNOLOGY

Future directions include potentially bloodless renal parenchymal incision without hilar clamping with the use of hydro-jet technology. This technology employs a high-pressure water jet to perform selective tissue dissection in a relatively bloodless manner. Spared intrarenal vessels may then be controlled with clips or bipolar coagulation, and the renal collecting system suture repaired (130). Basting et al. (131) reported the initial clinical experience using water jet resection in 24 patients undergoing open surgery for renal-cell carcinoma, nephrolithiasis, complicated cysts, or oncocytoma. The hydro-jet device produces parenchymal incision along the desired line without violating the intrarenal vasculature and collecting system. Resection time ranged from 14 to 40 minutes, and intraoperative blood loss was reportedly minimal. No significant postoperative complications occurred. Histologic investigation of tissue samples with standard light microscopy after hematoxylin–eosin staining demonstrated sharp tissue incision with no thermal alterations or deep necrosis and only a small disruption zone at the dissection margins. The authors concluded for the efficacy of water jet dissection in organ-sparing kidney surgery. Recent series regarding the use of hydro-jet during laparoscopic partial nephrectomy in the animal model showed promising results. Shekarriz et al. (130) and Corvin et al. (132) have recently performed detailed evaluations of the hydro-jet device in the porcine animal model. Moinzadeh et al. (133) staged bilateral laparoscopic partial nephrectomy without renal hilar vessel control using the Helix Hydro-jet[®d] in a survival bovine model. Parenchymal hydro-dissection was performed with a high velocity ultracoherent saline stream at 450 pounds per square inch (psi) through a small nozzle with integrated suction at the tip. The denuded intrarenal parenchymal blood vessels were precisely coagulated with a bipolar instrument (BIClamp[®d]) and transected. All LPNs were completed successfully without open conversion. Eighteen of 20 LPNs (90%) were performed without hilar clamping. Mean hydro-jet partial nephrectomy time was 63 minutes (range, 13–150), estimated blood

---

[d]ERBE, Tubingen, Germany.

loss was 174 cm^3 (range, 20–750), and mean volume of normal saline used for hydrodissection was 260 cm^3 (range, 50–1250). Pelvicalyceal suture repair was necessary in five of 10 (50%) chronic kidneys. Follow-up involved biochemical, radiologic, and histopathologic evaluation at designated euthanasia intervals (one, two weeks, and one, two, and three months). No animal developed a urinary leak. Histological sections from the acute specimen revealed a thin (1 mm) layer of adherent coagulum at the amputation site with minimal thermal artifact. At two weeks, a layer of adherent fibroinflammatory pseudomembrane with giant cell reaction was seen.

However, clinical application of such a technology in the laparoscopic environment is still awaited (134).

LASERS

The first use of laser technology for organ surgery in the animal model was over 30 years ago. Since then, there had been significant improvement in laser technology as well as in understanding of the laser's mechanism of action. Laser partial nephrectomy using a variety of lasers has been described (135–141). The initial animal experiments were performed open surgically, most with hilar clamping.

More recently, Ogan et al. (140) at the University of Texas Southwestern investigated lasers for laparoscopic partial nephrectomy in five farm pigs undergoing bilateral laparoscopic partial nephrectomy using a 980-nm diode laser. Mean operative time was 2.1 hours, including a mean lasing time of 84 minutes. Adjunctive hemostatic clips were required in three cases to control the larger, more centrally located vessels. The use of fibrin glue in all cases prevented the assessment of the sealing effect of the laser on the collecting system. Histological analysis of the chronic specimens revealed a necrotic margin of 3–5 mm at two weeks. Subsequently, the same group of investigators employed clinicaly the 2100 nm wavelength pulsed Ho:YAG laser to perform laparoscopic partial nephrectomy in one adult male with a complex cyst, one pediatric patient with a nonfunctioning lower pole duplicated system, and one adult male with a 2.5 cm exophytic renal tumor (141). Estimated blood loss in the two adult patients was <50 and 500 cm^3, respectively. Fibrin glue, oxidized cellulose, and argon beam coagulator were used, and hilar clamping was not performed. No complications were reported. Thereafter, these authors tested the feasibility of laser tissue welding for laparoscopic partial nephrectomy in five pigs (142). An in-house solder consisting of 30% human serum albumin was concentrated to 50%. Chromophore indocyanine green was added to allow selective absorption of an 800-nm laser. After hilar clamping, the lower pole of the porcine kidney was resected with cold endoshears. The albumin solder was dripped onto the cut surface of the kidney, and laser soldering performed. Reportedly an albumin mixture covering was created over the treated surface of the vessels as well as the collecting system. Estimated blood loss was 43 cm^3, with a warm ischemia time of 11.7 minutes. None of the chronic kidneys had evidence of urinary leak on ex vivo retrograde pyelogram at two weeks. Gross and histologic examination revealed the solder adherent to the parenchymal surface. The acute extension of the cauterized area into the renal parenchyma was 0.5 mm. Data on the extent of cautery on the chronic specimen were not provided.

Moinzadeh (143) investigated the technical feasibility and short-term outcomes of potassium-titanyl-phosphate laser laparoscopic partial nephrectomy without vascular hilar clamping in the survival, robust calf model. Bilateral transperitoneal laser LPNs of the mid/lower pole was performed using the 80 W potassium-titanyl-phosphate laser on six Jersey calves, each weighing 76–94 kg. The left kidney ($n = 6$) of each calf underwent chronic laparoscopic partial nephrectomy with one-month follow-up, while the right kidney ($n = 6$) underwent acute laparoscopic partial nephrectomy with immediate euthanasia. Two techniques, ablative vaporization ($n = 5$), and wedge resection ($n = 7$), were evaluated. Renal parenchymal resection and hemostasis were achieved solely with the laser, without any adjunctive hemostatic sutures or bioadhesives. All 12 procedures were successful laparoscopically without open conversion, 11 of which (92%) without hilar clamping. Mean total operative time was 2.9 hours (range, 1.5–5), and blood loss was 119 cm^3 (range, 25–300). Mean lasing time was 56 minutes (range, 20–100), with an average energy use of 54 kJ. Any pelvicalyceal entry was efficiently suture repaired laparoscopically with a running vicryl stitch. Mean preoperative and postoperative hemoglobin (10.38 and 10.52 g/dL) and serum creatinine (0.46 and 0.4 mg/dL) were similar. Retrograde pyelography, renal arteriography, and histologic analyses showed no evidence of urinary leak or arteriovenous fistula at one-month follow-up. Shortcomings of such technique included considerable smoke generation during laser laparoscopic

partial nephrectomy (no irrigation of the smoke away from the working field possible as during underwater procedures) leading to increased operative time and higher CO_2 inflow-rate requirement necessitating two insufflators. However, the authors anticipated smoke evacuation to be less of a problem in the clinical setting, given the smaller peritoneal volume in the human (~3 L) as compared to the calf (~10 L).

The American Cancer Society estimated the incidence of new renal cancer cases and deaths for the year 2004 at 22,080 and 7870, respectively.

Nephron-sparing surgery has emerged as a preferred option in the treatment of most renal tumors less than 4 cm in patients with an existing or potential compromise of renal function and in select tumors with a normal contralateral kidney. Long-term cancer control and renal function after partial nephrectomy has been reported as being similar to radical nephrectomy.

The benefits of nephron sparing minimally invasive therapies include maximal renal sparing, decreased morbidity, decreased hospital stay, and shorter recovery.

Cryoablation is the destruction of cells by consecutive rapid freeze and thaw cycles leading to complete and reproducible necrosis of renal parenchyma occurring at temperatures of –19.4°C or less.

INTRODUCTION

The American Cancer Society estimated the incidence of new renal cancer cases and deaths for the year 2004 at about 22,080 and 7870, respectively (1).

Historically, a large number of new renal cancer cases were diagnosed at an advanced stage; however, as a result of new noninvasive imaging modalities, there has been an increase in the number of incidentally detected renal masses. Radical nephrectomy has been the gold standard for the management of renal cancers since its description by Robson et al. (2), but as the transition to diagnosis of asymptomatic smaller renal masses occurred, surgical treatment of renal masses also evolved.

Nephron-sparing surgery has emerged as a preferred option in the treatment of most renal tumors less than 4 cm in patients with an existing or potential compromise of renal function and in select tumors with a normal contralateral kidney (3–5). Long-term cancer control and renal function after partial nephrectomy has been reported as being similar to radical nephrectomy (3,4).

Myriad nephron sparing minimally invasive treatment options are being advocated for treatment of carefully selected patients. These include laparoscopic partial nephrectomy and needle-invasive or noninvasive ablative procedures such as cryoablation, radiofrequency, high-intensity focused ultrasound, interstitial laser, microwave thermotherapy, and photon irradiation.

The benefits of nephron sparing minimally invasive therapies include maximal renal sparing, decreased morbidity, decreased hospital stay, and shorter recovery.

Cryoablation is the oldest and most well studied of all the needle-invasive and noninvasive modalities. Cryoablation is the destruction of cells by consecutive rapid freeze and thaw cycles leading to complete and reproducible necrosis of renal parenchyma occurring at temperatures of –19.4°C or less (6).

Temperature monitoring using thermocouples during porcine renal cryosurgery demonstrated complete homogeneous necrosis of tissues reaching temperatures of –19.4°C or lower. Distance beyond the cryoprobe and direct visualization of the iceball proved to be less reliable predictors of tissue necrosis (7). Renal cryoablation has been reported via open (8,9), laparoscopic (10,11), and percutaneous surgery (12).

Liquid nitrogen or argon gas is circulated through vacuum-insulated probes and forced through a small aperture at the tip of the probe.

Rapid freezing causes:

■ Cytotoxic intracellular and extracellular ice crystals increasing the extracellular osmotic concentration resulting in pH changes, protein denaturing and mechanical disruption of cellular membranes.
■ Acute injury to the vasculature causing hyperpermeability of the microcirculation, which results in thrombosis, vascular occlusion, ischemia, and edema leading to delayed cell death (13,14).

Alternately, cellular damage may be produced by vascular injury or freezing induced immunological sensitization. This immunological sensitization is a novel concept and it has been recently shown that cryoablation of advanced renal cancer may have a survival advantage compared to nephrectomy in murine model by Hedican et al. (15).

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

Laparoscopic cryoablation is ideal for small volume renal cortical masses, suspicious for renal cell carcinoma, less than 4 cm (Table 1).

Indications for renal cryoablation include:

■ Renal mass lesion less than 4 cm
■ Elderly patients with comorbidities particularly hypertension, diabetes, renal stones, renal insufficiency, cerebrovascular accidents, and congestive heart failure—poor surgical candidates
■ Solitary kidney with peripheral renal mass less than 4 cm
■ Transplant kidney with peripheral renal mass less than 4 cm
■ von Hippel-Lindau with metachronous renal cell cancers

Contraindications to renal cryoablation include locally advanced and/or metastatic disease and uncorrected bleeding disorders. Laparoscopic or percutaneous cryoablation should be approached cautiously in patients with renal lesions close to renal hilum and pelvicalyceal system. However, Sung et al. showed intentional freezing of collecting system did not result in urinary leak (24).

Intraoperative ultrasound should be performed to rule out multifocal lesions where multiple probes or an alternative treatment modality (i.e., open or laparoscopic radical nephrectomy) could be considered.

To some, cystic renal masses are not ideal for renal cryoablation secondary to decompression of cysts, which might lead to instability of probes and imperfect freezing.

PREOPERATIVE PREPARATION

The preoperative preparation for renal cryoblation is the same as for open or laparoscopic approach.

Thorough history and physical examination is mandatory. A complete blood count, basic metabolic panel, urine analysis, and culture are routinely performed.

> Intraoperative ultrasound should be performed to rule out multifocal lesions where multiple probes or an alternative treatment modality (i.e., open or laparoscopic radical nephrectomy) could be considered.

> The preoperative preparation for renal cryoblation is the same as for open or laparoscopic approach.

Abbreviation: OR, operating room.

Metastatic evaluation usually includes a chest radiograph and abdominal computed tomography scan. A bone scan is reserved for patients with abnormal calcium and/or alkaline phosphatase levels. Magnetic resonance imaging is indicated in patients with contrast allergy or renal insufficiency. The majority of these patients may require preoperative clearance from an internist or a specialist for the comorbidities. Patients should sign an informed consent, which includes a detailed discussion about the limitations, expectations, and possible complications.

Patients should be informed about the potential for performing a radical nephrectomy laparoscopic or open if the situation demands.

We routinely perform bowel preparation with 300 mL of magnesium citrate with clear liquid diet a day prior to surgery and usually admit patients on the day of surgery. Patients are usually typed but not cross-matched for blood. Coordinating the procedure with an experienced radiologist in intraoperative laparoscopic ultrasound is often helpful.

> Patients should be informed about the potential for performing a radical nephrectomy laparoscopic or open if the situation demands.

TECHNIQUE

At our center, cryoablation is performed for tumors 4 cm or less in size. Many cystic and hilar lesions are excluded. Laparoscopy is used to expose the renal mass, using a transperitoneal approach for anterior/anterolateral tumors, and retroperitoneal for posterior/posterolateral tumors.

Operating Room Setup

The patient position and approach depends upon the exact location of the renal mass. The patient is placed in flank position with the affected side up. The primary surgeon, the first assistant, and the scrub nurse stand facing the abdomen (transperitoneal approach) or facing the spine (retroperitoneal approach). The second assistant (optional) will be on the opposite side. The monitor towers are stationed at the patient's shoulders and angled slightly toward the feet at an eye level comfortable to the operating personnel. The tower containing the laparoscopic insufflator, light source, and camera should be across the primary surgeon to facilitate monitoring of the pressure recordings. The harmonic and electrocautery generator units are at the patient's feet across from the primary surgeon. The suction irrigator/aspirator system is hung on the anesthetic pole on the side of the primary surgeon at the head of the table. The scrub nurse's Mayo stand is placed directly above the patient's legs and the remaining laparoscopic instruments are placed on another table in an L-shaped configuration for easy access (Fig. 1).

Patient Positioning

The operation table is padded with two layers of foam to provide adequate padding and minimize the risk of neuromuscular injury. After induction of anesthesia, placement of Foley catheter, and orogastric tube the patient is placed in semiflank position (15–20° from vertical) for transperitoneal approach or full flank position for retroperitoneal approach with the kidney rest at the level of twelfth rib. Kidney rest is elevated minimally and the table is flexed slightly to increase the space between the rib cage and the iliac crest. The down leg is flexed and the upper leg is placed straight with three or more pillows between the legs oriented at right angles to the legs. Venodynes and stockings are routinely used to prevent deep venous thrombosis. Two arm boards are placed side by side at the level of shoulder with foam padding. A soft foam axillary roll is positioned two fingerbreadths below the axilla to prevent brachial plexopathy. Three or more pillows are placed inline between the upper extremities to support the upper arm. The safety strap is applied over the lower extremities at the level of calves. A cautery pad is strapped on the upper thigh and a 3-inch. wide cloth tape is used to strap the patient from the edge of the table to the opposite edge of the table. The upper torso is stabilized by using 3-in. wide cloth tape from the edge of the table at the level of shoulders and is split into two strips past the elbows and is attached to either side of the arm boards. Care is taken to reposition all electrocardiogram leads, wires, and intravenous lines so that they are not under the patient at any point. A pneumatic warming device may be used on the upper torso to prevent hypothermia (Fig. 2).

Trocar Placement

Transperitoneal Approach

Peritoneal insufflation is obtained by inserting a Veress needle midway between the umbilicus and the superior iliac crest just lateral to the rectus muscle. The abdomen is insufflated up to 15-mmHg pressure and then a 10-mm or 5-mm nonbladed trocar is passed in

to the abdomen using an optiview system for the camera, depending on the surgeon's choice of using 5- or 10-mm telescope. A second 10-mm port is placed at the lateral margin of the umbilicus and the third port is placed in a subcostal position, just lateral to midline, halfway between the xiphoid and the umbilicus. The second and third ports could be 5 or 10 mm depending the side of the lesion and the dominant hand of the surgeon. An additional 5-mm port may be necessary on the right side to retract the inferior margin of the liver, about two fingerbreadths below the costal margin in the mid-axillary line.

We have a low threshold to use an open Hasson cannula technique for the abdomens with a history of previous surgery and if complicated adhesions are anticipated (Fig. 3).

We have a low threshold to use an open Hasson cannula technique for the abdomens with a history of previous surgery and if complicated adhesions are anticipated (Fig. 3).

FIGURE 2 ■ Patient's positioning for laparoscopic transperitoneal cryoablation.

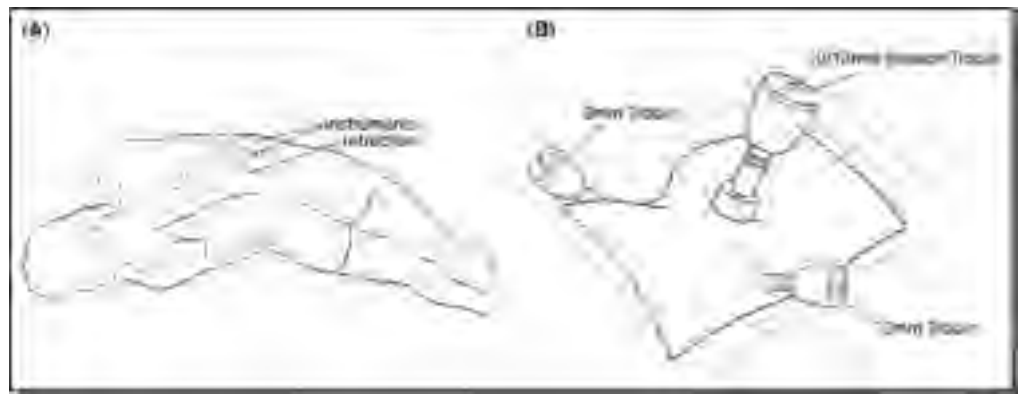
FIGURE 3 ■ Trocar placement for transperitoneal approach.


FIGURE 4 ■ Trocar placement for retroperitoneal approach. (**A**) Place 3 trocars lateral to the erector spinae muscle just below the 12th rib, (**B**) three fingerbreadths above the iliac crest in the anterior axillary line.

Retroperitoneal Approach

The open Hasson canula technique is routinely used. A horizontal 2-cm incision is placed 1 cm below and lateral to the tip of the twelfth rib. Then the latissimus dorsi muscle fibers are bluntly separated and retroperitoneum entered by opening the anterior lamella of the thoracolumbar fascia. Blunt finger dissection is performed to develop space by pushing the peritoneum away from the psoas major muscle. We found it is not necessary to use a balloon for formal dilatation of the retroperitoneal space, as we have not needed that much working space for renal cryoablation.

Alternatively, a trocar mounted balloon[a] could be used to develop adequate working space by instilling 800 to 1000 cc as described by Gill and his associates. A 10-mm blunt tip trocar[a] is placed after removing the balloon dissection device and it is secured by inflating the internal retention balloon and cinching external foam cuff. A Hassan cannula could also be used and it is tightly fixed by using fascial sutures around the trocar. Two more secondary ports are placed under vision, one 5-mm trocar is placed three fingerbreadths above the iliac crest in the anterior axillary line and the other 5-mm trocar is placed lateral to the erector spinae muscle just below the twelfth rib (Fig. 4A and B).

Exposure of the Lesion

The camera is inserted via the lower quadrant port and the surgeon operates with the subcostal and periumbilical ports in the transperitoneal approach. The Harmonic scalpel™[a] is typically used to incise the line of Toldt and for subsequent exposure of the renal mass through the Gerota's fascia.

Intrarenal lesions need intraoperative ultrasound to locate the lesions and exclude multicentric lesions. Ultrasound can also assess for other lesions in the remainder of the kidney. Extensive mobilization of colon, spleen, ureter, and hilum is not necessary. In the retroperitoneal approach, the camera is inserted via the middle port and surgeon operating through the medial and lateral ports. Maintaining the orientation and identifying the psoas major muscle are very important in this approach. We routinely use laparoscopic ultrasound to help localize the renal mass and Gerota's fascia is incised and the renal mass is dissected by opening the perinephric fat. Once the renal lesion is identified and well exposed, the cryoablation technique is similar in both approaches. After finishing the procedure, hemostasis should be checked by lowering the pnuemoperitoneum to 5 mmHg and the larger abdominal ports are closed using a port closure device. We perform a simple closure of retroperitoneal ports.

INSTRUMENT LIST

- ■ 10- or 5-mm laparoscope (0° and 30°)
- ■ Maryland dissector

We found it is not necessary to use a balloon for formal dilatation of the retroperitoneal space, as we have not needed that much working space for renal cryoablation.

Intrarenal lesions need intraoperative ultrasound to locate the lesions and exclude multicentric lesions.

---

[a]Ethicon, Somerville, NJ.

- Diamond flex triangle retractor[b]
- Veress needle
- Three nonbladed 10/12-mm trocars, one 5-mm nonbladed trocar
- Blunt tip trocar
- Trocar mounted preperitoneal balloon dilator[d]
- 10-mm Optiview introducing cannula[e]
- Endoshears
- 5-mm harmonic shears
- Irrigator-aspirator
- 10-mm clip applier and vascular stapler in the room available
- 10-mm right angle dissector
- Carter-Thomason fascial closure device[c]
- 4-0-monocryl sutures
- Flexible 10-mm laparoscopic ultrasound probe with ultrasound machine
- Biopty gun
- Surgicel[d], Tisseel[e], argon beam coagulator
- Two laparoscopic needle drivers
- Cryoprobes: 2.4, 3.0, 5 mm, Cryomachine (Accuprobe[f])
- Benzoin, steristrips 1/4 in., three band aids
- Standard open tray for flank surgery

Cryoablation is performed using an argon gas-based system that operated on Joule–Thompson principle (Accuprobe). Cryoprobes are available in diameters of 2.4 (sharp tip), 3.0, and 5.0 mm (blunt tips). The number and size of probes used in a case vary depending on the size and site of the tumor. The smaller probes (2.4 and 3.0 mm) are often passed percutaneously as a result of the relatively short shaft length; the 5-mm probe can be placed percutaneously or via a port.

- Once exposed and verified by the ultrasound examination of the lesion, the tumor is biopsied prior to cryoablation.
- Under direct laparoscopic and ultrasound guidance, the tumor is punctured with an appropriate sized probe and cryoablation is initiated using two 10-minute freeze cycles followed by passive thaws.
- The freeze cycle is continued to 1 cm beyond the tumor margin.
- The cryolesion is monitored with real time ultrasonography (Fig. 5).

FIGURE 5 ■ Picture showing renal cryoablation in progress (**A**) with real-time ultrasound monitoring (**B**).

FIGURE 6 ■ Pre-and postoperative magnetic resonance imaging scans showing an exophytic enhancing renal mass (*left*) and nonenhancing cryoablated lesion.

When cryoprobes are placed percutaneously, a 14 French red rubber catheter tubing is placed around the probe to protect skin and abdominal wall from cryoinjury. Before removal, passive thawing is allowed until the probe loosened spontaneously, and a piece of tightly rolled surgicell is placed into the cryoprobe defect, or an injection of Tisseel[i] is performed and held with direct pressure for 5 to 10 minutes. Next, the insufflation pressure is reduced to 5 mmHg to confirm hemostasis. Postoperatively, serial hematocrits are obtained for the first 24 hours. Magnetic resonance imaging is obtained at 3, 6, 9, and 12 months and then annually. We obtain magnetic resonance imaging scans with T1, T2 weighted, and gradient echo images performed before, during and after intravenous administration of gadalonium (Fig. 6).

Failure of cryolesion regression after six months warrants renal biopsy, possible repeat cryoablation, or partial/radical nephrectomy.

> Failure of cryolesion regression after six months warrants renal biopsy, possible repeat cryoablation, or partial/radical nephrectomy.

RESULTS

To date, our series at the University of Wisconsin (unpublished data) includes 31 patients with a mean follow-up of 14.3 months (range, 1–39). There were 21 men and 10 women, 16 tumors were on the right and 15 on the left side. Eighteen patients were treated retroperitoneal and 13 transperitoneally. The mean tumor size was 2.54 cm. A double freeze, active thaw technique was utilized with two 10-minute freeze cycles. Mean operating time was 136 minutes and the mean blood loss was 57 mL. The hospital stay was 1.9 days. Global complication rate was 6%. One patient with postoperative hemorrhage

---

TECHNICAL CAVEATS AND TIPS

- Careful preoperative planning regarding the approach, number, size, and placement of cryoprobes is advantageous.
- The specific choices of probe number and size depends on the size and site of the renal mass lesion.
- Hilar lesions, lesions close to pelvi-caliceal system and cystic lesions are generally avoided in our practice.
- Liberal use of intraoperative ultrasound imaging by an experienced radiologist is very valuable in localizing the lesion and to rule out multicentric lesions.
- Adequate mobilization of kidney and exposure of renal mass makes subsequent planning and placement of cryoprobes safer and more reliable.
- The importance of placing more than one cryoprobe to achieve adequate coverage of the whole tumor could not be over emphasized. We believe most of the recurrent tumors are persistent tumors, which were missed in the earlier freezing.
- We also believe that a margin of 10 mm is necessary to achieve adequate and dependable cell death.
- We routinely perform double freeze and thaw cycles of 10 minutes duration each to achieve our goal of complete destruction of malignant cells.
- Venous bleeding is usually encountered and can be controlled by pressure, packing with surgicel and fibrin sealants.
- Adequate hemostasis should be ensured at intra-abdominal pressures of 5 mmHg before concluding the procedure.
- Patients should be advised to avoid strenuous activity for the next two weeks to prevent postoperative hemorrhage.

underwent nephrectomy and one patient had change of mental status secondary to narcotics. Three patients died of unrelated causes. Three lesions showed peripheral enhancement at the previously cryoablated site. One patient with peripheral rim enhancement with an increase in size of the cryoablated site with nodular enhancement in the subsequent follow-up scans and biopsy consistent with active disease underwent partial nephrectomy. The other two patients had no further nodular enhancement with decrease in size of the cryoablated site (25).

Gill and coworkers (23) reported their three-year follow-up of laparoscopic renal cryoablation in 56 patients. All patients were treated with a double freeze-thaw cycle, under laparoscopic and ultrasonographic guidance. Follow-up consisted of magnetic resonance imaging on postoperative day 1 and at months 3, 6, 12 and semiannually thereafter until the cryolesion was no longer visible. In addition, computed tomography guided biopsies of all patients were performed at six months postoperatively. Mean patient age was 65 years. Mean preoperative tumor size was 2.3 cm (range, 1.5–3.7). Follow-up biopsies post cryoablation showed residual tumor in two patients (3.6%). New renal lesions developed at a different site in 3 patients (5.4%). At three years the overall patient survival and cryoablation-specific survival was 89% and 100%, respectively.

A meta-analysis of the clinical laparoscopic cryoablation series reported so far showed that the mean tumor size was between 2.0 and 2.54 cm (10,16–23). The recurrence rate is low, anywhere between zero and two cases per series. Shingleton et al. (26) reported their experience and analyzed the possible causes for the persistence of the tumor (14%) requiring retreatment. Large tumor size and tumor masses abutting the pelvi-calyceal system or the renal vessels were found to be the major causes of failures. Tumor size (2/14) and location (11/14) were found to be the most important factors leading to treatment failures.

> Complications of renal cryoablation are similar to partial nephrectomy, but special precautions should be taken to avoid unnecessary morbidity. Renal lacerations, perinephric hemorrhages, liver laceration, pancreatic injury, ureteroelvic junction stricture, and complete bowel obstruction have been reported.

Complications of renal cryoablation are similar to partial nephrectomy, but special precautions should be taken to avoid unnecessary morbidity. Renal lacerations, perinephric hemorrhages, liver laceration, pancreatic injury, ureteroelvic junction stricture, and complete bowel obstruction have been reported (9,12,18,19,27,28).

The cytocidal effect and durability of cryoablation appears promising. However, the ideal cryogenic probe system and optimal mode of delivery have yet to be defined. Intra and extracorporeal monitoring of cryolesions is still evolving and its accuracy is dependent on the skill and experience of the surgeon. There are not enough data regarding the treatment of tumor margins in the larger lesions and the safety of cryoablation for the lesions near the collecting system and renal hilum.

The next major challenge is the evaluation of clinical results. Limited postcryoablation imaging and biopsy results have been reported. Decrease in size of the tumor/absence of growth and lack of enhancement on computed tomogram/ Magnetic resonance imaging may be viewed as oncological success. Rukstalis et al. (9) recommend routine follow-up biopsy although to date only six months biopsy data are available. Serial biopsies at regular intervals are ideal but an optimal biopsy schedule is yet to be determined and biopsies are not without sampling errors and patient morbidity. Computed tomography-guided percutaneous cryoablation is also available in many centers.

SUMMARY

- Cryoablation is the most studied of the needle ablative therapies.
- Clinical studies have shown promising short-term results and acceptable safety profile.
- Cryoablation of renal lesions is minimally invasive, safe, and effective for peripheral lesions less than 3 to 4 cm in size in carefully selected individuals.
- More data are required to provide reliable treatment of tumor margins for larger lesions and the safety of using ablative techniques near collecting system and renal hilum.
- Watch for computed tomography-guided percutaneous cryoablation.

INTRODUCTION

Technological advances are changing the way renal tumors are diagnosed and treated. Many are now discovered incidentally with increasing use of diagnostic imaging modalities such as ultrasound, computed tomography, and magnetic resonance imaging (1,2). At the same time, advances in laparoscopy and minimally invasive surgery are changing the way renal tumors are treated, with reduced morbidity and more rapid recovery, while striving to maintain oncologic efficacy. First performed in 1990 by Clayman et al., laparoscopic nephrectomy demonstrated the feasibility of minimally invasive renal surgery (3). Subsequently, laparoscopic radical nephrectomy for renal tumors was demonstrated to be technically feasible and oncologically effective (4,5). Concurrently, nephron-sparing surgery, in the form of open or laparoscopic partial nephrectomy, has been shown to be a safe therapeutic alternative for the treatment of small renal tumors (<4 cm) (6–9).

Ablative treatments for renal cell carcinoma are currently being developed further reducing the morbidity associated with nephron-sparing surgery. These treatments also present a reduced technical challenge when compared to more conventional partial nephrectomy. Cryoablation (10–12) and radiofrequency ablation (13–15) currently comprise the ablative modalities that are in clinical use, although promising modalities such as high-intensity–focused ultrasound (16,17) and stereotactic radiosurgery (18) are under development. The purpose of this chapter is to discuss radiofrequency ablation treatment and results.

MECHANISM OF ACTION

Radiofrequency ablation uses monopolar alternating electric current delivered directly into the target tissue, where the native impedance of the tissue leads to heat generation. Where heating is sufficient, lethal temperatures are produced and the tissue is ablated. Specifically, a radiofrequency electrode is positioned into the target tissue and a grounding pad placed on the body. A computer-controlled generator applies alternating electrical current with a frequency within the radio segment of the electromagnetic spectrum. This current flows from the probe to the grounding pad. The radiofrequency voltage creates an electric field that exerts a force on the ions within the tissue fluid adjacent to the electrode causing them to vibrate as the current alternates polarity. Frictional dissipation of this ionic current causes heating of the tissues as an inverse function of tissue impedance. Heat is not directly supplied by the probe itself (19). The heating of tissue decreases with distance from the probe (heat = 1ength/radius) and relies on the thermal conductance

properties of the treated tissue (20,21). The treatment zone is that area that achieves temperatures sufficient for cell death by either of these two mechanisms. Overall, heat distribution in the tissue surrounding the probe is a function of tissue impedance, native tissue temperature, thermal conductivity, and heat loss through the circulation.

The exact mechanism of cell death caused by radiofrequency ablation is not completely understood. Most investigators believe thermal effects are the source of tissue injury, although the direct effect of the electrical field on the tissues is unknown (22). Heating of tissues to temperatures greater than 60°C routinely leads to desiccation and coagulative necrosis (23). Exposure to high temperatures also has direct effects on cellular components including the cell membrane, cytoskeleton, and nucleus. At supraphysiologic temperatures fluidity of the cell membrane increases, altering the kinetics of membrane proteins. These temperatures also denature the proteins that make up the cytoskeleton effecting cellular architecture. In the nucleus, high temperatures significantly impair deoxyribonucleic acid replication, in addition, cellular metabolism and electrophysiology are adversely affected by the high temperatures created during ablation (22). radiofrequency ablation also has a direct effect on tissue perfusion by causing microvascular and arteriolar occlusion within the ablated zone leading to ischemia of treated tissues (24). The overall effect is a predictable zone of necrosis surrounding the radiofrequency probe.

PATIENT SELECTION: INDICATION AND CONTRAINDICATIONS

General indications for radiofrequency ablation of renal tumors are the same as with conventional nephron-sparing surgery surgery and include the following: contrast-enhancing (≥10–12 Hounsfield units), small renal masses (<4 cm), tumor in solitary kidney, bilateral tumors, and renal insufficiency.

Contraindications for laparoscopic radiofrequency ablation generally are ones that prevent the creation of a pneumoperitoneum including multiple adhesions, history of peritonitis, and difficulty with ventilation. Contraindications for a percutaneous radiofrequency ablation approach include anterior renal tumors, colon or small bowel within 1 cm of the tumor, a large spleen or liver interfering with probe passage, and tumors immediately adjacent to the ureter or the renal pelvis (15).

PREOPERATIVE PREPARATION

Magnetic resonance imaging or computed tomography utilizing 3-mm axial cuts with and without enhancing contrast is used to delineate the tumor. If planning a percutaneous approach, a computed tomography in a prone or flank position can be helpful in avoiding needle access problems on the day of the procedure (15). In particular, it may reveal an impediment to the potential needle pathway by bowel or other organs. The prone position may also shift the kidney anteriorly to allow access to a tumor that otherwise would have been inaccessible on the supine view.

Preoperative preparations include blood coagulation screening, urine cultures, electrolytes, and creatinine. Patients are instructed to take a bowel preparation solution, such as magnesium citrate, the day before surgery.

LAPAROSCOPIC RADIOFREQUENCY ABLATION TECHNIQUE

The laparoscopic approach to radiofrequency ablation of a small renal mass is indicated for anterior, medial, and some lateral renal tumors where the ureter, colon, or small bowel are within 1 cm of the tumor and risk injury.

In addition, the path for percutaneous radiofrequency needle placement for a posterior renal tumor is occasionally impeded by a large spleen, liver lobe, or lung parenchyma. In these cases, if radiofrequency ablation is intended, a laparoscopic approach is indicated.

The patient is positioned in a modified flank position, and three or four transperitoneal laparoscopic trocars are placed as with laparoscopic nephretomy. The kidney is then mobilized within Gerota's fascia, and the tumor is identified and evaluated with laparoscopic ultrasound. The tumor is exposed and the overlying fat is excised and sent for pathologic analysis.

We use the radiofrequency interstitial tumor ablation Model 1500X electrosurgical generator and 15-gauge Starburst XL probe[a] that is a dry-probe, temperature-based

system. This radiofrequency system is Food and Drug Administration-approved for the ablation of all soft tissue tumors. The probe consists of nine active tines, five of which also contain a thermistor. The probe is introduced percutaneously at a location that permits near-perpendicular insertion into the renal tumor (Fig. 1). The tines are deployed to a diameter that ablates a zone 0.5 to 1.0 cm greater than the tumor diameter measured on computed tomography and intraoperative ultrasound, in order to ensure complete coagulation of both the tumor and a margin of normal kidney parenchyma. The Starburst XL design is particularly well suited for kidney tumor ablation. The tines deploy in a forward direction from the needle tip so that when the probe is placed perpendicular to the tumor surface, the surgeon can be confident that the greatest energy is deposited at the deep tumor margin—the region of highest blood flow and most likely site of incomplete ablation.

Energy is maintained at less than 150 W until the average temperature of the tines reached a target temperature of 105°C (per the manufacturer's recommendation). Once the target temperature is reached, it is maintained for three to eight minutes, depending on the size of the tumor (Table 1). At no time during treatment is the impedance allowed to exceed 80 ohms. The lesion created by the radiofrequency probe is a direct function of its deployed diameter and the minimum time activated (Table 1). As such, real-time ultrasound monitoring of the ablation is not necessary because activating the probe for longer periods of time does not change the lesion size. After a 30-second cool down period, a second cycle is performed using the same settings, tine deployment, and time. If the tumor is not spherical or larger than 4 cm, the probe is repositioned and tines redeployed.

An advantage of the temperature-based system is that during the cool down period, passive tissue temperatures are monitored in real time. If the treated tissue maintains a temperature above 65°C to 70°C, the surgeon should be confident that cell death has occurred.

Following treatment, the tract is ablated as the probe is withdrawn to prevent bleeding and to minimize the risk of tumor seeding. Track ablation is stopped once the probe is withdrawn from the kidney.

Based on our laboratory experience, the renal hilum should not be occluded during laparoscopic ablation (23). Although it likely increases the ablation diameter and shortens the time to reach the target temperature by eliminating the circulatory heat sink, there is a risk of intravascular thrombus propagation and unpredictable normal parenchyma damage.

Depending on tumor size and location, the ablated tumor can be left either in situ or excised. Tumors that are endophytic or located in the mid-pole are left in situ with our protocol. In these cases, diagnostic biopsies are taken after ablation using a laparoscopic 5-mm toothed biopsy forceps (Fig. 1). Biopsies are not taken before ablation to minimize the risk of bleeding and tumor seeding (25). Tumors that are exophytic or in a favorable polar location can be completely excised in a hemostatic fashion without hilar

An advantage of the temperature-based system is that during the cool down period, passive tissue temperatures are monitored in real time. If the treated tissue maintains a temperature above 65°C to 70°C, the surgeon should be confident that cell death has occurred.

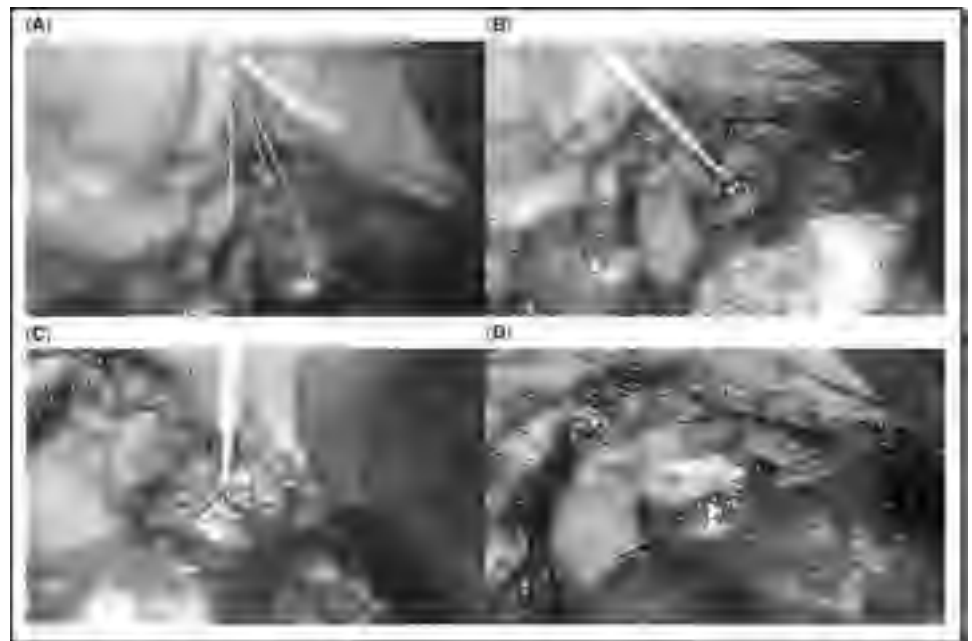
FIGURE 1 ■ (A) The tines are deployed beside the tumor to check appropriate ablation diameter. (B) The probe is inserted perpendicular to the tumor. Tines are deployed and confirmed with a laparoscopic ultrasound. (C) The ablation is underway. (D) The ablated renal tumor after a biopsy.


TABLE 1 ■ Renal Tumor Radio Frequency Ablation Settings

Tumor size (cm)	Target temperature (°C)	Time at target temperature (min)	No. of cycles
<1.0	105	3	1(2)
1.0–2.0	105	5	2
2.0–3.0	105	7	2
3.0–4.0	105	8	2

TABLE 2 ■ Summary of Laparoscopic RFA

Port placement as per standard laparoscopic nephrectomy or partial with 12-mm port in lower abdomen to accommodate laparoscopic US probe
Use laparoscopic US to localize tumor
Start dissecting Gerota's off of tumor, beginning at medial edge
Completely expose tumor surface
Hilar dissection, mobilization of kidney is unnecessary
Posterior located tumor can be approached via retroperitoneoscopy
RFA probes should be used according to manufacturer's instructions
RITA XL probes are inserted perpendicular into the tumor
Tines are deployed to diameter 0.5 cm beyond tumor diameter as measured on preoperative CT
Laparoscopic US is used to confirm deployment of tines
Ablate according to tumor size (Table 1)

Abbreviations: RFA, radiofrequency ablation; CT, computed tomography; US, ultrasound.

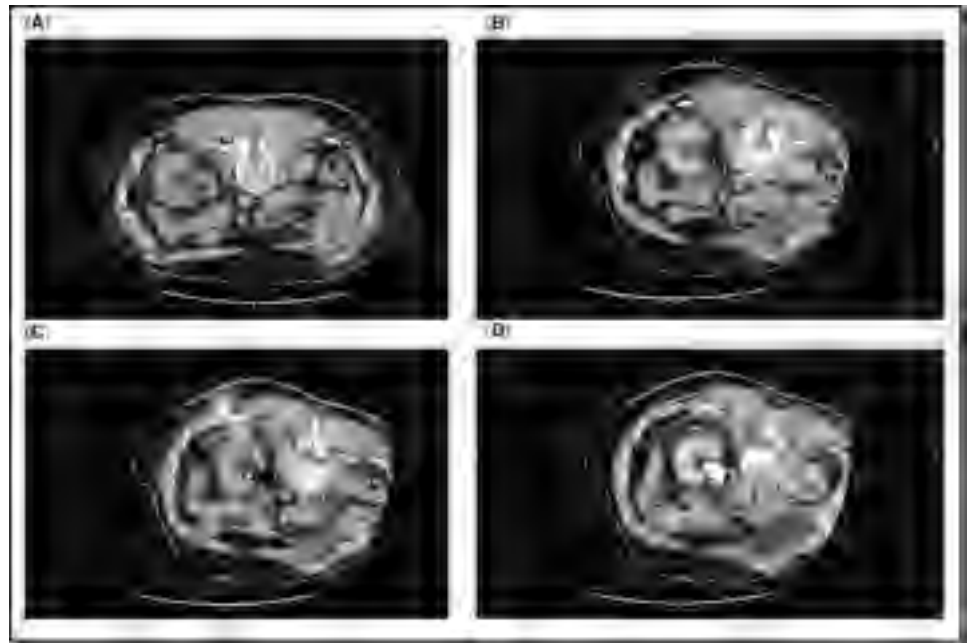
occlusion (26). The specimen is placed in a laparoscopic bag and extracted through one of the trocar sites at the conclusion of the case. Adjunctive hemostatic measures, such as argon beam coagulation, fibrin glue, and/or oxidized cellulose can be applied in these cases to prevent delayed bleeding (Table 2).

PERCUTANEOUS RADIOFREQUENCY ABLATION TECHNIQUE

Percutaneous radiofrequency ablation can be performed under intravenous sedation and local anesthesia or general anesthesia. We prefer general anesthesia, as kidney location can be contrasted and is reproducible expediting the procedure. After induction of anesthesia, a parenteral intravenous antibiotic is administered, an orogastric tube placed and a urethral catheter inserted. The patient is then placed prone or in a flank position on the computed tomography gantry with arms secured to ensure clearance through the scanner.

With the assistance of an interventional radiologist, intravenous contrast is first administered to accurately image the lesion. If iodinated contrast is contraindicated, a small dose or gadolinium can be administered. Alternative, ultrasound guidance may be employed. However, we discourage its routine use due to the technology's inherent resolution variability. First, a 20-gauge Chiba needle is usually directed to the peripheral rim of the renal tumor as a "finder needle." Placement is confirmed with repeat computed tomography imaging. An 18-gauge core biopsy needle is passed adjacent to the Chiba needle into the peripheral margin of the tumor. Following computed tomography confirmation of positioning, multiple tissue cores are obtained. A radiofrequency interstitial tumor ablation Starburst XL probe is then placed along side the Chiba needle to the same depth. When repeat computed tomography imaging demonstrates adequate positioning of the radiofrequency probe, the tip is advanced to just within the peripheral tumor margin and the Chiba needle is withdrawn. We prefer the "finder needle" technique to minimize the number of radiofrequency probe positioning attempts and thereby the risk of peri-lesion breeding and, "theoretical," tumor cell spillage. Similar to the laparoscopic technique, the tines of the radiofrequency probe are then deployed for an ablation diameter approximately 0.5 to 1.0 cm beyond the computed tomography-measured tumor diameter. Prior to ablation, successful deployment of the radiofrequency tines is confirmed by repeat computed tomography imaging which should demonstrate coverage of the entire tumor as well as a rim of normal parenchyma at the deep tumor margin (Fig. 2).

Radiofrequency ablation is performed utilizing the same protocol as described for the laparoscopic radiofrequency ablation. If adequate tumor coverage is not accomplished because of tumor size or shape, the radiofrequency probe is repositioned in a different portion of the tumor for a second round of treatment. Following the ablation, the probe is withdrawn slowly through Gerota's fat in "track ablate" mode to prevent bleeding and the "theoretical" risk of tumor seeding. In this mode, the probe track is heated to 75°C or greater. Immediate postablation contrast computed tomography imaging is repeated to assess whether the mass has been successfully ablated (Table 3).

FIGURE 2 ■ (A) A small left posterior renal tumor is seen in the noncontrast phase while the patient is prone. (B) Contrast has been given and the patient is slightly rotated to optimize probe angle. (C) The tumor has been targeted and the tines are deployed beyond the tumor margin. (D) The postablation defect. Note the lack of contrast uptake by the lesion.


RADIOFREQUENCY ABLATION FOLLOW-UP

Standard follow-up of patients includes computed tomography or magnetic resonance imaging with and without intravenous contrast at 6 weeks, 6 months, 12 months, and then every 6 months thereafter. With increasing experience, we anticipate that less frequent imaging will be necessary. Ablation is successful if the lesion along with a margin of normal parenchyma no longer enhances on contrast imaging (<10–12 HU). For treatment failures, our protocol is either to retreat or surgical extirpation. This decision is based on the location of the failure, the response to the original treatment and the patient's health and preference. For the radiofrequency-assisted partial nephrectomy group, surveillance is similar to that of conventional partial nephrectomy patients.

PROS AND CONS

Laparoscopic radiofrequency ablation has the advantage of approaching anteriorly located tumors safely and easier than percutaneous radiofrequency ablation. Also bowel and ureter that abut a tumor can be mobilized to prevent burn injuries.

During laparoscopic radiofrequency ablation, incisional biopsies, which have a higher diagnostic rate than needle core biopsies, can also be obtained using a laparoscopic 5-mm cup biopsy instrument (25).

Percutaneous radiofrequency ablation has the advantage of an outpatient procedure that avoids a pneumoperitoneum, which may be poorly tolerated by select

> During laparoscopic radiofrequency ablation, incisional biopsies which have a higher diagnostic rate than needle core biopsies can also be obtained using a laparoscopic 5-mm cup biopsy instrument.

TABLE 3 ■ Summary of Percutaneous RFA

Obtain prone CT prior to ablation day to rule out any impediment for the ablation needle path
Ensure that bowel and ureter are not abutting the tumor
Use an 18-gauge needle to seek out tumor location on CT
Deploy tines and confirm tine coverage of tumor
Tru-cut biopsy can be obtained once RFA probe position is confirmed
Ablated according to manufacturer's recommendation
Track ablation while removing probe, stop ablation before probe starts coming through abdominal wall to prevent burn injuries
Obtain final contrast-enhanced CT to confirm ablation

Abbreviations: RFA, radiofrequency ablation; CT, computed tomography.

patients. Also, computed tomography guidance provides greater resolution than ultrasound guidance, which is important for probe placement and confirmation of tine deployment. Smaller endophytic tumors are also better visualized with computed tomography.

TECHNICAL CAVEATS/TIPS

- There are a few important technical caveats to facilitate laparoscopic radiofrequency ablation.
- Ultrasound is essential to localize the tumor and to gauge the deployment of the times during laparoscopic radiofrequency ablation.
- However, monitoring the ablation lesion is not necessary, because setting the tines to the desired diameter on the probe handle will ensure appropriate heat distribution to the tumor (27).

Only dissection of Gerota's fascia is necessary to expose the tumor surface. Hilar dissection is unnecessary, which minimizes the risk of vascular injury. A separate abdominal wound should be made with a No. 11 blade to allow perpendicular trajectory of the radiofrequency ablation probe into the center of the exposed renal tumor. If necessary, some perirenal fat or laparoscopic pledgets can be used to prop the kidney up to optimize probe angle. Track ablation should be utilized while removing the probe from the tumor on completion of the ablation. Finally, we recommend injecting fibrin glue down the ablation track for tumors that are close to the collecting system. This may prevent urine leaks.

RESULTS: EXPERIMENTAL STUDIES

Zlotta et al. first described the use of radiofrequency ablation to ablate human renal tumors in an ex vivo model and subsequently ablated human tumors in vivo immediately prior to nephrectomy (28). Although the results were encouraging the authors called for animal experiments to better characterize the effects of radiofrequency ablation on renal tissue. Walther et al. performed a similar study treating 14 tumors (none greater than 4 cm in size) in four patients with radiofrequency ablation just before surgical excision (29). No toxicity related to radiofrequency ablation was observed. They reported subtle detectable changes in treated tissue, but importantly cited that the excision immediately after ablation did not allow enough time necessary for the changes of coagulation necrosis to be seen. Gill et al. performed laparoscopic and percutaneous impedance-based radiofrequency ablation in a porcine model (24). In this report the authors described the acute ultrasonic appearance of radiofrequency ablation lesions as an irregular hyperechoic area that could not be reproducibly identified. Arteriograms demonstrated occlusion of the intrarenal vessels in the areas of radiofrequency ablation, with a normal appearance of the remainder of the vessels. Later, this same group published the acute and chronic histopathologic effects of impedance-based radiofrequency ablation on renal tissue, observing extensive coagulative necrosis and marked inflammation in the areas of treatment (30). Early radiofrequency ablation-mediated changes consisted of blurring of chromatin, increased cytoplasmic eosinophilia, loss of cell border integrity, and interstitial hemorrhage. As time progressed there was degeneration of nuclear and cellular features and an inflammatory infiltrate at the border of the lesion. Ultimately they observed spontaneous resorption and autoamputation of the treated portion of the kidney. Corwin et al. (23) evaluated the tissue effects of temperature-based radiofrequency ablation with and without hilar occlusion. This study investigated the effect of any heat sink phenomenon due to renal blood flow in a porcine model (23). Acutely they observed coagulative necrosis within the ablated lesion with preserved renal architecture and minimal cellular changes, consisting of loss of distinct cytoplasmic borders, variable appearance of nuclei, and increased eosinophilia.

Importantly, nicotinamide adenine dinucleotide staining confirmed complete nonviability in all parts of the radiofrequency ablation lesion. Although hilar clamping caused a slight increase in lesion size, the difference was not statistically significant. Furthermore, clamping did not appear to have any effect on tumor viability within the radiofrequency ablation lesion, as complete cell death occurred regardless of hilar occlusion. However, in some cases, hilar occlusion resulted in unpredictable lesion size and large parenchymal infarction.

Little experimental data exist regarding the oncologic adequacy of radiofrequency ablation as a primary treatment for renal tumors. The lack of comparable animal models for renal cell carcinoma makes this difficult to obtain. Nakada and coworkers evaluated the efficacy of radiofrequency ablation, cryoablation, and radical nephrectomy as treatment for implanted VX2 tumors, an aggressive tumor model, in rabbits (31). They found radiofrequency ablation, cryoablation, and nephrectomy to be equally efficacious in treating these tumors when compared to untreated controls. Our group has reported a case of nephrectomy for ureteropelvic junction almost one year after radiofrequency ablation of a renal tumor in a human patient. Microscopic examination demonstrated a giant cell reaction in the area of the ablated tumor with no evidence of residual renal cell carcinoma (32).

A study by Rehman et al. recently compared the effects of microwave, cryoablation, impedance and temperature-based mono- and bipolar radiofrequency ablation, and liquid and gel chemoablation on porcine kidneys (33). Of all the techniques tested, temperature-based radiofrequency ablation (radiofrequency interstitial tissue ablation system) and cryotherapy were the only two methods to result in complete tissue necrosis with no skip areas. The authors concluded that with current technology, cryotherapy and multitine temperature-based radiofrequency ablation were the only modalities that offer complete necrosis within the sphere of treatment.

RESULTS: CLINICAL STUDIES

Radiofrequency ablation moved quickly from experimental studies to utilization in clinical series. Zlotta et al. (28) and Walther et al. (29) performed radiofrequency ablation in human patients prior to nephrectomy or partial nephrectomy demonstrating its safety in a small number of patients. Later, McGovern et al. reported the first use of radiofrequency ablation with the intent to treat renal carcinoma in 1999 (34). This patient, an elderly individual who refused surgery for a growing 3.5 cm enhancing mass, had a 17-gauge radiofrequency ablation probe placed percutaneously under ultrasound guidance and the tumor treated for 12 minutes. Contrast-enhanced computed tomography scan two hours after the ablation showed a nonenhancing region in the treated area enveloping the previously enhancing tumor. Contrast-enhanced computed tomography at one and three months confirmed nonenhancement in the treated region. The authors cited the need for extended follow-up to determine long-term efficacy. They later reported their experience treating nine tumors in eight patients (including the initial patient above) with a range of tumor sizes of 1.2 to 5 cm, including three lesions smaller than 3 cm and six lesions larger (35). The seven patients with normal renal function were imaged at six-month intervals. Two larger tumors (4.4 and 5.0 cm) demonstrated persistent enhancement and were treated with additional radiofrequency ablation. With a mean follow-up of 10.3 months (range, 3–21) no patient had manifestations of renal cell carcinoma.

Hall et al. recently reported an innovative combination of embolization with polyvinyl alcohol and percutaneous radiofrequency ablation in a 67-year-old patient with a 2.5×3.0 cm tumor in a solitary kidney (36). A computed tomography scan performed at eight weeks post ablation showed a complete lack of contrast enhancement in the treated area. At three months post ablation, a biopsy revealed fibrous tissue and necrotic cellular debris with no evidence of malignancy. We have successfully employed this same technique in a few central or large ($\geq$4 cm) tumors to reduce the circulatory heat sink.

Pavlovich et al. reported a series of 24 percutaneous temperature-based ablations in 21 patents using ultrasound and computed tomography guidance (14). With a mean tumor diameter of 2.4 cm, and no tumors exceeding 3 cm, 19 ablations were considered satisfactory at the time of treatment based on reaching and maintaining a tissue temperature of 70°C at all probes during therapy. Follow-up with contrast-enhanced computed tomography was performed at two months with 19 tumors free of enhancement (18 tumors that were thought to be satisfactorily treated and 1 tumor that did not meet the target temperature criteria.) Effects on the kidney were reported in 17 patients, with no change in serum creatinine identified but microscopic proteinuria (1+) appearing in four patients two months after radiofrequency ablation. They concluded that percutaneous radiofrequency ablation was well tolerated but required further evaluation to determine long-term efficacy. The same group recently published the results of familial renal tumors treated with a higher power generator (200 W) (37). Seventeen patients with a total of 24 hereditary renal tumors ranging from 1.2 to 2.85 cm were treated with the Cool-tip Radiofrequency System[b]. Nine were treated laparoscopically and eight

---

[b]Radionics, Burington, MA.

percutaneously. At a median follow-up of just over one year, the median tumor or thermal lesion diameter decreased from 2.26 to 1.62 cm. Only one centrally located lesion (4%) demonstrated contrast enhancement (greater than 10 HU) at 12 months. One patient developed a ureteropelvic junction obstruction, which was repaired at nine months with excision of the previously ablated tumor. There was no evidence of viable tumor tissue on pathological examination.

Our group has reported the results of 13 tumors less than 4 cm in diameter (mean size, 2.4 cm) treated with computed tomography-guided percutaneous radiofrequency ablation and 13 patients with 17 tumors (mean tumor size, 1.96 cm) treated with laparoscopic radiofrequency ablation (15,26). The laparoscopic group included patients with tumors treated and left in situ and other patients who had the tumor treated and excised, known as radiofrequency ablation-assisted laparoscopic partial nephrectorny. In the percutaneous group, 12 of the 13 tumors were completely ablated with the first treatment, as evidenced by absence of enhancement on follow-up computed tomography imaging. The one tumor that demonstrated enhancement of a residual peripheral rim on a six-week computed tomography scan was retreated with radiofrequency ablation. Follow-up contrast-enhanced computed tomography imaging shows no persistent enhancement of this tumor. In the laparoscopic in situ group at least six-month follow-up was available in eight patients, with all eight showing no evidence of tumor. One patient in the radiofrequency ablation-assisted laparoscopic partial nephrectorny group showed a margin positive for ablated tumor cells, i.e., the tumor cells were present at the surgical margin, but these tumor cells appeared to be ablated by the radiofrequency ablation treatment. This patient continued to be disease-free at one-year follow-up. We have seen one patient with disease recurrence in the treatment bed. This patient was initially treated with cryotherapy and suffered a recurrence prompting percutaneous radiofrequency ablation. Although initial follow-up imaging after radiofrequency ablation demonstrated no contrast enhancing lesions, later studies revealed an enhancing nodule. This nodule has since been retreated with radiofrequency ablation. Similar to the experience of Pavlovich et al., we have not identified any significant changes in renal function or blood pressure attributable to radiofrequency ablation (38). Our series has since grown to over 100 patients, with only two treatment failures and one local recurrence after a mean follow-up of 14 months. There has been no evidence of distant metastasis. Three deaths have occurred, unrelated to the renal tumor (stroke, primary lung cancer and pneumonia).

Recently, a number of groups have published additional results using image-guided percutaneous radiofrequency ablation to treat small renal tumors (Table 4). Although follow-up has been short, averaging nine months, the success rate has ranged 81% to 100%.

Although these studies and others are encouraging, some investigators have questioned the totality of tumor destruction with radiofrequency ablation and which patients are appropriate candidates for radiofrequency ablation. Rendon et al. performed impedance-based radiofrequency ablation followed by either immediate nephrectomy or nephrectomy one week after ablation (42). Of the five tumors followed by immediate nephrectomy, hematoxylin and eosin stained sections in four showed histologic evidence of peripheral tumor viability in approximately 5% of the tumor volume. Of the six tumors followed by one-week delayed nephrectomy, three demonstrated residual viable tumor at the periphery. These areas of tumor viability may have been eliminated by the creation of larger areas of ablation extending beyond the tumor. They concluded that radiofrequency ablation is a promising technique but raised questions concerning the ideal size and location of tumors eligible for such treatment. Michaels et al. treated 15 patients with 20 tumors with temperature-based radiofrequency ablation immediately prior to partial nephrectomy (43). They observed areas of morphologically unchanged tumor by standard hematoxylin and eosin staining in all 20 specimens, and evidence of

> Recently, a number of groups have published additional results using image-guided percutaneous radiofrequency ablation to treat small renal tumors. Although follow-up has been short, averaging nine months, the success rate has ranged 81% to 100%.

TABLE 4 ■ Recent Percutaneous Radiofrequency ablation Series

Studies	Tumors treated	Approach/ technology	Mean follow-up (range) (mo)	Outcome
Su et al. (39)	35	PC/TB (18) and IB (17)	9 (0–23)	11/13 (with 12 mo follow-up) no enhancement
Mayo-Smith et al. (40)	32	PC/IB	9 (1–36)	26/32 no enhancement
Farrell et al. (41)	35	PC/TB (12) and IB (23)	9 (1–23)	35/35 no enhancement

nicotinamide adenine dinucleotide activity in four of the five specimens evaluated. In contrast to the study above, they observed these areas of viability within the ablation defect. They concluded that current radiofrequency ablation regimens are ineffective for total tumor destruction, though they acknowledged that their conclusion was based only on immediate removal of the tumor. In contrast, Matlaga et al. similarly studied tumors that had been treated with radiofrequency ablation prior to radical or partial nephrectomy with dramatically different results (35). In their series of 10 patients, 8 demonstrated complete tumor nonviability based on hematoxylin and eosin staining as well as nicotinamide adenine dinucleotide staining. Two tumors showed evidence of viability. However, the authors noted that failure of radiofrequency ablation was expected in both cases, as one tumor did not reach adequate temperatures during treatment and the other was too large (8 cm in diameter) to be treated with the probes they employed during the studies. They concluded that radiofrequency ablation does completely ablate renal tumors with minimal collateral damage to surrounding renal tissue.

SUMMARY

■ To date, radiofrequency ablation results are promising and demonstrate excellent intermediate-term efficacy.
■ The ability to perform radiofrequency ablation both percutaneously under computed tomography guidance and laparoscopically makes it a versatile tool in the management of small renal masses.
■ As we gain better understanding of the management of small renal masses, the role of ablative technologies such as radiofrequency ablation will be better defined.

COMMENTARY

Harrison K. Rhee and John A. Libertino
Lahey Clinic Medical Center, Burlington, Massachusetts, U.S.A.

Several treatments have been challenging open radical nephrectomy, the gold standard treatment for renal cell carcinoma. Open partial nephrectomy has been shown to have similar oncologic results while preserving nephron mass and renal function. Laparoscopic radical nephrectomy has been shown to have less morbidity than open radical nephrectomy and is quickly becoming the treatment of choice for those masses not amenable to partial nephrectomy. Specialized centers have been pushing the forefront of minimally invasive, extirpative surgery with the routine use of laparoscopic partial nephrectomy. Research into nonextirpative, ablative techniques such as cryoablation and radio frequency ablation has given urologists even more treatment options when addressing renal lesions. The ultimate goal of each of these techniques is

to effectively eradicate tumors with maximal oncologic efficacy while minimizing morbidity and mortality. The aforementioned procedures have certain difficulties with each of those tasks, and radiofrequency ablation is no exception.

Avoiding significant open or laparoscopic surgery is the major benefit of radiofrequency ablation. This benefit includes decreased blood loss, lower analgesia requirement, shorter hospital stay, quicker return to normal activities, and preservation of nephron mass when compared with radical nephrectomy. Rare complications such as extension of the coagulation lesion into surrounding organs or thrombosis of major renal vessels have been avoided with selection of small, peripheral, posterior tumors. While the benefits of this therapy may outweigh the need for surgical resection in the patient with significant comorbidities, the majority of patients with renal masses require a procedure with established, long-term cure rates.

Despite the benefits of radiofrequency ablation, treatment efficacy has not been fully established. Technology to evaluate radiofrequency ablation in real time is not currently adequate to determine the true extent of lesions at the time of treatment. Data from several groups has shown that persistent or new enhancement on computed tomography scan after treatment mandate two or more total treatments for primary radiofrequency ablation failures. Also, the use of nonenhancement of the lesion on computed tomography scan after treatment does not fully establish the treatment margins as adequately as histology. Clinical trials where tissue is immediately resected after treatment have shown conflicting results regarding histologic evidence of cell viability. Because treatment effects may not be fully realized on immediate examination, we believe that further data needs to be gathered with treatment and delayed resection for pathologic evaluation. This should be correlated with contrast-enhancement evaluation on computed tomography-scan because the ultimate goal would be to evaluate treatment efficacy by noninvasive means.

Several situations may push radiofrequency ablation up the treatment algorithm. As mentioned, in those patients with comorbidities that preclude surgical resection with open or laparoscopic radical or partial nephrectomy, radiofrequency ablation may be a viable treatment alternative. This group of patients may be the ideal group for radiofrequency ablation therapy although long-term, disease-free follow-up may not be easily evaluated secondary to non–disease-specific mortality. Laparoscopic partial nephrectomy demands excellent skills including the very difficult task of intracorporeal suturing for reconstruction of the collecting system and for ligation of bleeding vessels. Therefore, a potential use of radiofrequency ablation may be as an intraoperative adjunct to this procedure by facilitating hemostasis and decreasing blood loss. radiofrequency ablation treatment of lesions may preclude the need for hemostatic suturing and allow a clean operative field for further closure of the surgical defect.

Further long-term results regarding overall survival, disease-free survival, morbidity, and mortality need to be established across institutions to fully compare this technique to current therapies of surgical resection. As further data regarding the clinical significance of small renal lesions becomes available, the utility of minimally invasive, nonextirpative, ablative therapies such as radio frequency ablation may become more clear. Until these data become available, radiofrequency ablation will remain an investigational modality that should only be offered to those patients who are unable to undergo surgical resection.

LAPAROSCOPIC RADICAL NEPHROURETERECTOMY: TECHNIQUES FOR THE MANAGEMENT OF DISTAL URETER AND BLADDER CUFF

Gary W. Chien, Marcelo A. Orvieto, and Arieh L. Shalhav
Section of Urology, University of Chicago Pritzker School of Medicine, Chicago, Illinois, U.S.A.

INTRODUCTION

The standard surgical treatment of upper tract urothelial carcinoma is radical nephroureterectomy with complete excision of the ipsilateral bladder cuff. This was proposed by Kimball and Ferris in 1933 (1), after the authors found a high incidence of tumor in the remaining ureter following a radical nephrectomy for upper tract urothelial carcinoma. Some 40 years later, Strong and Pearse in 1976 quantified an average of 30% recurrence rate of urothelial carcinoma in the ureteral stump when incomplete nephroureterectomy was performed (2). Thus, a radical nephroureterectomy with complete excision of the bladder cuff is the standard surgical treatment of upper tract urothelial carcinoma (3,4).

In the open approach, the kidney is removed along with the ureter and its bladder cuff. The surgery can be performed with one large incision to remove the kidney, the ureter, and the bladder cuff. This is achieved through a midline or thoracoabdominal incision. Alternatively, two separate incisions can be made, i.e., a flank or subcostal and a Gibson incision.

Laparoscopic nephroureterectomy is becoming increasingly common as laparoscopic radical nephrectomy has now become the "gold standard" for the treatment of localized renal cell carcinoma (5). The advantages of laparoscopic radical nephrectomy over the open approach can also be applied to the laparoscopic nephroureterectomy. These include less intraoperative blood loss, less postoperative pain, faster recovery, and better cosmesis. However, to date there are few series reported with long-term follow-ups (6).

Although rare case reports of trocar site recurrence have been reported (7), the more crucial issue regarding oncologic control of laparoscopic nephroureterectomy is the management of the distal ureter and the bladder cuff.

As surgeons are attempting to keep the procedure as minimally invasive as possible, multiple techniques have been described.

> Although rare case reports of trocar site recurrence have been reported, the more crucial issue regarding oncologic control of laparoscopic nephroureterectomy is the management of the distal ureter and the bladder cuff.

TECHNIQUES FOR MANAGEMENT OF DISTAL URETER AND BLADDER CUFF

To decrease the morbidity of nephroureterectomy, various endoscopic methods have been described for the management of the distal ureter and the bladder cuff. McDonald et al. (1953) first described the "pluck" technique in which the ipsilateral ureteral orifice was resected via a transurethral approach (8). Once the distal ureter was disconnected from the bladder, the bladder defect was fulgurated. The nephrectomy portion of the

surgery was then performed in an open fashion via a flank or subcostal incision, and the disconnected ureter was "plucked" out together with its bladder cuff.

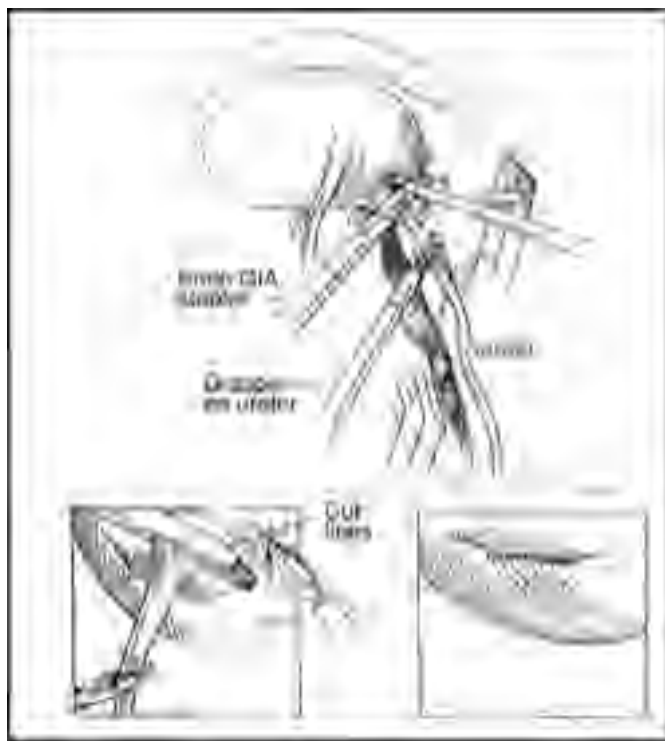
Because the distal ureter, which is resected, is left open, the "pluck" method has been criticized for tumor seeding in the retroperitoneum, which has been documented (9,10).

For laparoscopic nephroureterectomy, numerous methods have been described for the management of the distal ureter, all with a goal to achieve a minimally invasive technique while not compromising the oncologic efficacy. These techniques each present with their advantages but also with their shortcomings.

GIA Staple Division Following Transurethral Dissection

In 1991, Clayman et al. reported the first laparoscopic nephroureterectomy (11). For the management of the distal ureter and bladder cuff, the authors described placing a 7 French ureteral catheter (5 mm diameter and 10 cm length) with an occlusion balloon cystoscopically under fluoroscopic guidance. The balloon was inflated with contrast material. Then, the bladder cuff was created transurethrally until 1 cm of ureteral tunnel was developed. The occlusion balloon prevents tumor seeding prior to the laparoscopic nephroureterectomy. The ureter was laparoscopically dissected down to the detrusor muscle. The ureter was retracted cranially and the bladder cuff was divided with a laparoscopic endoscopic gastrointestinal anastomosis (Endo-GIA) stapler (Fig. 1). The bladder was then tested for water-tightness. In a series of 25 patients at a mean follow-up of two years, the Washington University Group reported a 23% recurrence in the bladder and 15% in the retroperitoneum (12). One patient had urine leakage from the stapled line, which resolved with conservative management.

The advantage of this technique is that intraoperative urine extravasation and the theoretical tumor seeding in the retroperitoneum is minimized due to occlusion with a balloon, then closure with a stapler. There are several disadvantages, including the need to perform fluoroscopy, with repositioning of the patient. Also, injury to the contralateral ureter can occur during stapling of the ipsilateral bladder cuff, because it is not visualized in an extravesical approach. Moreover, it is difficult to assess whether an adequate margin of the bladder cuff has been resected in an extravesical approach, and there is a potential of leaving viable urothelial tissue within the staple line. This tissue may not be visible during cystoscopic examination; thus it cannot be evaluated on follow-up. The theoretical risk of developing bladder stones is concerning, although this has not been shown to occur in the pig model (13) or in humans up to seven years (12).

FIGURE 1 ■ Diagram demonstrating the use of Endo-GIA for stapling the bladder cuff. *Source*: From Ref. 28


Laparoscopic Pluck Technique

The "pluck" method was adopted by Keeley and Tolley (14). The authors performed 25 laparoscopic nephroureterectomy in this fashion with a mean follow-up of 32.9 months (15). Sixteen percent of the patients had died of the disease, and the bladder/retroperitoneal recurrence rates were not reported. As mentioned previously, because the ureteral orifice is not occluded during transurethral resection, the retroperitoneum near the resected orifice may be seeded during the nephrectomy by tumor-laden urine. Furthermore, because the distal ureter is not marked, i.e., with suture or clip, it is difficult to assess whether the entire ureter with its bladder cuff is removed when it is plucked.

Intravesical Laparoscopic Method

Gill et al. described a method using two needlescopic ports inserted suprapubically into the bladder (Fig. 2) (16). The bladder is distended with irrigation. Under cystoscopic visualization, two 5-mm balloon tipped ports are inserted suprapubically into the bladder one fingerbreadth superior to the pubic bone on either side of the midline. A 5-mm Endoloop[®] [a] is inserted through the port on the same side as the affected ureter, and the loop is positioned around the ureteral orifice. A 6 French ureteral catheter is then passed retrograde over a glide wire into the targeted renal pelvis. The bladder cuff is resected transurethrally with electrocautery using a Collins knife. The ureteral orifice is tented by a grasper from one of the ports, and an Endoloop is used to cinch down and occlude the ureter via the second port. The distal ureter with its bladder cuff is dissected with the Collins knife, using anterior retraction with a grasper. The bladder cuff is circumferentially detached in a full thickness manner, en bloc with the intramural ureter. Continuous wall suction to both suprapubic ports are used to minimize extraperitoneal irrigant absorption. Once completed, the patient is repositioned, the remaining nephrectomy is then performed laparoscopically via a retroperitoneoscopic approach.

In a series of 42 patients from the Cleveland Clinic with a mean follow-up of 11.1 months, there was a 23% recurrence rate in the bladder and none in the retroperitoneum (17). One patient experienced extraperitoneal fluid extravasation, which resolved with conservative drainage.

The advantage of this technique compared to the pluck procedure is that urine extravasation from the affected kidney is minimized by obstructing the ureter with an endoloop, thus decreasing the risk for tumor seeding. Also, with an anterior retraction using the Endoloop, cystoscopic mobilization of the ureter is performed more extensively, and subsequent plucking of the ureter is facilitated. The disadvantage is that irrigant extravasation may cause possible hyponatremia during a long procedure. Also, the patient must be repositioned intraoperatively, lengthening the total surgical time. This procedure is technically difficult and requires a vast laparoscopic experience.

FIGURE 2 ■ Intravesical method demonstrating two needlescopic ports inserted suprapubically into bladder. The Endoloop is cinched down to occlude the ureter, after the bladder cuff is resected with electrocautery.

[a]Ethicon, Somerville, NJ.

Transurethral "Intussusception" Technique

A novel technique of managing the distal ureter and bladder cuff during an open radical nephroureterectomy was introduced by Angulo et al. (18). The "intussusception" technique was performed by placing a ureteral stone basket into the ureter of the affected side. A standard open radical nephroureterectomy is performed, and the stone basket is advanced to the proximal ureter with clips just proximal to the basket. The ureter is transected just distal to the clips, and the stone basket is advanced into the retroperitoneum and opened. The ureteral wall tissue is insinuated into the basket, which is placed on gentle traction. The ureter is then intussuscepted in its entirety into the bladder. The ureter is detached from the bladder with a transurethral resectoscope using a Collins knife (Fig. 3) (18).

The authors reported no complications in their series of 21 patients, with a mean follow-up of 44.6 months. Twenty percent of the patients had recurrence in bladder and none in the retroperitoneum (18). However, this procedure can only be used for renal pelvic tumors, as it may lead to seeding if the tumor is in the ureter. Moreover, the "stripping" of ureter may leave residual tissue behind if it is torn. Once torn, it may be difficult to retrieve it in the retroperitoneum. This occurred in 9.5% (2/21) of the patients in the authors' series. In addition, a large defect is left in the bladder, necessitating prolonged bladder drainage.

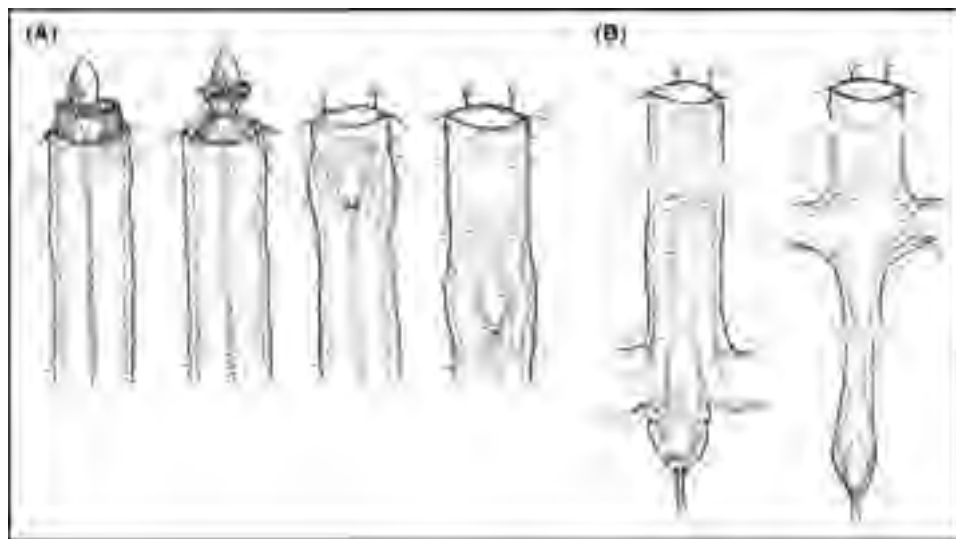
Hand-Assisted Techniques

Hand-assisted laparoscopic nephroureterectomy has been advocated by some (19–22), because it provides the surgeon with tactile sensation and an incision adequate for intact specimen removal. Herein, we present two hand-assisted laparoscopic nephroureterectomy techniques.

Intravesical Technique

Gonzalez et al. described making a midline, periumbilical incision, which was used as the hand-assisted port (20). Prior to the dissection of the kidney, two large clips were placed on the proximal ureter to prevent any potential tumor spillage during nephrectomy. For the distal ureter, a suprapubic 10-mm laparoscopic trocar is placed, and a 24-French nephroscope is placed through the trocar. The distal ureter is resected using a Collins knife, with the aid of the surgeon's hand to elevate the ipsilateral hemitrigone into view. Once the bladder cuff is free, the surgeon's hand was used to remove the specimen intact (Fig. 4). Neither the suprapubic cystotomy nor the bladder cuff resection site was closed with suture. Foley catheter was removed by day 10 postoperatively.

The advantages with this technique are that because it is hand assisted, only one trocar site is necessary transvesically to resect the bladder cuff. No patient repositioning is necessary for a transurethral procedure. However, because the authors report only one case of this method, the oncologic efficacy of this technique is not evaluated.

FIGURE 3 ▪ (A) "Intussusception" technique demonstrating the ureter which is sectioned below the ureteropelvic junction. The tip of the catheter is tied to the proper ureter and later intussuscepted when the catheter is pulled out. (B) The catheter is retracted on a light tension until the ureter is totally everted in a tent fashion. A transurethral resection is then performed around the everted ureteral orifice.


Modified Pluck Technique

Another similar method utilizing a modification of the pluck technique was introduced by Wong and Leveillee (21). The ureter is clipped and dissected distal to the intramural hiatus prior to any kidney dissection. A transperitoneal hand-assisted laparoscopic nephroureterectomyis then performed. Subsequently, by placing the ureter on tension with the surgeon's hand, the remaining ureteral dissection is performed transurethrally with a Collins knife. The complete specimen is then removed en bloc through the hand port. Again, the bladder is not closed, and a cystogram is performed on the seventh postoperative day; if it is normal, the catheter is removed.

The authors recently presented a mean follow-up of 13.2 months on 27 patients (22). Ten patients have had intravesical recurrences (37%) and no retroperitoneal recurrence was noted. The advantage to this approach is that no additional incision is made to resect the distal ureter and the bladder cuff. Further, the authors describe a modified dorsal lithotomy position where the laparoscopic and transurethral surgeries can be performed simultaneously without repositioning (Fig. 5). The theoretical risk of tumor spillage/seeding from the resected ureter is minimized because the distal ureter is clipped prior to any kidney dissection. The disadvantages of this procedure can also be associated with those of the pluck technique. The bladder is left open to heal by secondary intention. Although not mentioned in the authors' description, the simultaneous laparoscopic and transurethral procedures likely presents with technical difficulty during surgery.

Although each one of the above mentioned techniques has its advantages, they all present with their own shortcomings. Technical shortcomings include incomplete resection of the ureteral orifice, tumor spillage, an open bladder left to heal by secondary intention, exposed staples, trapped mucosa within staple lines, leaking trocars, and time-consuming patient repositioning/draping. The most important issue for the management of the distal bladder cuff is its oncologic efficacy.

In a review of the world literature, selected series of laparoscopic nephroureterectomy are outlined in Table 1. The mean follow-up ranged from 11.1 to 32.9 months with the bladder recurrence rate ranging from 10.5% to 50% (12,15,17,19,22,25,26). Although this is comparable to the well-published rates of 21% to 23% in the open series (23,24), more studies with a longer follow-up and a larger number of patients are needed to demonstrate adequate cancer control of the various modalities in distal ureter treatment.

For this and the fact that urothelial carcinoma is an aggressive tumor, we still advocate an open Gibson incision with the standard approach of transvesical bladder cuff resection, following a laparoscopic nephrectomy. Through this incision we remove the intact specimen, including the kidney, ureter, and the bladder cuff.

> The most important issue for the management of the distal bladder cuff is its oncologic efficacy.

OPEN MANAGEMENT OF THE DISTAL URETER AND BLADDER CUFF FOLLOWING LAPAROSCOPIC RADICAL NEPHROURETERECTOMY

During the operation, the anesthetized patient is first placed in a modified 45° lateral decubitus position at the chest and 30° at the pelvis with the table flexed at the flank and no kidney rest. The abdomen, genitalia, and the flank are prepped and

FIGURE 4 ■ Surgeon's left hand through hand assist port is used to push hemitrigone upward toward abdominal wall to facilitate bladder cuff resection using the Collins knife.

FIGURE 5 ■ Patient in a modified dorsal lithotomy position, allowing simultaneous hand-assisted laparoscopic nephroureterectomy and access to urethra.*Source*: From Ref . 21.

draped in the standard surgical fashion. A urinary catheter is placed on the surgical field prior to the start of surgery. Then, a transperitoneal laparoscopic radical nephrectomy is performed. We believe the transperitoneal, rather than the retroperitoneal access is a superior approach for laparoscopic renal cancer surgery. It allows for a wider space to maneuver, thus allowing for a radical nephrectomy to be performed without violating the Gerota's fascia. Early clipping of the ureter immediately following division of the renal pedicle will prevent tumor cells in the urine from flowing down the ureter.

Once the laparoscopic radical nephrectomy and dissection of the ureter down to the bladder have been performed, the trocars are removed and the pneumoperitoneum released. The operating table is then turned laterally so that the patient is more supine. Of note, the patient is not repositioned. The exposure of the bladder is performed by making a classic 12 to 15 cm Gibson. The space of Retzius is entered extraperitoneally. The anterolateral aspect of the bladder and the intramural ureter are dissected. The bladder is filled with 240 mL of sterile water through the urinary catheter until it is visually distended. An anterior 4-cm longitudinal cystotomy is made, and the bladder is exposed with self-retaining retractors. A 3-0 Vicryl (polyglactin 901) suture is placed through the ureteral orifice and tied. With an anterior retraction on the suture, the ureteral orifice with a 2 cm bladder cuff is encircled and dissected with electrocautery. This is performed in a retrograde fashion until the ureteral dissection connects with the plane of the antegrade, or laparoscopic, dissection of the ureter. Once freed, a 10 cm peritoneotomy is made just superior to the bladder. The kidney is grasped and removed intact with the ureter and its bladder cuff en bloc. The ureteral orifice defect and the anterior cystotomy are closed in two layers, followed by closure of the peritoneotomy. An abdominal extraperitoneal drain is placed, and typically removed on postoperative day 2 when the drain output is less than 50 mL per eight hours. The patients are advanced to regular diet as tolerated, and are discharged home by postoperative day 2 or 3. An indwelling urinary catheter

TABLE 1 ■ Selected Recent Series of Laparoscopic Nephroureterectomy

Authors	No. of patients	Approach	Management of distal ureter	Mean follow-up time (mo)	Recurrence in bladder (%)	Recurrence in retro-peritoneum (%)
McNeill et al. (2000) (15)	25	Transperitoneal	Pluck	32.9	N/A (16% died)	N/A
Gill et al. (2000) (17)	42	Retroperitoneal	Transvesical	11.1	23	0

Abbreviation: HAL-NU, hand-assisted laparoscopic nephroureterectomy.

is left in the bladder for five days, at which time a cystogram is performed. If the cystogram shows no extravasation, it is removed.

The postoperative follow-up protocol includes cystoscopy and urine sampling for cytology every three months for two years, every six months for two years, and then annually if no bladder tumor recurs. Baseline abdominal computerized tomography is performed two to three months postoperatively. Chest X-ray and abdominal computed tomography with intravenous contrast are performed yearly for five years, then biannually.

SUMMARY

- Various minimally invasive methods in the treatment of the distal ureter and bladder cuff during laparoscopic nephroureterectomy have been described.
- Although each one of the techniques has its advantages, they all present with their own shortcomings.
- The most important issue for the management of the distal bladder cuff is its oncologic efficacy.
- Longer follow-up with larger series of patients is needed to assure their oncologic efficacy. Until then, the open approach to the management of the distal ureter and bladder cuff following a laparoscopic nephrectomy remains the standard of care.

COMMENTARY

John M. Fitzpatrick
Department of Surgery, University College Dublin, Dublin, Ireland

The minimally invasive treatment of urological disease has advanced considerably in the last 25 years. Those of us who remember open nephrolithotomies being performed on the same kidney for the third or fourth time will have seen the full extent to which invasive surgery has in many areas become a thing of the past. The new dawn of minimally invasive surgery in urology was heralded by the advent of percutaneous nephrolithotomy developed by Wickham, Marberger, and Alken in Europe and Segura and Clayman in the Unites States. In a relatively short time, this became the standard way of removing stones from the kidney.

However, extracorporeal shock wave lithotripsy was introduced at almost the same time, and with this new, all-encompassing technology, we felt that nothing else was required to treat stones. However, it became clear that the best way of clearing the kidney of large stones was a combination of shock wave lithotripsy and percutaneous nephrolithotomy. In other words, minimally invasive surgery still had a very important role to play.

Laparoscopic surgery was popularized in general surgery and urology at more or less the same time. Clayman and his colleagues developed a technique for nephrectomy and nephroureterectomy, and Gill popularized the techniques of radical nephrectomy and partial nephrectomy. What became clear was that to learn these techniques required intensive training and mentoring. The fact that these techniques have become so widely popular is testament to the skill and patience of these opinion leaders.

The benefit to patients of the laparoscopic approach has been made clear in a large number of publications. The fact that laprascopic radical nephroureterectomy is, in fact, an endoscopic re-creation of the open procedure makes it easy to understand these advantages. The major limitation, apart from the loss of three-dimensional visualization and of tactile properties, is the use of a phrase that I do not like—the "learning curve." I believe that most urologists realize that the concept of a learning curve can be avoided by careful tuition and mentoring.

In the future, it is likely that every department will have a section of laprascopic urology. My belief is that this will continue to grow and that the science will be developed with the improvement of technology. Whether robotic surgery will interfere with this progress remains to be seen. It behooves us all to encourage the development of laprascopic urology, which is definitely a benefit to our patients.

INTRODUCTION

Transitional cell carcinoma of the renal pelvis and ureter, or upper tract transitional cell carcinoma, is an uncommon disease for which specific epidemiologic data are not available (1). Tumor stage and grade remain the major prognosticators of recurrence and survival. The upper urinary tract may have patchy involvement by carcinoma in situ, and multifocality is common (2,3). Carcinoma in situ of the upper urinary tract has an incidence of 23% in nephroureterectomy specimens, and the incidence of upper tract transitional cell carcinoma appears to be increasing (4). Of patients with a history of bladder transitional cell carcinoma, 4% to 21% develop upper tract transitional cell carcinoma during 15-year follow-up (5,6). Conversely, approximately 25% to 75% of patients first presenting with upper tract transitional cell carcinoma subsequently develop de novo bladder transitional cell carcinoma (7,8). Patients with a history of transitional cell carcinoma in any location have a high risk of subsequent recurrence in a residual ureteral orifice or retained ureteral stump (8). Endoscopic and laparoscopic techniques have dominated efforts to minimize the morbidity associated with radical removal of the kidney, ureter, and bladder cuff for treatment of upper tract transitional cell carcinoma. Because the first endourologic approach to the distal ureter was proposed in 1952 (9), numerous other minimally invasive approaches to the distal ureter and bladder cuff have been described (10). Clayman et al. reported the first laparoscopic approach to nephroureterectomy in 1991 (11). These initial procedures had long operative times, but patients experienced less perioperative morbidity than those undergoing open nephroureterectomy (12). Approximately 400 patients have been reported as having undergone the procedure via conventional transperitoneal (13–17), conventional retroperitoneal (18–21), hand-assisted transperitoneal (22–25), and hand-assisted retroperitoneal (26,27) approaches with a variety of laparoscopic, endoscopic, and open surgical methods for excision of the distal ureter and bladder cuff. Few publications have reported the long-term results of therapy for upper tract transitional cell carcinoma in a substantial number of patients (2); fewer still have reported the long-term results of laparoscopic radical nephroureterectomy. Most of the literature on laparoscopic radical nephroureterectomy is dominated by small, single-institution series of 25 or fewer patients, with a handful of larger series (14–16,18,23,27). This chapter will review the current status of laparoscopic radical nephroureterectomy, in specific regard to the various approaches to the upper tract and bladder cuff, morbidity, oncologic outcomes, port site, and ureteral stump recurrences.

NEPHRECTOMY

The findings of contemporary single-institution series describing the most clinically significant experience with laparoscopic radical nephroureterectomy are listed in Table 1 and are stratified by type of laparoscopic approach. To date, no prospective randomized

studies comparing conventional and hand-assisted laparoscopic radical nephroureterectomy have been performed. Retrospective studies have found that operative times for the conventional approach are longer than are those for the hand-assisted approach, that blood loss, narcotic use, and hospitalization are equivalent for the two approaches, but that convalescence is longer in those undergoing hand-assisted laparoscopic radical nephroureterectomy (29). Laparoscopic nephrectomy has been found to cost 21% less than open and hand-assisted laparoscopic nephrectomy, a finding that is likely applicable to laparoscopic radical nephroureterectomy (30). A hand-assisted approach for laparoscopic radical nephroureterectomy may be cumbersome because the incision is often too high for adequate distal ureter and bladder dissection or too low for comfortable renal dissection, causing substantial ergonomic discomfort to the surgeon (27).

Various rationales for the use of either the transperitoneal or retroperitoneal approach exist (31). Concerns regarding tumor spillage in the peritoneal cavity with the transperitoneal approach have not been documented in the literature, although this remains a real possibility. Transperitoneal laparoscopy has not been found to result in a significant incidence of postoperative ileus in comparison to retroperitoneal laparoscopy (Table 1). This is possibly because of the minimal bowel manipulation that occurs even with the transperitoneal laparoscopic approach. A randomized prospective trial of laparoscopic transperitoneal versus retroperitoneal radical nephrectomy identified only a faster operative time and easier control of the renal vessels as advantages of the retroperitoneal approach, and no difference in the rates of postoperative ileus (32). The hand-assisted retroperitoneal approach is relatively novel and unlikely to become widely used. Experience with this operation remains limited to a few institutions in Asia. Laparoscopic radical nephroureterectomy has been found to be marginally (6%) more economically efficient than open nephroureterectomy at centers where laparoscopy is routinely performed (33). With the continued decline in operative times and reduced reliance on disposable equipment, the cost of laparoscopic radical nephroureterectomy will continue to decrease.

Differences between laparoscopic approaches to the upper urinary tract during laparoscopic radical nephroureterectomy likely reflect different practice patterns, variable definitions of outcome, small numbers of patients, and the influence of the learning curve rather than clinically relevant differences in technique. In general, the retroperitoneal approach avoids entry into the peritoneal cavity, provides faster access to the renal vessels, and has a shorter operative time. Limited data suggest that hand-assisted laparoscopic radical nephroureterectomy is associated with a shorter learning period and operative time but at the potential cost of a longer convalescence, higher operative expenses, and reduced ergonomic comfort for the surgeon. Overall, recent data demonstrate that laparoscopic radical nephroureterectomy can be feasibly performed, with overall favorable

perioperative outcomes, regardless of the type of laparoscopic approach used for the nephrectomy portion of the procedure.

THE CURRENT STATUS OF LAPAROSCOPIC RADICAL NEPHROURETERECTOMY, DISTAL URETERECTOMY, AND BLADDER CUFF EXCISION

A variety of different methods for excising the distal ureter and bladder cuff during conventional and hand-assisted laparoscopic radical nephroureterectomy have been described. The findings of contemporary single-institution series describing the most clinically significant experience with laparoscopic radical nephroureterectomy are listed in Table 2, stratified by type of distal ureter and bladder cuff approach. These methods can generally be classified into five typical approaches as listed in Table 3, although various other modifications have been described in the literature. In 1952, McDonald et al. described the first endoscopic method of distal ureter and bladder cuff excision, which was performed on a patient presenting with extensive tumor in a residual ureter after having already undergone nephrectomy (9). The ureter was disconnected from the bladder by transurethral resection also known as the "pluck" procedure) of the perimeatal bladder and intramural ureter. The open distal end of the ureter was sealed with fulguration, and the remaining detached ureter was then "plucked" through the open incision by traction. This technique and its various modifications have been described in several contemporary series of laparoscopic radical nephroureterectomy (13,14,37,38). Local recurrences after transurethral resection of the ureteral orifice have been reported in several publications (see the section Local Recurrences: Port Site and Ureteral Stump). It is unlikely that fulguration provides a meaningful seal against urinary leakage, and the risk of leaving a discontinuous, isolated segment of ureter in the extraperitoneal space exists. This approach may be useful for patients who have no ureteral or bladder tumors and have undergone pelvic surgery such that an additional lower abdominal incision would add substantial morbidity.

In 1953, McDonald described another endoscopic technique of distal ureterectomy, in which cystoscopic incision of the perimeatal bladder wall is performed and a ureteral catheter is placed. During nephrectomy, the ureter is divided, and the residual segment is tied tightly to the ureteral catheter with a suture. The ligated ureter is stripped, or intussuscepted, through the urethra by traction on the ureteral catheter (39). In 1983, Clayman et al.

TABLE 3 ▪ Indications and Contraindications for Various Approaches to Distal Ureter and Bladder Cuff Excision

Technique	Indications	Contraindications
Transurethral resection	Renal pelvic tumor with difficult pelvic anatomy	Prior pelvic radiation Distal or intramural ureteral tumor CIS of upper urinary tract or nonvisualized lower ureter Active bladder disease
Intussusception	Renal pelvic tumor with difficult pelvic anatomy	Any ureteral tumor Any CIS of bladder or upper tract; or Active bladder disease
Laparoscopic stapling	Renal pelvic, proximal, or mid ureteral tumor	Distal or intramural ureteral tumor; or Perimeatal bladder tumor
Transurethral detachment and ligation (Cleveland Clinic technique)	Renal pelvic, proximal, mid ureteral or distal (not intramural) ureteral tumor	Intramural ureter tumor; or Active bladder disease Avoid active bladder disease
Open transvesical	Any UTTCC Distal or intramural ureteral tumor Invasive distal ureteral tumor	
Open extravesical	Renal pelvic, proximal, mid, and distal ureteral tumor Distal ureteral tumor or CIS	Invasive intramural ureteral tumor Untreated perimeatal bladder tumor

Abbreviations: UTTCC, upper tract transitional cell carcinoma; CIS, carcinoma in situ.

described 18 patients who underwent this procedure during open nephroureterectomy; 14 of them were followed up for five years with no local recurrences (40). The use of this method is still occasionally reported in contemporary series of laparoscopic radical nephroureterectomy (27).

Laparoscopic stapling of the distal ureter and associated bladder cuff is a newer technique that is performed in conjunction with cystoscopic unroofing and scarification of the ureteral orifice (15,16). Stone encrustation along the staple line has not been a problem on long-term follow-up in the limited number of patients who have undergone the procedure, although the staples may be visible on cystoscopy (15,41). The small segment of tissue within the incorporated staple line on the specimen side is unavailable for pathologic evaluation of margins, whereas at the other end, the same tissue remains viable and a potential source of extravesical recurrence (42). This method has the unique advantage of keeping the urinary tract closed, which may be advantageous for patients with a history of radiation therapy, or other risk factors for prolonged leakage, and for those in whom urine or irrigant extravasation must be avoided (15).

A novel method of en bloc transurethral detachment and ligation was described in 1999 (43). A ureteral catheter is initially threaded through an Endoloop® tie[a] and into the ureter. The bladder cuff is circumferentially incised, and the intramural ureter is dissected using a Collins knife aided by two suprapubic, transvesically placed 5 mm laparoscopic ports. The endoloop is then used to ligate the ureter against the catheter, preventing spillage from the upper urinary tract into the extravesical space during the subsequent laparoscopic approach. In the initial set of patients, no differences in the rates of bladder, local, or distant recurrence were noted between those undergoing laparoscopic and open nephroureterectomy after 11 months (18). An analysis of 59 cases with two years of follow-up revealed the transurethral detachment and ligation technique to be oncologically feasible, and was associated with significantly fewer positive margins and local recurrences than laparoscopic stapling (35). A variation of the transurethral detachment and ligation technique has also been described in a smaller number of patients undergoing hand-assisted laparoscopic radical nephroureterectomy (44). This method, in general, comes closest to mimicking the classic open approach of distal ureter and bladder cuff resection, but requires a variety of instruments, can be technically challenging, requires patient repositioning, and is contraindicated in patients with active bladder disease.

Open dissection remains one of the most common methods of excising the distal ureter and bladder cuff. Patient repositioning is usually not required, and this one incision is used for simultaneous intact extraction of the en bloc specimen. An open approach may

---

[a]Ethicon, Somerville, NJ.

be performed transvesically or extravesically, usually via a low Gibson, modified Pfannenstiel, or lower midline incision. Some surgeons insert a ureteral catheter at the beginning of the procedure to facilitate dissection, but it is usually not necessary. Care must be taken to avoid injury to the contralateral ureteral orifice. Note that, even with open nephroureterectomy, a residual ureteral stump has been reported in up to half of patients (45), with recurrences in the stump occurring in 30% to 64% of these cases (3,46). Thus, an open approach does not guarantee complete ureteral resection or negative margins. In particular, an extravesical approach performed by palpation only risks a residual stump (Fig. 1). Contemporary pathologic practice does not typically identify or confirm the presence of bladder mucosa at the distal margin of resection; it is thus the surgeon's responsibility to visually confirm the presence of this tissue during open, laparoscopic, or endoscopic surgery (Fig. 2).

At our institution, most patients undergo cystoscopy and transurethral resection of tumor within 24 to 48 hours prior to surgery. Those found to have bladder tumors are given intravesical Mitomycin-c (40 mg) in the recovery room immediately following transurethral resection of tumor. Our routine practice includes intact, en bloc specimen extraction with an open bladder technique, usually via a lateral extraperitoneal approach typically used for extravesical dissection. However, the superior vesical artery and the lateral pedicle of the bladder are first fully divided, allowing the entire intramural ureter to be readily dissected down to the ureteral hiatus. The bladder is then opened using Metzenbaum scissors or electrocautery, the bladder cuff is excised under direct vision, and formal bladder repair is performed (Fig. 2). Thus, visual resection of the entire cuff is performed. Such dissection may be difficult in obese patients, in those who have undergone pelvic surgery, and in the setting of prior pelvic radiation. Open transvesical excision by bisecting the bladder is the primary technique used when tumors are located in the intramural ureter, or in cases of suspected invasion of the distal/intramural ureter. The influence of selection factors notwithstanding, caution should be exercised when performing a transurethral resection or stapling procedure for excision of the distal ureter and bladder cuff. However, these alternatives provide the surgeon with operative flexibility and are viable options in individual cases of anatomic difficulty. The number and variety of approaches to excision of the distal ureter and bladder cuff and the absence of a standardized approach attest to the difficulty of integrating surgical anatomy with transitional cell carcinoma biology. Additional indications and contraindications for these techniques based on patient and tumor factors are presented in Table 3.

MORBIDITY ASSOCIATED WITH LAPAROSCOPIC RADICAL NEPHROURETERECTOMY

In comparison to open surgery, minor complications after laparoscopic radical nephroureterectomy have been reported in 6% to 40% of patients and major complications in 6% to 24% of patients (Table 1). Open nephroureterectomy has been associated with a 29% overall complication rate (15,18). Patients undergoing laparoscopic radical nephroureterectomy experience fewer pulmonary complications than those undergoing

FIGURE 1 ■ Retrograde ureterogram after radical open nephroureterectomy showing residual 5-cm ureteral stump.

FIGURE 2 ■ Radical nephroureterectomy performed laparoscopically with open bladder cuff resection. The renal pelvis is bisected, showing multiple papillary tumors, and the bladder cuff is evident.

open nephroureterectomy, possibly as a result of reduced splinting, improved ambulation, and reduced narcotic usage postoperatively (13,15). This benefit is highly relevant in this population, which has a high incidence of tobacco use. Perioperative morbidity and mortality rates after laparoscopic or open nephroureterectomy are probably higher than those encountered with other forms of elective surgery, a difference that is likely attributable to the interrelated causative factors of heavy tobacco exposure and advanced age (7,13,14).

ONCOLOGIC EFFICACY

Table 4 lists the histopathologic results of specimens obtained via laparoscopic radical nephroureterectomy from large single-institution published series, representing a total of 198 international patients. Most lesions in these patients (52–94%) were high grade. Most patients with low-stage, low-grade transitional cell carcinoma of the upper urinary tract have favorable long-term outcomes after nephroureterectomy, whereas those with high-stage, high-grade disease have significantly poorer survival rates (2,4). One- and two-year follow-up data thus far show cancer-specific survival rates of 63% to 97% in 154 patients after laparoscopic radical nephroureterectomy compared with 53% to 87% in 156 patients after open nephroureterectomy followed up for 1.5 to 4 years (Table 5). Positive margin rates have not been consistently reported by all institutions but appear to be equivalent for the few studies reporting results of both approaches. Bladder recurrence rates in the open (24–64%) and laparoscopic (9–54%) groups were within expected ranges. Rates of local and distant recurrence were likewise comparable between open (0–24% and 0–23%, respectively) and laparoscopic (0–15% and 0–23%, respectively) groups. All patients who underwent open nephroureterectomy had longer follow-up. This lead-time bias accounts for the perceived higher rates of bladder, local, and distant recurrence in these open cohorts (Table 5). In one of the largest published series of open nephroureterectomy, Hall et al. (2) reported five-year disease-specific survival rates of 100%, 92%, 73%, and 41% in 252 patients with stage Ta/Tis, T1, T2, and T3 disease, respectively (Fig. 3). While most recurrences for this disease tend to occur within the first two years, follow-up for laparoscopic radical nephroureterectomy is limited, not only temporally but also by small patient numbers, and the availability of long-term data will be critically important in unequivocally establishing oncologic efficacy. The data thus far, however, supports its continued selective application.

ADJUNCTIVE PROCEDURES DURING LAPAROSCOPIC RADICAL NEPHROURETERECTOMY: LYMPHADENECTOMY AND ADRENALECTOMY

Up to one-third of patients who undergo nephroureterectomy may be found to have lymph node metastasis (48). No specific data are available to assess the impact of lymphadenectomy for upper tract transitional cell carcinoma during laparoscopic radical nephroureterectomy. However, data from open series and data from the treatment of bladder transitional cell carcinoma, from which some of the natural history of disease can be extrapolated, suggest an important role for lymphadenectomy in these cases. In one respect this role may be only limited to staging. This would strongly influence consideration of follow-up imaging and adjuvant strategies because patients with lymph

node metastasis have a high risk of distant failure and are unlikely to be cured by surgery alone. In another respect, lymphadenectomy may have a therapeutic role in a subset of patients, as those found to have minimal nodal disease are potentially curable (49). As lymphadenectomy adds minimal morbidity and because preoperative imaging can miss minimal nodal disease, our routine practice has been to perform a regional lymphadenectomy in patients undergoing laparoscopic radical nephroureterectomy, either en bloc with the renal specimen or as a separate procedure. Involvement of the adrenal by transitional cell carcinoma, on the other hand, is very unusual. If preoperative computed tomography scan shows no abnormalities of the adrenal and if deemed surgically feasible, sparing of the adrenal during laparoscopic radical nephroureterectomy appears reasonable in most cases.

LOCAL RECURRENCES: PORT SITE AND URETERAL STUMP

Port site metastasis is a rare event. Biologic, pathophysiologic, and technical factors can facilitate its occurrence, particularly in diseases such as transitional cell carcinoma that

have a propensity for local implantation (50,51). There have been seven reported cases of port site recurrence of transitional cell carcinoma, only three of which occurred during laparoscopic radical nephroureterectomy for suspected transitional cell carcinoma (Table 6) (47,56–58). Of the remaining four, two occurred during laparoscopic pelvic lymph node dissection (59,60), one after laparoscopic biopsy of bladder transitional cell carcinoma (51), and one after nephrectomy for tuberculous kidney harboring unsuspected transitional cell carcinoma (58). The three cases of port site metastasis during laparoscopic radical nephroureterectomy represent less than 1% of all reported cases of laparoscopic radical nephroureterectomy (14–16,18,20,21,24, 26,27,29,44).

Less recognized but possibly more clinically significant is disseminated recurrences after endoscopic excision of the distal ureter and bladder cuff, procedures that predate laparoscopic techniques (52–55). Recurrences after transurethral resection of the ureteral orifice are the most frequently reported. This procedure may be associated with irrigant extravasation, urine spillage from the upper urinary tract into the extraperitoneal space despite attempted "sealing" by fulguration (which is unlikely to provide effective sealing), and residual discontinuous segments of the distal ureter. All these events increase the risk of extravesical tumor recurrence, resulting in iatrogenic T3-4 disease that may not be seen cystoscopically or radiographically (51). At particular risk are patients whose upper urinary tract has not been completely evaluated: an occult distal ureteral tumor or ureteral carcinoma in situ may be present in addition to an obvious renal pelvic tumor. carcinoma in situ of the ureter may not be visible endoscopically or radiographically. Also, patients with distal or intramural ureteral tumors are poor candidates for any form of endoscopic resection of the distal ureter (13,14); in particular, those with possible invasive distal ureteral tumors are best served by an open transvesical technique (Table 3).

The outcome in these cases is often grave, the clinical experience is limited, and the optimal choice of therapy is unclear (Table 6). In the absence of distant disease, wide surgical excision appears to offer a chance at a disease-free interval. Radiation therapy for pelvic extravesical disease occurring at the endoscopic site appears to be uniformly followed by death, although local palliation may be provided. In the presence of additional distant disease, an initial trial of up-front systemic therapy may be most preferable, with additional therapy rendered depending on the response to therapy.

SUMMARY

It is now accepted that laparoscopic radical nephroureterectomy results in less blood loss, less postoperative pain, faster oral intake recovery, shorter hospitalization, and a more rapid recovery than does open nephroureterectomy (14,15,18,20,27,44,61). The morbidity rate after laparoscopic radical nephroureterectomy in this classically high-risk population likewise appears consistently favorable. No studies have shown a clear-cut advantage of the transperitoneal or retroperitoneal approach. Differences in perioperative outcomes between laparoscopic techniques have been investigated in a limited number of retrospective studies (Table 1), but it is still unclear how clinically significant these differences are. Limited published data suggests that hand-assisted laparoscopic radical nephroureterectomy is more expensive but that the cost may be offset by shorter operative times.

The most challenging aspect of laparoscopic radical nephroureterectomy is excision of the distal ureter and bladder cuff. A variety of endoscopic, laparoscopic, and open methods may be used, but they have not been prospectively studied. The high prevalence of multifocal disease and carcinoma in situ in patients with upper tract transitional cell carcinoma should be considered in planning any endourologic or laparoscopic approach to the distal ureter and bladder cuff (4,7,35,62). Caution is warranted with transurethral resection procedures, as these are the most commonly associated with disseminated recurrence. Even with the open approach, complete excision is not guaranteed if performed blindly. Despite the considerable improvement in perioperative outcomes with laparoscopic radical nephroureterectomy, long-term oncologic follow-up data are not yet available, and intermediate-term follow-up data remain limited. The data suggest that survival rates for patients with low-stage, low-grade disease are favorable, whereas patients with high-stage, high-grade disease continue to experience markedly diminished survival, a finding consistent with results found with open surgery. If one were to extrapolate recent bladder cancer treatment data on the optimal use of neoadjuvant therapy for patients at high risk, it would seem that patients with high-grade, high-stage

tumors are probably best served by neoadjuvant chemotherapy, considering especially the significant reduction of renal reserve that occurs following nephrectomy, necessitating lower doses of chemotherapy and thus lower treatment efficacy. The role of laparoscopic radical nephroureterectomy in the postchemotherapy setting is largely uninvestigated, and will probably be evaluated at only a few centers of excellence.

COMMENTARY

J. deKernion
Department of Urology, UCLA Medical School, Los Angeles, California, U.S.A.

Laparoscopic nephroureterectomy is a natural outgrowth of the parent procedure laparoscopic radical nephrectomy. Currently, in practice locations that have the necessary expertise, it is the method of choice for confined tumors of the renal pelvis and ureter. The procedure has not received the same warm embrace as laparoscopic nephrectomy, primarily because of the requirement for complete removal of the ureter with a cuff of bladder. Nonetheless, at our institution, barring any specific contraindications, it is the preferred method of managing these kinds of malignancies.

The authors of the chapter discuss the benefits and limitations quite thoroughly. In my view, the primary benefits are the more rapid recovery and return to normal activity and less postoperative pain. We and others have modified the open operation to minimize morbidity. In my experience, unless the tumor is very large and invading outside of the collecting system, blood loss is very minimal, and I doubt that the laparoscopic technique has any significant advantage over the open method in that respect. A small flank incision, combined with a small muscle-splitting or midline suprapubic incision, is often adequate for these tumors. However, even with the modified incisions and modern improved pain management, there is a slightly longer hospitalization and longer interval of disability than one sees with laparoscopic nephroureterectomy.

As nicely discussed in this chapter, the potential "Achilles' heel" of the procedure is the necessity for the removal of the bladder cuff. Many methods have been described. I am very concerned about simply pulling up the bladder and applying a staple line. I have suggested a modification, which is basically the technique I use when performing the open procedure. The ureter is kept under traction and carefully dissected down into the muscle of the bladder until a large funnel-shaped section of the bladder mucosa is free circumferentially. One can then apply a clamp and divide the bladder mucosa with certain removal of not only the ureteral orifice but also of the surrounding bladder mucosa and submucosa. An alternative method is to simply make a small, muscle-splitting, McBurney-type incision for removal of the kidney and dissect the distal ureter through the same incision. Whatever technique is utilized, the laparoscopic nephroureterectomy is only acceptable if it achieves the same cancer control end result as can be achieved by the open technique.

Another issue of concern to me is that of the regional lymph node dissection. For renal pelvic tumors on the left side, this is very straightforward and requires only the removal of the hilar and periaortic lymph nodes. However, on the right side, the lymph node drainage of the kidney is such that the nodes behind the cava and in the interaortocaval region are the ones that would be most likely involved. This poses greater technical difficulty for the laparoscopist. The same concerns exist for tumors in the mid or distal ureters, because the adjacent lymph nodes should be excised. Certainly, node dissection is only important in patients with high-grade or large invasive tumors.

Tumors that seem to invade through the renal pelvis or the ureter still may be managed best by the open technique, which would allow for more extensive dissection and frozen-section monitoring. However, as the laparoscopic surgeons gain more skill, they may indeed be able to manage such patients with equal success as the traditional surgeon.

As for the future, some consensus has to be reached about the most appropriate methods for managing the distal ureter and its insertion into the bladder. Those techniques that assure complete removal of the ureter, including the orifice and a cuff of bladder, should be adopted, and the others should be abandoned. The issue of lymph node dissection must be confronted. The development of more sensitive and accurate radiolabeling imaging techniques may resolve this issue for us. Until then, the laparoscopic surgeon must be willing to perform appropriate staging, regional lymph node dissection for

patients with high-grade tumors. Admittedly, the value of modern adjuvant chemotherapy in these circumstances has not been clearly defined, but knowledge of the lymph node status gives the urologic oncologist valuable information for making that decision. Large, high-grade lesions, which may invade through the ureter or collecting system, should probably still be managed by the open technique, because inadvertent spillage of tumor in these patients can result in local recurrence.

Laparoscopic nephroureterectomy has already largely replaced the open technique in most institutions. It is the method of choice for patients in whom there is no contraindication, and who harbor tumors that are amenable to the laparoscopic approach.

KIDNEY CANCER SPECIMEN EXTRACTION: INTRACORPOREAL MORCELLATION

Maxwell V. Meng

Department of Urology and UCSF Comprehensive Cancer Center,
University of California School of Medicine, San Francisco, California, U.S.A.

INTRODUCTION

The laparoscopic approach to the removal of solid organs has evolved over the past decade. Within the genitourinary system, the most significant impact has been for upper urinary tract tumors, and currently laparoscopic radical nephrectomy and nephroureterectomy are well accepted for renal and urothelial malignancies, respectively. Recent data from multiple centers have demonstrated both the safety of the procedures and excellent long-term cancer outcomes (1–3).

Despite the increased application of the minimally invasive approach and excellent descriptions of the various surgical techniques, debate persists regarding the optimal method of specimen retrieval. Some perform intact specimen removal from an extended port site, lower abdominal incision, or the vagina (4–6); others remove the kidney piecemeal after intracorporeal fragmentation within an impermeable bag (7,8).

BACKGROUND

The minimally invasive approach was initiated for the diagnosis and management of pelvic conditions, and primarily developed and propagated by gynecologic surgeons. In parallel fashion, the early considerations for specimen handling and extraction were within the realm of the gynecologists. Issues of specimen removal were relevant for both laparoscopy and transvaginal surgery in the removal of the entire uterus or after myomectomy for fibroids.

Descriptions of piecemeal removal of the uterus, using a minimally invasive technique, date back to the late 1800s. These methods of uterine removal involved the bivalving, intramyometrial coring, or wedge morcellation of the uterus through the transvaginal route (9–11). Subsequently, laparoscopy was employed to either facilitate the transvaginal operation or completely perform the hysterectomy or myomectomy (12). The specimen was typically quite large and therefore required fragmentation to preserve the benefits of improved cosmesis and shorter convalescent time. Typically, the tissue was cut or fragmented within the peritoneal cavity and the pieces removed through a trocar or a minilaparotomy incision. Specialized laparoscopic instruments were developed to facilitate the tissue retrieval, such as a manual tissue punch with the instrument shaft containing the cored fragments. The instrument has been modified with motorization of the cylindrical blade (13). The currently available commercial morcellators, designed for gynecologic applications, include the manual serrated edged macro-morcellator[a], Moto-Drive serrated edged macro-morcellator, and electro-mechanical Steiner morcellator.[b] Nevertheless, the methods remain tedious

---

[b]Karl Storz, Tuttlingen, Germany.

and time-consuming; moreover, it is important to note that the application pertained solely to extirpative laparoscopy for benign uterine diseases and morcellation was performed without specimen isolation. Thus, issues of tumor dissemination have been secondary in the removal of uterine tissue.

Several principles and lessons emerge from the existing experience. First, little data address the application of laparoscopy to the removal of solid organs harboring tumor. The majority of minimally invasive procedures involved either the uterus or spleen, where malignant diseases were excluded. In most cases, simple morcellation without an entrapment sac was performed. Second, previous studies raise significant concerns regarding cellular seeding or spillage. Cases of endometriosis and retained tissue fragments, as well as splenosis, have been reported after intraperitoneal morcellation of the uterus and spleen, respectively (14–16). In addition, dissemination of uterine cancer has been reported after morcellation of a specimen with unsuspected adenocarcinoma (17). Third, one must be cautious and adhere to basic oncologic principles. Although laparoscopic hysterectomy is increasingly applied for lower stage endometrial, cervical, and ovarian carcinoma, additional studies are needed to confirm the efficacy and appropriateness. However, what is clear is that essential elements cannot be overlooked, including lymphadenectomy and careful pathologic examination of the specimen. Thus, laparoscopic hysterectomy for endometrial cancer entails intact specimen retrieval through the vagina and accurate staging, impacting subsequent therapy. The role of specimen morcellation for laparoscopic nephrectomy remains to be completely evaluated. Fourth, adjacent structures must be protected and iatrogenic injury considered during the morcellation process. Injuries have been reported to vasculature, bladder, ureter, and bowel during both manual and electrical morcellation of the uterus.

DESCRIPTION OF METHOD

Over the past decade, the operative techniques of laparoscopic nephrectomy and nephroureterectomy have evolved, with reductions in operative time and morbidity. This has been facilitated by advances in instrumentation as well as surgeon experience. However, the methods of specimen morcellation and extraction have changed very little and are described in the following sections.

Entrapment Devices

Two primary devices are commercially available for containing the kidney specimen—the LapSac[®c] and EndoCatch Gold[®d]. The LapSac is available in several sizes, summarized in Table 1. The bag is constructed of two layers, an outer nylon and an inner polyurethane coating, with a polypropylene drawstring. In addition, integral tabs are located on opposite sides of the bag. The LapSac is supplied sterile and intended for one-time use only. The disposable EndoCatch system consists of a pouch contained within a shaft, 11.5 inch in length. The mouth of the pouch is 2.5 inch wide, attached to a continuous ring to facilitate opening, and 6 in. in length. The device is available with shaft diameters of both 10 and 15 mm, with a larger bag.

Both devices are currently used to entrap renal specimens; the use of other, homemade tools (e.g., gloves and sealable bags) has been reported but may only have the benefit of reduced costs and is untested. Advantages of the EndoCatch include the ease of introduction through a trocar, and the deployment mechanism and ring to open the mouth and keep it open. The choice of device for entrapment during intact specimen removal is a matter of surgeon preference. However, to date, morcellation within the EndoCatch cannot be advocated, and we recommend using the LapSac for this purpose.

In our experience, as well as that of others, the dual layer construction of the LapSac is more resistant to perforations. While the EndoCatch pouch is slightly distensible and susceptible to tearing, the LapSac material is more rigid. The manufacturers of the EndoCatch report that the material is impervious to "infectious cells of 0.027 microns in diameter," but the permeability to cancer cells is unknown (18). Urban et al. have examined this issue for the LapSac. After high-speed electrical tissue morcellation of a porcine kidney, a total of 20 apparently intact LapSacs were tested for permeability to bovine serum albumin, indigo carmine, or murine bladder tumor cells (19). In all tests,

there was no increase in dialysis of substance through the bag over time, up to 18 hours. In one case, a single tumor cell was noted on the hemocytometer at both one and three hours, and was thought to represent contamination given the lack of increasing numbers of cells over time as would be expected from ongoing leakage via a perforation.

Introduction of LapSac®

The LapSac is packaged as a flattened sheet and an introducer is required to aid in placing the bag intracorporeally (Fig. 1). The introducer is a stainless steel instrument with two prongs (25.5cm) and an aluminum handle. One prong is introduced into the LapSac, opposite the side where the drawstring exits. Then, the bag is tightly rolled around the introducer to create a small-diameter cylinder. The entire unit of bag and introducer is introduced into the abdomen through the largest trocar, preferably 11 or 12mm, after the specimen is placed lower in the abdomen. The bag is grasped with atraumatic forceps and slid off the introducer, aided by an in-and-out pushing motion of the introducer. Once the bag and string are entirely within the body, it is unrolled in the upper abdomen on either the spleen or liver for the left and right side, respectively.

Opening Bag and Specimen Entrapment

The mouth of the bag is opened using a grasper on each of the tabs (i.e., anterior and posterior), and the specimen is placed into the bag. Some advocate the placement of an additional port to facilitate triangulation of the mouth. However, we routinely perform transperitoneal laparoscopic radical nephrectomy using four ports, and are able to entrap the kidney using a total of three instruments. Although this can be a challenging task, coordination between the surgeon and the assistant can reduce the time to under a minute or two.

Maneuvers to aid specimen manipulation, particularly with larger masses, include placing the patient in the Trendelenberg position, obtaining a firm grasp on Gerota's fascia distant from the tumor, and dragging the specimen as far into the bag as possible prior to releasing the forceps; then, the remainder of the specimen can be maneuvered by pushing with the grasper. In addition, we utilize the largest LapSac in nearly all situations.

Several groups have reported techniques to simplify specimen entrapment using the LapSac. Sundaram et al. described threading a hydrophilic guidewire through the holes surrounding the mouth of the bag, alongside the existing drawstring (20). After intracorporeal introduction, the elasticity of the wire helps open the mouth of the bag while the rigidity eases positioning. Pautler et al. constructed a reusable instrument, similar to the EndoCatch, to which the LapSac is attached using a Prolene suture threaded through the drawstring-holes (21). The bag is rolled around the instrument, inserted through a port, and deployed within the body, opening the ring (15 cm diameter) along with the mouth of the bag. Similarly, User and Nadler adapted the EndoCatch II device for the LapSac (22). After removal of the original sack from a 15mm instrument, the large LapSac (8×10 in.) is fixed circumferentially to the ring with silk sutures, and the drawstring is tied to the deployment suture on the EndoCatch. The LapSac is then tightly rolled around the closed ring and drawn into the shaft, aided by lubrication; the preparation time was reported to be 10 to 15 minutes. The modified device is introduced directly through the skin at the site of the largest port and opened, simultaneously expanding the flexible ring and mouth of the LapSac. Retraction of the plunger pulls the drawstring, closing the bag, and the silk sutures are either broken or cut to allow bag closure.

Bag Exteriorization and Draping

The drawstring and then the edges of the LapSac are withdrawn through the skin. If desired, the skin as well as the underlying fascia can be incised to increase access to the specimen within the bag. Expansion to 2–3 cm permits easier morcellation and extraction of larger fragments; however, the port site then necessitates closure. We meticulously drape around the exteriorized bag, minimizing skin exposure and potentially reducing the likelihood of tumor seeding. The skin is covered using polyethylene film[e] and a second layer of surgical towels is clipped around the LapSac. Several surgical clamps are securely fixed to the edges of the bag to provide upward traction.

Specimen Morcellation

A number of methods exist to fragment the specimen within the LapSac. After completion, we examine the tissue fragments and attempt to separate gross tumor from normal renal parenchyma and perinephric fat. Finally, we inspect the bag for unsuspected perforation.

We routinely perform manual morcellation using a ringed forceps, where there are no sharp edges or teeth within the jaws. It is introduced through the externalized LapSac mouth and repeatedly applied to the specimen, yielding small fragments. Others have utilized Kelly clamps, Krause forceps, or placental clamps. We prefer avoiding instruments with narrow or pointed tips, which may inadvertently damage or perforate the bag. During manual morcellation, we maintain upward traction on the LapSac to fix the specimen close to the abdominal wall as well as to minimize folds of the material, which may be caught within the morcellating instrument. In addition, we prevent fluid produced during the process from spilling outside the bag.

Manual morcellation can be tedious and time consuming. In an early series, the reported median time required for kidney entrapment and morcellation was 42 and 53 minutes, respectively (8). Thus, alternative methods and equipment have been tested. Initially, a high-speed electrical laparoscopic morcellator was commonly used, but is currently unavailable. The device consisted of a recessed blade that cut tissue directly in contact with the tip, and fragments were evacuated via suction attached to the handle. Other similar instruments have been adapted. The Steiner morcellator was described in 1993 for the rapid laparoscopic removal of tissues from the abdomen (13). The cylindrical instrument consists of (i) a coring knife at the end that is (ii) rotated by an electrical microengine. Tissue is brought into contact with the exposed cutting tip using a grasper through the center of the instrument. The electrical prostate morcellator (VersaCut™[f]) has been applied to renal specimens. The instrument is designed for intravesical morcellation of prostatic tissue after laser enucleation, with an exposed side-cutting blade. Without a fluid-filled environment, the shaft rapidly overheats and ceases to function.

Landman et al. compared the high-speed electrical laparoscopic to the Steiner and prostate morcellators on porcine kidneys in an ex vivo model, using both the LapSac and EndoCatch and various media (i.e., fluid, no fluid, CO_2) (23). The Steiner morcellator was most rapid and yielded the largest mean fragment size (2.97 g). The single case of bag perforation occurred with the high-speed electrical laparoscopic in the neck of the LapSac, and was thought to be due to thermal damage. Integrity of the EndoCatch was apparently maintained with both the Steiner and prostate morcellators, as assessed by permeability to dilute indigo carmine. Although the environment did not affect performance of the high-speed electrical laparoscopic, Parekh et al. suggested that the safety of the Steiner device was increased by morcellation within a fluid-filled LapSac (24).

More recently, Cai et al. morcellated porcine kidneys using the prostate morcellator (25). Introduction and internal visualization using a nephroscope increased morcellation time (86.9 minutes) but reduced LapSac perforation (10%) compared with direct insertion of the device and external (laparoscopic) visualization (47.1 minutes and 0.015 g fragments). Manual morcellation with a ring forceps was most rapid (15.1 minutes), resulted in larger fragments (1.36 g), and did not damage the bag. Thus, manual morcellation was superior to the electrical prostate morcellator in all aspects.

Interest has developed in the use of water jet technology to aid laparoscopic operations, primarily partial nephrectomy. The device uses high-pressure fluid flow to cut the parenchyma of organs, with preservation of vascular structures. Due to limitations of all electrical morcellators, Varkarakis et al. designed a device to apply a high-pressure (1200–1500 psi) saline stream for specimen ablation and removal (26). In a porcine model, advantages of water jet over manual morcellation included shorter time (5.65 minutes vs. 11.91 minutes) and reduced time per gram of tissue removed (1.42 sec/g vs. 2.98 sec/g). Renal parenchyma and fat were easily fragmented, and collagenous tissue was subsequently removed manually. However, evidence of microscopic perforation of the LapSac was present in 80% of the water jet group. In addition, pathologic evaluation, including cytology, was impossible with the foamy product of water jet morcellation.

None of the currently available devices to facilitate morcellation is ideal and all should be used cautiously in clinical situations. Even with the use of the LapSac and

[f]Lumenis, Santa Clara, CA.

direct observation of morcellation, small perforations occur frequently; the neck of the bags can also be damaged from the heat produced from rapidly rotating shafts. Thus, we continue to manually morcellate specimens when indicated. Landman et al. describe a modified method of manual morcellation using the EndoCatch sack, preferred because of the deployment ring (27). Through a 3 cm incision, manual morcellation was performed with direct observation of the specimen, and only visible portions of the kidney were grasped. There was no case of bag perforation and mean morcellation time in 12 patients was 11 minutes. This technique appears safe and rapid, and we also increase the incision length to allow "finger fragmentation" and removal of larger pieces. However, the benefit of easier specimen entrapment must be weighed against weaker bag material.

OUTCOMES OF MORCELLATION

Morcellation avoids the need for a larger incision and may maximize the minimally invasive approach. Improved cosmesis is a clear advantage of specimen fragmentation and piecemeal removal. Another potential benefit is the reduction of incisional hernias. Elashry et al. observed postoperative hernias in 17% of patients after intact kidney removal (28). Examination of the literature on laparoscopic donor nephrectomy and hand-assisted nephrectomy reveals that the incidence ranges from 0.6% to 5%, while port site hernia is nearly absent if one uses nonbladed trocars (29–31). However, theoretical limitations are associated with the process and other morbidity benefits remain to be proven.

Cancer Outcomes

A major concern of morcellation is cancer recurrence and port site metastasis. Recent data do not suggest that specimen morcellation for renal cell carcinoma compromises oncologic efficacy. Several centers performing laparoscopic radical nephrectomy combined with piecemeal specimen retrieval have reported excellent long-term outcomes, comparable to open radical nephrectomy (Table 2) (1,2,32,33). The process of morcellation, when performed appropriately, after laparoscopic nephrectomy improved outcome.

Three cases of port site metastasis have been documented after laparoscopic nephrectomy and specimen morcellation for renal carcinoma (Table 3) (33–35). In two cases, tumor (high grade, advanced stage) and patient (cirrhosis and ascites) characteristics likely contributed to the situation. In the other case, no risk factor or explanation is available and the potential etiology may have been unrecognized bag perforation during morcellation. There are no case reports of port site recurrence after laparoscopic radical nephrectomy and intact specimen retrieval, although the omission of a bag has been associated with port site recurrence after laparoscopic surgery for urothelial carcinoma and prostate cancer (36).

TABLE 2 ■ Oncologic Outcome After Laparoscopic Radical Nephrectomy and Specimen Morcellation

Ultimately, the role of specimen fragmentation in tumor seeding at the port site remains controversial and requires further investigation.

Ultimately, the role of specimen fragmentation in tumor seeding at the port site remains controversial and requires further investigation. Morcellation should be performed meticulously and cautiously, and the balance of risks and benefits should be discussed with the patient prior to the operation.

Pain and Convalescence

It was previously thought that patients undergoing specimen morcellation had reduced pain and more rapid recovery compared to intact removal, and the early experience confirmed this assumption (8). In a cohort of patients undergoing laparoscopic cytoreductive nephrectomy prior to immunotherapy, the group who had the specimen morcellated had reduced postoperative narcotic use, shorter duration of hospitalization, and earlier time to interleukin-2 administration.

Subsequent comparisons have not demonstrated a significant difference between intact and morcellated kidney retrieval. The technique of the group from Nagoya, Japan has evolved from transperitoneal laparoscopy with intact extraction to retroperitoneoscopy to the current transperitoneal approach with fractionation. A retrospective analysis suggested that pain and convalescence were similar in the intact (29 mg morphine equivalent and 22.7 days) and fractionated (29 mg and 23.3 days) groups (37). Although it is difficult to compare data between various centers, the reported outcomes of intact specimen removal after retroperitoneal nephrectomy from the Cleveland Clinic compare favorably to all morcellation series, with low analgesic requirements (22 mg morphine equivalent), hospitalization (1.6 days), and convalescent time (4.2 weeks) (3). The mean incision size was 6.7 cm and morbidity was minimized using a muscle-splitting technique.

Dunn et al. also retrospectively reviewed patients undergoing laparoscopic radical nephrectomy and nonrandomized selection of intact or morcellated retrieval (38). Intact retrieval ($n = 21$) was comparable to morcellation ($n = 39$) in nearly all parameters measured, including hours to ambulation and oral intake, analgesic use, duration of hospitalization, and time to convalescence. The only significant difference was longer operative time in the intact group, likely reflecting the learning curve of laparoscopic nephrectomy because most intact removals were performed early in the series.

Gettman et al. prospectively examined the differences between retrieval methods in 12 patients undergoing transperitoneal laparoscopic nephrectomy (39). The two groups were similar with respect to pain and activity scores during the early postoperative period (1–14 days), and time to return to normal activity was not significantly different. The primary difference observed was the incision length (7.6 cm vs. 1.2 cm, $p < 0.05$). A larger prospective study was reported by Hernandez et al. (40). Although incision length was again shorter in the morcellated group (1.2 cm vs. 7.1 cm intact, $p < 0.001$), no differences in operative time, narcotic requirement, and length of hospital stay were noted. Thus, it is likely that the exact method of specimen removal after laparoscopic nephrectomy has little impact on early postoperative morbidity and that both methods are clearly superior to open radical nephrectomy as measured by subjective and objective parameters.

Thus, it is likely that the exact method of specimen removal after laparoscopic nephrectomy has little impact on early postoperative morbidity and that both methods are clearly superior to open radical nephrectomy as measured by subjective and objective parameters.

PATHOLOGIC CONSIDERATIONS

The inability to perform traditional pathological examination of the morcellated renal specimen has been used to support intact specimen removal (Fig. 2). Several aspects and limitations deserve consideration, including establishing a histologic diagnosis, assessment of surgical margins, and determination of tumor stage.

Diagnosis

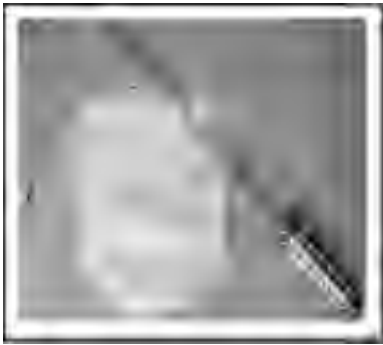
Laparoscopic radical nephrectomy is frequently indicated for solid renal masses and the suspicion of malignancy. In these cases, the identification of renal carcinoma, or absence of tumor, is critical for accurate diagnosis, patient counseling and follow-up, and determination of prognosis. In over 160 cases of laparoscopic radical nephrectomy with morcellation for suspected cancer at the University of California San Francisco, a histologic diagnosis could not be made in a single patient. In this case, preoperative imaging revealed a solid, enhancing 3 cm mass. After morcellation and retrieval, no tissue fragments were grossly suspicious for tumor and eventually complete processing and examination of the entire morcellated specimen did not show any renal pathology. Others have also observed the occasional inability to confirm a preoperatively


FIGURE 1 ■ LapSac® (5 × 8 inches) and an example of laparoscopic introducer.[g]
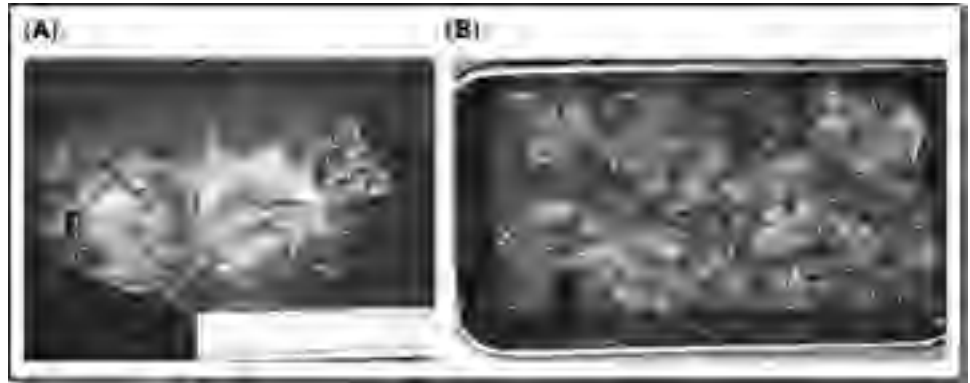

FIGURE 2 ■ (A) Intact kidney with grossly visible tumor. (B) Appearance of a kidney with mass after laparoscopic nephrectomy and manual morcellation.

> The morcellated specimen should be processed and examined, in its entirety if necessary, to identify any abnormal renal histopathology.

suspected malignancy. Barrett et al. identified no abnormal pathological findings in 3 of 66 morcellated specimens (5%), while Dunn et al. reported one case (3%) without a diagnosis (7,38). The morcellated specimen should be processed and examined, in its entirety if necessary, to identify any abnormal renal histopathology.

As illustrated in Figure 2, disruption of the renal architecture creates difficulty in sampling the morcellated specimen. In the intact specimen, only a small portion of the entire specimen requires preparation and examination for diagnosis and staging. Typically, several sections are taken from the mass itself, the margins of resection and renal vein, and any lymph nodes. In contrast, no standard or systematic method of specimen processing and analysis have been established after morcellation. To facilitate pathological analysis, a mathematical model has been proposed to guide the study of morcellated renal specimens. If no grossly abnormal fragments can be selected, a sizeable quantity of tissue is often submitted, but it is not feasible or practical to routinely examine the entire specimen. The basic question is "How much tissue does the pathologist need to prepare and examine for a diagnosis to be made?" Formal probability theory, using the hypergeometric distribution, describes the probability of randomly selecting a portion of desired sample (i.e., tumor) from a total population (i.e., entire specimen) containing a fixed fraction of desired sample (41). Figure 3 illustrates the model for tumors comprising specific fractions of the entire specimen. As expected, examining an increasing percentage of the specimen increases the probability of finding tumor. The model assumes random sampling of the specimen. In some cases, the specimen can be fractionated on the basis of gross appearance, helping focus the search for tumor and decreasing the amount of tissue that needs to be examined. This effectively reduces the total volume of specimen and shifts the sampling curve in Figure 3 to the left. Tables 4 to 6 summarize the data in another fashion, describing the quantity of tissue that must be sampled to ensure a diagnosis at 50%, 75%, and 95% confidence levels. These findings have yet to be validated in prospective studies. Nevertheless, the model provides a framework for both the surgeon and the pathologist with which to approach the pathologic examination of fractionated specimens. Additional factors of time, cost, and manpower will impact the actual protocols at individual institutions.

Landman et al. studied the pathologic findings after in vitro electrical morcellation of both Formalin-fixed and fresh radical nephrectomy specimens (42). Ten sections from each specimen were submitted for evaluation and provided the pathologic data. Tumor histology, grade, and stage were all evaluable and accurate when compared with analysis of intact tissue in 13 of 14 cases. It was recommended that "multiple sections from the morcellated specimen should be submitted."

To improve pathologic diagnosis, Pautler et al. proposed that needle biopsy could be performed after specimen entrapment in a retrieval bag, but prior to morcellation (43). Needle biopsy material, obtained after five passes, yielded congruent diagnoses in 89% of patients; however, morcellated tissue was sufficient for diagnosis in all 15 cases and the needle biopsies did not provide additional information. The relatively large lesions (mean smallest dimension 8.6 cm) likely increased biopsy accuracy of the random sampling, and the utility for smaller lesions remains unclear. In addition, blind needle biopsy raises concern for potential bag perforation.

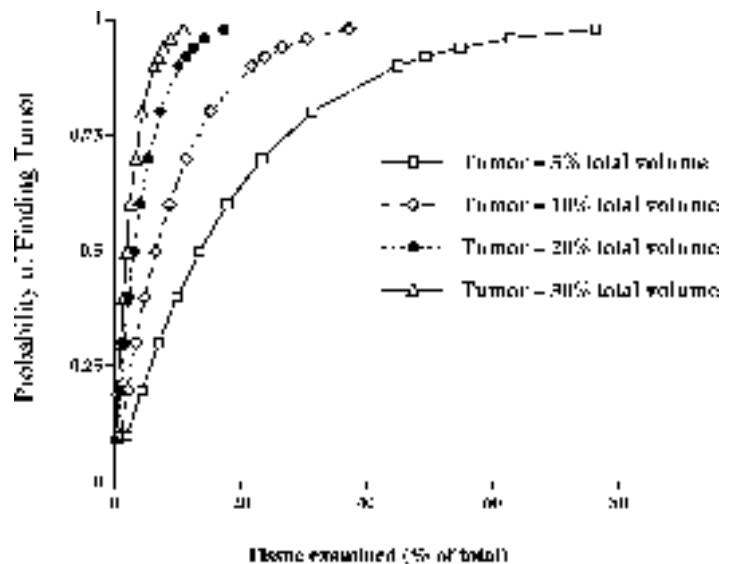
FIGURE 3 ■ Pathologic sampling model based on the hypergeometric distribution. The probability of identifying tumor plotted as a function of amount of tissue sampled for various tumor/total specimen fractions.


We have attempted to complement the diagnosis on histology by examining cytological findings in bag washings after morcellation (44). The LapSac was rinsed ex vivo with 30 mL of normal saline and the fluid sample was processed using routine cytologic protocols. In all 22 cases, cellular material was obtained and subject to examination. Concordant benign histology and cytology findings were observed in all nine patients without renal cell carcinoma, while cytology detected confirmed renal carcinoma in 69% of cases. Despite the reduced sensitivity, positive bag cytology permitted easy detection

and classification of carcinoma into both type and grade. Moreover, in three cases of cancer (23%), cytology provided additional information compared to histology alone, including higher tumor grade and mixed pathology. Advantages of bag cytology include simplicity of specimen acquisition, standard technique of processing, and incorporation during assessment for perforation. Further investigation is required to assess whether the potential information provided by an additional test is useful and cost-effective.

Tumor Staging

The over-riding controversy regarding specimen morcellation is the reduced ability to determine tumor stage. While the importance of histologic diagnosis is well-accepted, the clinical utility of precise pathologic staging is less clear.

> The over-riding controversy regarding specimen morcellation is the reduced ability to determine tumor stage.

Proponents of intact specimen extraction cite the inaccuracy of staging by preoperative imaging studies (3). Computed tomography overestimated and understaged tumors in 10% and 9% of patients, respectively. It is assumed that morcellation destroys the ability to identify pathologic features such as invasion into the renal vein, perinephric fat, and adrenal gland. However, Landman et al. suggested that morcellated fragments can yield evidence of perinephric fat involvement (100%) and rein vein thrombus (100%) (42). Pautler et al. also provided evidence that perinephric invasion can be identified after manual morcellation, although the true accuracy cannot be determined (43). We have made similar observations, with identification of higher pathologic stage despite morcellation.

The imprecision of clinical staging based on imaging compared to pathologic staging of an intact specimen will always remain. Furthermore, adverse pathologic features such as extension into fat or the renal vein are associated with worse oncologic outcomes. This information is important for determining surveillance regimens as well as patient counseling. However, outside of clinical trials, adjuvant therapy is not currently indicated in these situations. Therefore, the actual clinical impact of not recognizing microscopic fat invasion is limited. Indeed, the excellent five-year outcomes of the laparoscopic approach, with morcellation, for smaller renal tumors confirm the efficacy of the operation and absence of clinical implication. If more advanced stage is suspected on imaging studies and consideration of adjuvant therapy is dependent on this information, intact specimen retrieval should be performed. Future molecular characterization and stratification of renal tumors, and less dependence on pathologic stage, may predict recurrence or need for secondary treatment and shift preference toward morcellation.

> Future molecular characterization and stratification of renal tumors, and less dependence on pathologic stage, may predict recurrence or need for secondary treatment and shift preference toward morcellation.

In addition to affecting accurate pathologic staging, morcellation also obscures the nature of surgical margin status. Similar to higher pathologic stage, the presence of a positive surgical margin does not necessarily change postoperative treatment but would potentially increase the frequency of subsequent imaging. Nevertheless, accurate evaluation of surgical margins plays several roles. Negative surgical margins confirm the oncologic adequacy of the laparoscopic approach to the kidney with tumor. The excellent cancer outcomes, without significant rates of local tumor recurrence, indirectly indicate that the laparoscopic technique has not been associated with increased rates of positive surgical margins. This may be important to document as the techniques are increasingly performed (i) by those less experienced with laparoscopy, and (ii) in patients with larger and more advanced cancers. A positive surgical margin portends a worse prognosis and allows appropriate counseling of the patient, while the confirmation of a negative surgical margin is reassuring to both the patient and physician.

Few studies have addressed the question of surgical margin status in morcellated laparoscopic specimens. In an in vitro model, various substances were tested for their ability to mark the margins of bovine kidneys prior to manual morcellation (45). Undiluted india ink was superior to methylene blue and indigo carmine with respect to covering the surface, retention after washing, and microscopically visible after routine processing and hematoxylin-eosin staining. India ink is clinically safe and has been extensively used in vivo in humans. Overall, accurate pathologic study of renal specimens will become more crucial as minimally invasive surgery grows, and novel and alternative methods of determining surgical margin as well as biological behavior are necessary.

> Overall, accurate pathologic study of renal specimens will become more crucial as minimally invasive surgery grows, and novel and alternative methods of determining surgical margin as well as biological behavior are necessary.

SUMMARY

■ The ability to remove the entire kidney laparoscopically, and widespread dissemination of the technique, has created the dilemma of specimen retrieval.

- Current data indicate that careful manual morcellation is safe and does not compromise oncologic outcomes, but only further observation will confirm this.
- When performed properly, specimen morcellation after laparoscopic nephrectomy is acceptable, and is particularly appropriate in those undergoing cytoreductive nephrectomy prior to systemic immunotherapy.
- The impacts of morcellation on pathological assessment are primarily theoretical and do not typically alter treatment schemes.
- The primary benefit of specimen morcellation is cosmetic. After laparoscopic nephrectomy, the exact method of specimen handling is likely unimportant with respect to pain and convalescence.
- The decision of how to remove the kidney is ultimately based on patient and surgeon preference and made after thorough discussion of the relevant issues.

INTRODUCTION

Testicular cancer, the most common tumor in men between 15 and 35 years of age, evoked widespread interest because the dramatic improvement in survival mainly achieved with the combination of improved diagnostic techniques, tumor markers availability, effective chemotherapeutic regimens, and modifications of surgical techniques led to the decrease in patients mortality from more than 50% before 1970 to less than 5% in 1997 (1).

With all means of imaging techniques available currently, 25% to 30% of patients with testicular cancer will be understaged while some of these patients will be overstaged (2). Retroperitoneal lymphadenectomy is the most sensitive and specific method for testicular cancer staging and has also a therapeutic value. Because open retroperitoneal lymph node dissection failed to cure all patients with metastatic nonseminomatous germ cell tumors, all our clinical stage I patients diagnosed as pathologic stage II received chemotherapy as the definitive treatment.

Open surgical retroperitoneal lymph node dissection associates with substantial morbidity with overall relapse rates up to 55% if employed as a single therapeutic measure (3,4). We have replaced open surgical retroperitoneal lymph node dissection by laparoscopic retroperitoneal lymph node dissection because it showed decreased postoperative morbidity, quicker convalescence, and improved cosmetic results. Its diagnostic accuracy equals that of the open approach (5,6). Laparoscopic retroperitoneal lymph node dissection is considered a safe method for low stage germ cell tumors with minimal invasiveness (7,8).

> Because open retroperitoneal lymph node dissection failed to cure all patients with metastatic nonseminomatous germ cell tumors, all our clinical stage I patients diagnosed as pathologic stage II received chemotherapy as the definitive treatment.

THERAPEUTIC CONCEPTS AND PATIENT SELECTION

Nonseminomatous Germ Cell Tumors Clinical Stage I

Surveillance, risk-adapted primary chemotherapy, and retroperitoneal lymphadenectomy are advocated for the management in this stage, although with overall disagreement on the optimal treatment regimen (9,10).

- ■ *If surveillance is opted:*
  15% to 20% of patients will relapse (11,12). Death rates are up to 10% in the relapsing patients (13). The primary advantage of surveillance is to avoid the morbidity of open surgery, which is minimized by the introduction of the modified unilateral retroperitoneal lymph node dissection and the nerve-sparing technique, which is feasible by laparoscopic means.

■ *If risk-adapted primary chemotherapy is opted:*
In several studies involving more than 200 high-risk patients with nonseminomatous germ cell tumors of the testes (embryonic carcinoma as the primary tumor or tumors with vascular or lymphatic invasions) treated with two cycles of bleomycin, etoposide, and cisplatin (BEP) a relapse rate of 2.7% was found . Median follow-up in some studies approached eight years (11,14).

CAVEATS

- The risk of slow growing retroperitoneal teratomas.
- The risk of chemoresistant cancer relapses.
- Follow-up protocol is not clear.
- A total of 4% to 50% of patients in this group will be overtreated.
- Relapse in patients under treatment because they are considered low-risk.

■ *Retroperitoneal lymphadenectomy:*
Laparoscopic retroperitoneal lymph node dissection is our preferred choice because it has equal diagnostic accuracy, but lower morbidity than open surgery. At the time of this writing, 103 patients with clinical stage I disease underwent laparoscopic retroperitoneal lymph node dissection between August 1992 and June 2004 with a mean follow up of 62 months (range, 6–113) (Table 1).

All patients diagnosed having nonseminomatous germ cell tumors clinical stage I are candidates for diagnostic laparoscopic retroperitoneal lymph node dissection as the first line of management. Laparoscopic retroperitoneal lymph node dissection is followed by surveillance if the retroperitoneal lymph nodes histology is negative or two cycles of chemotherapy if lymph nodes metastases are found.

All patients diagnosed having nonseminomatous germ cell tumors clinical stage I are candidates for diagnostic laparoscopic retroperitoneal lymph node dissection as the first line of management. This is followed by surveillance if the retroperitoneal lymph nodes histology is negative or two cycles of chemotherapy if lymph nodes metastases are found.

Nonseminomatous Germ Cell Tumors Clinical Stage II

Neither retroperitoneal lymphadenectomy nor chemotherapy alone can be expected to be curative in this stage.

Classical options for the management of nonseminomatous germ cell tumors stage II:

■ If tumor markers are negative, retroperitoneal lymph node dissection followed by (i) surveillance if histology is negative or (ii) two cycles of chemotherapy in cases of positive histology.

■ Primary chemotherapy. If tumor markers normalize, surgical removal of residual retroperitoneal masses is performed.

In an attempt to reduce the morbidities of this combined treatment, we have reduced the dose of chemotherapy from the usual three to four cycles to two cycles for clinical stage IIB disease which is obviously the minimum dose required for complete tumor control (10). Chemotherapy in these patients is followed by laparoscopic retroperitoneal lymph node dissection even if there is no residual tumor clinically.

At the time of this writing, 42 patients with clinical stage IIB disease treated with two cycles of primary chemotherapy underwent laparoscopic retroperitoneal lymph

TABLE 1 ■ Laparoscopic Retroperitoneal Lymph Node Dissection: Results of 103 Stage I Patients

No. of patients	Histology findings (clinical stage I)	Adjuvant treatment	Recurrences
103	26 patients (25.2%) active tumor (pathologic stage II)	2 cycles bleomycin, etoposide, and cisplatin	No
	77 patients (74.8%) no tumor found (pathologic stage I)	No	5 recurrences (4.9%) →3 pulmonary →1 contralateral retroperitoneal nodes (pathologic review was false negative) →1 tumor marker recurrence 5 patients lost follow-up

TABLE 2 ■ Laparoscopic Retroperitoneal Lymph Node Dissection: Results of Stage IIB and IIC Patients

No. of patients	Histology findings (clinical stage II)	Adjuvant treatment	Recurrences
42	16 patients (38%) mature teratoma	No	→1 to external iliac lymph nodes
II B	26 patients (62%) no tumor found	No	No
17	10 patients (58.8%) no tumor found	No	No
	5 patients (29.4%) mature teratoma	No	→1 retrocaval (outside the surgical field)
IIC	1 patient (5.9%) active tumor	2 cycles chemo	No
	1 patient (5.9%) seminoma	2 cycles chemo	No

node dissection between February 1995 and June 2004 with a mean follow up of 53 months while 17 patients clinical stage IIC disease had three to four cycles of primary chemotherapy followed by laparoscopic retroperitoneal residual mass excision over the same period (Table 2).

All patients diagnosed having nonseminomatous germ cell tumors clinical stage IIA, or IIB with positive tumor markers, are treated with two cycles of chemotherapy bleomycin, etoposide, and cisplatin followed by laparoscopic retroperitoneal lymph node dissection

If indicated, laparoscopic excision of residual retroperitoneal masses in selected patients with nonseminomatous germ cell tumors clinical stage IIC treated with a minimum of three cycles of chemotherapy is feasible (5,15).

CONTRAINDICATIONS FOR LAPAROSCOPIC RETROPERITONEAL LYMPH NODE DISSECTION

Contraindications for laparoscopic retroperitoneal lymph node dissection include:

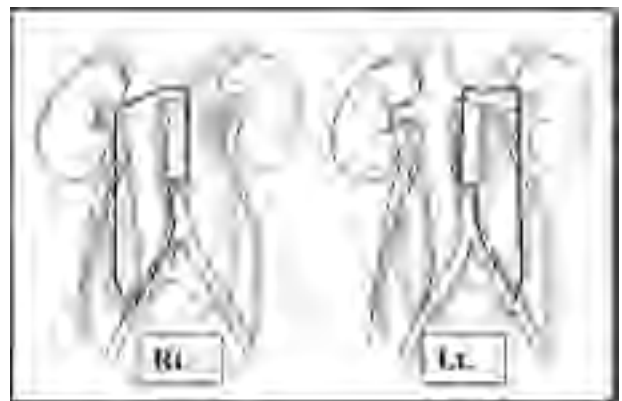
- Elevated tumor markers
- Severe pulmonary fibrosis that prevents pneumoperitoneum
- Uncontrolled bleeding diathesis
- Patients with a high body mass index benefit more from laparoscopy than slim patients as regards postoperative pain and morbidity, but do not experience more complications (16). Although laparoscopic retroperitoneal lymph node dissection may be technically more challenging in obese patients, so far we had no conversion to open surgery in this patient population.

PREOPERATIVE PREPARATION

Preoperative preparation includes:

- Low-fat diet started one week preoperatively and continued two weeks postoperatively to prevent chylous ascites
- Typing and cross-matching of two units of blood
- Bowel preparation with clear liquid diet and oral laxatives the day before surgery
- Low-dose systemic antibiotics on call to surgery.

> All patients diagnosed having nonseminomatous germ cell tumors clinical stage IIA, or IIB with positive tumor markers, are treated with two cycles of chemotherapy bleomycin, etoposide, and cisplatin followed by laparoscopic retroperitoneal lymph node dissection. If indicated, laparoscopic excision of residual retroperitoneal masses in selected patients with nonseminomatous germ cell tumors clinical stage IIC treated with a minimum of three cycles of chemotherapy is feasible.

FIGURE 1 ■ Stage I lymph node templates.


TEMPLATES

Weissbach and Boedefeld defined templates that included practically all primary landing sites of lymph node metastases occurring in patients with stage I nonseminomatous germ cell tumors (17). The right template comprises 97% of all the primary landing sites of lymph node metastases while the left template comprises 95% of all the primary landing sites of lymph node metastases in this stage (Fig. 1).

If all lymphatic tissues within the templates are excised, there is a minimal risk of metastasis being overlooked.

> If all lymphatic tissues within the templates are excised, there is a minimal risk of metastasis being overlooked.

Right Template

The right template includes:

- Interaortocaval lymph nodes
- Pre-aortic tissue between the left renal vein and the inferior mesenteric artery
- Precaval tissue
- All tissues lateral to the vena cava and the right common iliac artery
- The right ureter, which represents the lateral border of the dissection.

Left Template

The left template includes:

- Periaortic tissue between the left renal vein and the inferior mesenteric artery
- All tissue lateral to the aorta and the left common iliac artery
- The left ureter, which represents the lateral border of the dissection
- Interaortocaval lymph nodes and the lymphatic tissue ventral to the aorta below the inferior mesenteric artery, which are preserved.

The authors had investigated the primary lymphatic metastatic spread in 139 patients with testicular cancer. All solitary metastases were detected ventral to the lumbar vessels whereas metastases dorsal to the lumbar vessels were only detected in 3 out of 25 patients with multiple metastases who had ventral metastases as well. Therefore it was concluded that the primary landing sites were invariably located ventral to the lumbar vessels whereas dorsal metastases resulted from further tumor spread (18). As a result, we no longer routinely transect lumbar vessels for removal of dorsally located lymphatic tissue. This is not required for the diagnostic retroperitoneal lymph node dissection in clinical stage I disease and has made the laparoscopic procedure easier, faster, and safer.

PATIENT POSITIONING

- After general anesthesia is established, a nasogastric tube and a urinary bladder catheter are placed.
- The patient is placed with the ipsilateral side elevated 45° off the operating table, so that he can be brought into supine or lateral decubitus positions by rotating the table without repositioning
- The table is flexed at the umbilicus and if necessary, the Trendelenburg's or anti-Trendelenburg's positions are used (Fig. 2).

FIGURE 2 ■ Patient positioning.

FIGURE 3 ■ Trochar placement.

TROCAR PLACEMENT AND PNEUMOPERITONEUM

- A Veress needle is routinely used for the initial stab incision to create pneumoperitoneum, whereas Hasson cannula is used only if indicated.
- 5-mm and 10-mm trocars are used
- The primary-port trocar (for the laparoscope) is placed at the umbilicus.
- Two secondary trocars are inserted at the lateral edge of the rectus muscle 8 cm above and below the umbilicus.
- A fourth trocar is placed at the anterior axillary line in the best point for retraction (Fig. 3).

PROCEDURE

Transperitoneal Laparoscopic Retroperitoneal Lymph Nodes Dissection (4,19)
Right Side

- The peritoneum is incised at the internal inguinal ring then along the line of Toldt from the ceacum to the right colic flexure (Fig. 4).
- Cephalic dissection is carried out parallel to the transverse colon and lateral to the duodenum along the vena cava up to the hepatoduodenal ligament. Caudally, the dissection is continued along the spermatic vessels down to the internal inguinal ring (Figs. 5 and 6).
- The colon, duodenum, and the head of pancreas are reflected medially until the anterior surface of the vena cava, aorta, and left renal vein are completely exposed (Fig. 7).
- The spermatic vein is dissected free along its entire course, clipped, and transected (Figs. 6–8).
- Care must be taken during dissection of the spermatic vein where it drains into the vena cava as rupture at this point may occur.

Care must be taken during dissection of the spermatic vein where it drains into the vena cava as rupture may occur.

FIGURE 4

FIGURE 5

FIGURE 6

FIGURE 7

FIGURE 8

FIGURE 9

- The spermatic artery is clipped and transected at its crossing over the vena cava.
- Dissection of the right template starts at this point.
- Cranial to caudal the lymphatic tissue overlying the vena cava is split open; then the lateral and anterior surfaces of the vena cava are dissected free (Fig. 9).
- Subsequently, both renal veins are dissected free.
- Lymphatic tissue overlying the right common iliac artery is incised up to the origin of the inferior mesenteric artery.
- Cephalad to the inferior mesenteric artery dissection is continued upward along the left margin to the aorta. Thereby the ventral surface of the aorta is completely freed (Fig. 10).
- Lower border of left renal vein must be completely free at this point because it might be easily injured during the dissection of the interaortocaval lymph node package from caudal to cephalic direction (Fig. 10).
- Spermatic artery is now clipped at its origin (Fig. 11).
- A Fan retractor is used to retract the liver while dissecting the cranial portion of the template.
- Cranial to caudal the interaortocaval space is dissected, starting from the lower edge of the right renal artery down to the lumbar vessels and the lymphatic tissue is removed step by step (Fig. 12).
- The distal border of the dissection is the point where the ureter crosses the iliac vessels (Fig. 13).
- The lymphatic tissue is clipped distally (Fig. 13) and the dissection is continued cephalic until the lymphatic package is freed.
- Lymphatic tissues in this area are dense and care must be taken to prevent injury of the inferior mesenteric artery, which constitutes a land mark to preserve the left sympathetic nerves.
- The lumbar veins are exposed, but they are only transected in exceptional cases (Fig. 14).
- The right renal vein and artery is exposed lateral to the vena cava, which delineates the cranial border of the dissection (Fig. 15).
- The lymph nodes lateral to the vena cava and medial to the ureter are dissected free.
- The nodal package will be completely free and can be removed within a specimen retrieval bag.
- Drains are not required.
- Colon and duodenum are returned to their anatomic position and secured with one suture laterally and tied extracorporeal.

Left Side

- After incising the line of Told starting from the left colonic flexure down to the pelvic brim and distally along the spermatic vein to the internal inguinal ring, the splenocolic ligament is transected and the colon is dissected until the anterior surface of the aorta is exposed (Fig. 16).
- As an option one may leave the splenocolic ligament intact and incise the peritoneum lateral to the spleen all the way up to the diaphragm. Thereby the spleen and the tail of the pancreas are reflected medially.

> Lower border of left renal vein must be completely free because it might be easily injured during dissestion of the interaortocaval lymph node package from caudal to cephalic direction.

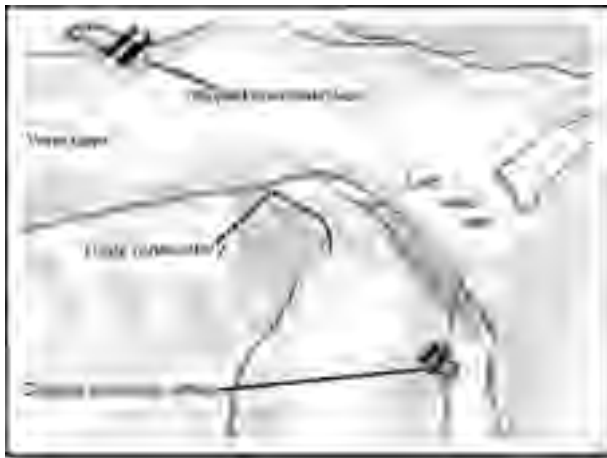
> Lymphatic tissues in this area are dense and care must be taken to prevent injury of the inferior mesenteric artery, which constitutes a landmark to preserve the left sympathetic nerves.


FIGURE 10

FIGURE 11

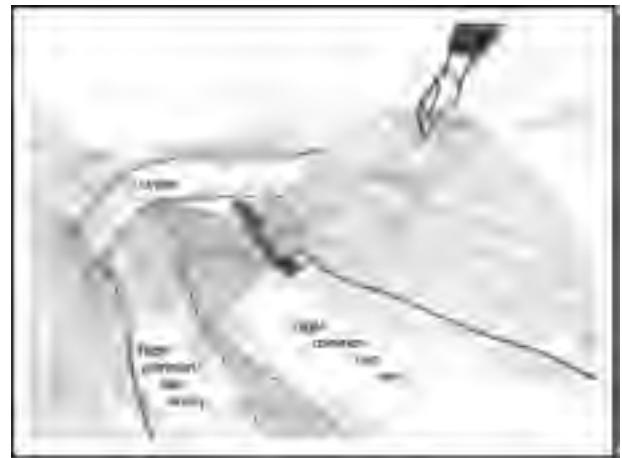
FIGURE 12


FIGURE 13

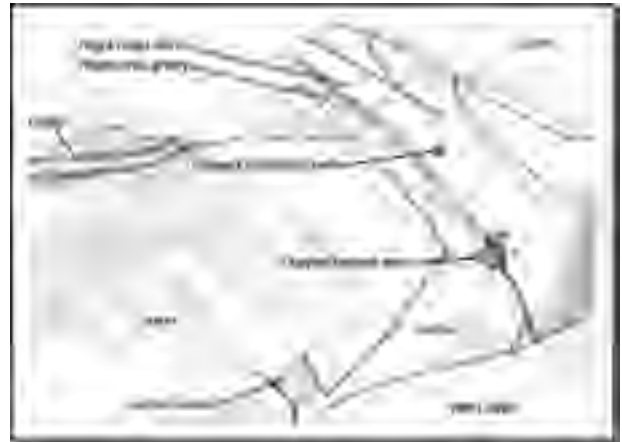
FIGURE 14


FIGURE 15

Dissection of the lymphatic template is started distally at the crossing of the ureter with the common iliac vessels.

- Normally the colon falls away from the operative field and retractors are only required in exceptional cases.
- The spermatic vein is dissected along its entire course from the internal inguinal ring up to the renal vein and excised. The ureter laterally is then identified and separated from the lymphatic tissue with care to preserve its blood supply (Fig. 17).
- The left renal vein is then completely freed at this point (Fig. 18).
- Lymphatic tissues overlying the common iliac artery are split open.
- Dissection of the lymphatic template is started distally at the crossing of the ureter with the common iliac vessels.
- The dissection is continued cephalad circumventing the inferior mesenteric artery on the left side and preserving it.
- Cephalad to the inferior mesenteric artery dissection is continued along the medial border of the aorta up to the left renal vein.
- The spermatic artery is clipped at its origin and transected (Fig. 19).
- The lateral surface of the aorta is dissected down to the origin of the lumbar arteries.
- The lumbar vein, which is draining into the left renal vein, is approached and transected between clips to gain access to the left renal artery (Figs. 20 and 21).
- The lumbar vessels are dissected and separated from the lymphatic tissue to the point at which they disappear in the layer between the spine and psoas muscle (Fig. 21).
- Lateral to that point the sympathetic chain is encountered.
- Although the left postganglionic fibers are readily identified, they are not preserved in template dissection because the right sympathetic chain remains intact providing undisturbed antegrade ejaculations.
- The nodal package will be completely free at this point and can be retrieved (Fig. 22).
- The colon is secured in its anatomic position with an extracorporeal tied suture.

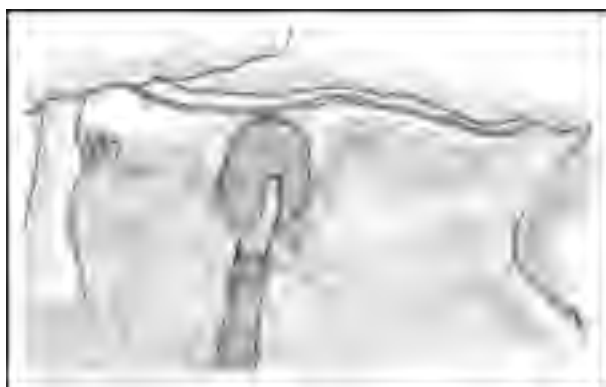
FIGURE 16


FIGURE 17

EXTRAPERITONEAL APPROACH (20)

General Technique and Patient Position

- The patient is placed supine under general anesthesia with the arms and legs apart (Fig. 23).
- The patient is placed close to the table edge.
- The surgeon stands ipsilateral to the tumor next to the assistant who holds the camera.
- A video monitor on the opposite side provides a comfortable view for each operator (Fig. 2).
- Although, the Trendelenburg's position is not necessary, slightly tilting the opposite side of the table lateral may sometimes be helpful.
- The trocar set consists of 10-mm balloon trocar, 10-mm trocar with reducer and a 5-mm ancillary operative trocar.
- The instrument set includes a 10-mm 0-degree video laparoscope, an irrigation suction device, two atraumatic grasping forceps, a bipolar forceps, monopolar scissors, a clip applier, and an endoscopic bag for lymph node removal.

FIGURE 18

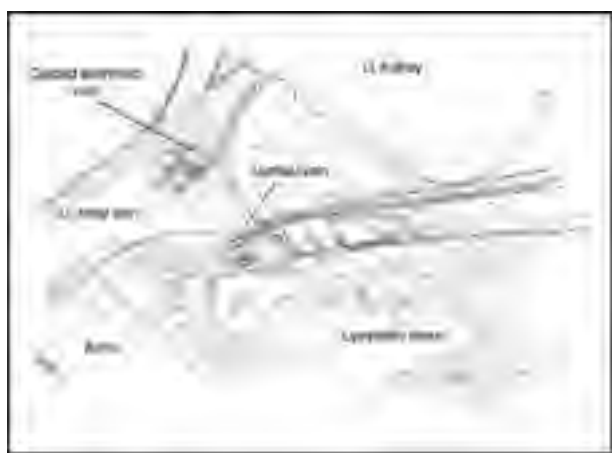
FIGURE 19


FIGURE 20
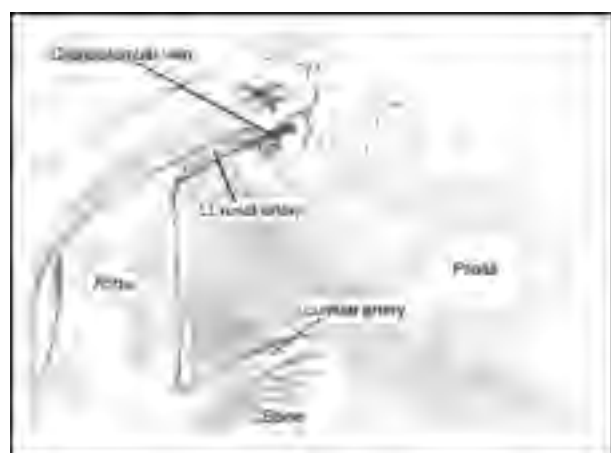

FIGURE 21

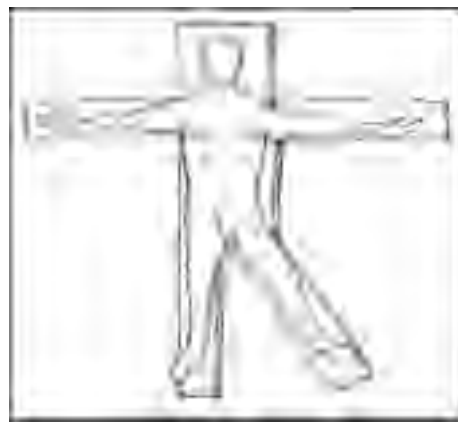
FIGURE 22


FIGURE 23

Extraperitoneal Space Preparation

- A maximum of 2-cm transverse incision is made ipsilateral to the tumor two finger breadth medial to the anterior iliac spine on the mid clavicular line high in the iliac fossa.
- The abdominal wall muscles are divided along their fibers until the peritoneum is visible.
- Bluntly, the peritoneum is progressively separated from the muscles using your forefinger until you can palpate the psoas muscle posterior, the lumbar spine medial, and the pulsation of the common iliac artery caudal.

Trocar Placement

Lymphatic tissues in this area are dense and care must be taken to prevent injury of the inferior mesenteric artery, which constitutes a landmark to preserve the left sympathetic nerves.

- A 10-mm operative trocar is introduced in the extra peritoneal space on the mid axillary line midway between the 11th rib and the iliac crest which is controlled by the finger through the iliac incision.
- Gas insufflations is connected to this trocar.
- The laparoscope is introduced through this trocar and under direct vision the forefinger completes the dissection of the extra peritoneal space as high as possible.
- At the anterior axillary line approximately 5 cm above and 3 to 4 cm medial to the operative trocar a 5 mm trocar is introduced under double control of the forefinger and the laparoscope.
- Through the iliac incision under direct vision a blunt tip 10-mm trocar is introduced and the distal balloon is inflated.
- Care in trocar placement and dissection is important because peritoneal perforation will result in pneumoperitoneum, which may preclude continuation of the planed procedure.
- The iliac trocar is used for the laparoscope and the other two are operative ports.
- The extra peritoneal space is developed until the ipsilateral great vessels are reached and the ureter is visible.
- If possible the ureter remains attached with the gonadal vessels on the posterior peritoneum.

The Template Dissection

The dissection technique is similar to that of the transperitoneal approach with some modifications.

Left Para-Aortic Dissection

No dissection is done along the anterior wall of the aorta below the origin of the inferior mesenteric artery, so that the superior hypogastric nerve plexus is not injured.

Posterior division of the lumbar arteriovenous vessels is not necessary and retrovascular lymphadenectomy may be performed by skipping between the lumbar pedicles.

- Lateral and upward the peritoneum is separated from the psoas muscle to enlarge the working space.
- The peritoneum and the duodenum are separated cranially from the anterior aspect of the great vessels until the left renal vein is completely visible.
- The lymphatic fat pad is then grasped and gently separated from the aorta by blunt and sharp dissection from the psoas muscle and sympathetic chain posteriorly, and the peritoneum and ureter anterolateral.
- Dissection progresses close to the ventral adventitial layer of the great vessels starting from the origin of the left common iliac artery up to the left renal vein.
- Posterolateral the left sympathetic chain and main postganglionic fibers arising from the second or third lumbar sympathetic ganglia to join the superior hypogastric plexus are carefully isolated from the lymphatic tissue and preserved.
- Cranially the left spermatic artery is controlled with bipolar coagulation at its origin and divided, then with bipolar coagulation the left renal vein is progressively dissected and the spermatic vein is clipped and divided close to the renal vein.

Avoid injury of a possible low renal artery or a lumbar vain during this dissection.

Early division of the right spermatic vessels is necessary to have the best exposure.

Avoid injury to the lumbar vessels or right renal artery while dissecting behind the left renal vein.

Right Para-Aortic Dissection

■ As on the left side, you start dissecting from the right common iliac vessels in a cranial direction to free the lateral and anterior surfaces of the vena cava then the medial part of the aorta up to the left renal vein.
■ All lymphatic tissue anterior, lateral, and posterior to the vena cava must be removed.
■ On the left side the lumbar veins are respected as much as possible.
■ Posterior vena caval dissection provides access to the interaortocaval nodes and facilitates their elevation from the perivertebral plane while sparing the main postganglionic nerves arising from the second or third right sympathetic ganglia.
■ The intervascular dissection is finished anteriorly between the two great vessels and up to the left renal vein.

Resection of the Spermatic Vessels and Final Steps

■ Resection of the spermatic vessels is the ultimate step.
■ The lumbar portion of the vascular pedicle is freed from the posterior peritoneum down to where it joins the ureter.
■ Now the instruments will be rearranged and the surgeon will use the iliac port for his instruments and the flank port for the laparoscope.
■ The spermatic vessels will be dissected down to the distal ligature and completely removed extraperitoneally.
■ The lymphatic tissue and the spermatic vessels are placed in an endoscopic bag and extracted through the iliac incision.
■ Drainage is not necessary.

TECHNICAL CAVEATS

■ Adequate homeostasis is of a crucial importance. Even minimal bleedings must be controlled and stopped instantly to provide a bloodless surgical field. The quality of the dissection had improved significantly since the introduction of grasping forceps for bipolar coagulation and dissection. These instruments are ideal for the dissection of delicate vessels such as the vena cava and renal veins. Broader bipolar forceps allows precise hemostasis without damaging the surrounding structures. The Harmonic scalpel may be used as well for a bloodless transection of the lymphatic tissue.
■ A protruding® segment of bowel can cause insufficient exposure and may render the operation difficult, dangerous, and even impossible. The fan retractor used for the liver can retract the duodenum as well. Retraction of the bowel can be achieved by a surgical sponge held with a traumatic grasper. An additional trocar can be inserted in the midline just caudal to the costal margin for the introduction of a second fan retractor if required in exceptional cases. Exposure could be achieved in all instances and we have never converted to open surgery because of insufficient exposure.
■ Acute bleeding is the most frequent complication. A small surgical sponge that is held with a traumatic grasper can be a substitute for the surgeon's finger to be used for dissection, retraction, or pressure to control bleeding vessels so that subsequent measures can be taken without the pressure of time. Small defects in veins and even the vena cava can be sealed by direct application of fibrin. A larger defect is approximated with an atraumatic grasper with or without the use of endoscopic clips even if they are not placed appropriately and tend to fall off then the defect is sealed by fibrin. The strength of the repair should be enhanced by the additional use of surgicel (oxidized regenerated cellulose) or similar hemostatic substances such as tachocomb. In exceptional conditions laparoscopic vascular suture repairs are feasible if needed (5,15,21).
■ Instruments for general and vascular surgery must be available in the operating room in the event of bleeding that may not be controlled by endoscopic means.

SUMMARY

■ To lower morbidity, retroperitoneal lymphadenectomy was modified over the past 35 years from extended suprahilar to bilateral infrahilar. Subsequently, a modified unilateral approach and then nerve-sparing procedures were refined.
■ These operative refinements were not associated with increase in relapse rates.
■ Significant factors for relapse include pathological stage ($p < 0.001$) and adjuvant chemotherapy in stage II disease ($p < 0.001$) (3).
■ The future in this field may encompass the development of a technique that could exactly locate a sentinel lymph node for testicular cancer. Thereby the retroperitoneal lymph node dissection, with its diagnostic accuracy and its therapeutic value, could be applied to selected patients only (22, 23).

LAPAROSCOPIC RETROPERITONEAL LYMPH NODE DISSECTION FOR CLINICAL STAGE I NONSEMINOMATOUS GERM CELL TESTICULAR CANCER: CURRENT STATUS

Sam B. Bhayani and Louis R. Kavoussi

Johns Hopkins Medical Institutions, Baltimore, Maryland, U.S.A.

INTRODUCTION

Clinical stage I nonseminomatous germ cell tumors can be approached by several successful treatment strategies.

Surveillance, primary chemotherapy, and open retroperitoneal lymph node dissection all demonstrate equivalent outcomes when applied appropriately. As such, morbidity of the treatment becomes the major factor when selecting treatment.

Surveillance fundamentally depends upon dedicated follow up that may be challenging in a younger patient population. Failure to detect recurrence early results in the suboptimal outcome compared with other treatment options. Primary chemotherapy, largely used in Europe, has equal efficacy as the open retroperitoneal lymph node dissection, and additionally will treat disease outside of the retroperitoneum (1). However, long-term side effects of primary chemotherapy remain, including cardiac toxicity, infertility, and late hematological malignancy.

Despite the proven efficacy of open retroperitoneal lymph node dissection, approximately 70% of patients have pathologically negative nodes, and may derive no therapeutic benefit from surgery (2–5).

Although the long-term morbidity of open retroperitoneal lymph node dissection is minimal, the procedure relies on a large and cosmetically undesirable incision, with significant convalescence times and permanent physical scars.

Laparoscopic retroperitoneal lymph node dissection was developed to allow for the diagnostic and therapeutic benefits of open retroperitoneal lymph node dissection, without its inherent morbidity. It may represent a minimally invasive alternative to open retroperitoneal lymph node dissection and primary chemotherapy. Proponents of the procedure are demonstrating its efficacy as a replacement for open retroperitoneal lymph node dissection (6).

DIFFERENCES IN LAPAROSCOPIC RETROPERITONEAL LYMPH NODE DISSECTIONS

Laparoscopic retroperitoneal lymph node dissection may be used as a staging or a therapeutic procedure.

As most patients undergoing open retroperitoneal lymph node dissection or chemotherapy are treated unnecessarily (as they have no metastases), a minimally morbid approach to staging the retroperitoneum is highly attractive. In European series, laparoscopic retroperitoneal lymph node dissection serves this purpose and helps delineate those who have metastases and require chemotherapy versus those who may be more safely observed.

Surveillance, primary chemotherapy, and open retroperitoneal lymph node dissection all demonstrate equivalent outcomes when applied appropriately. As such, morbidity of the treatment becomes the major factor when selecting treatment.

Despite the proven efficacy of open retroperitoneal lymph node dissection, approximately 70% of patients have pathologically negative nodes, and may derive no therapeutic benefit from surgery.

Laparoscopic retroperitoneal lymph node dissection may represent a minimally invasive alternative to open retroperitoneal lymph node dissection and primary chemotherapy.

Laparoscopic retroperitoneal lymph node dissection may be used as a staging or therapeutic procedure.

TABLE 1 ■ Treatment Options for Clinical Stage I Nonseminomatous Germ Cell Tumors

Treatment	Typical recurrence (%)	Recurrence treated with	Success rate (%)	Advantages	Disadvantages
Surveillance	30	3 cycles chemotherapy	>95	No patients treated unnecessarily	Requires rigorous follow-up; 3 cycles of chemotherapy significantly more toxic than 2
Primary chemotherapy	<5	Chemotherapy or surgery	>95	No invasive procedures	70% of patients treated unnecessarily
Open retroperitoneal lymph node dissection	<5	Chemotherapy	>95	Accurate staging	70% patients treated unnecessarily with laparotomy incision, 30% of pIIa patients recur
Staging laparoscopic retroperitoneal lymph node dissection with 2 cycles of chemotherapy for positive nodes	<5	Chemotherapy or surgery	>95	Accurate staging with advantages of laparoscopy	Patients with positive nodes receive 2 treatments (laparoscopy and chemotherapy)
Therapeutic laparoscopic retroperitoneal lymph node dissection	<5	Chemotherapy	>95	Accurate staging with advantages of laparoscopy	Most patients have received chemotherapy due to philosophy of oncologists; without chemotherapy results should mirror open retroperitoneal lymph node dissection. More studies needed

Abbreviation: RPLND, retroperitoneal lymph node dissection.

> As a staging procedure, laparoscopic retroperitoneal lymph node dissection is typically performed without retrocaval or retroaortic dissection, and is used to delineate pathologic status. The therapeutic efficacy of this more limited dissection is unknown.

As a staging procedure, laparoscopic retroperitoneal lymph node dissection is typically performed without retrocaval or retroaortic dissection, and is used to delineate pathological status (7). The therapeutic efficacy of this more limited dissection is unknown. As a therapeutic procedure, laparoscopic retroperitoneal lymph node dissection is also effective.

This approach, currently used at Johns Hopkins, limits relapses to outside the template, and may be offered as a singular, primary treatment option, analogous to open retroperitoneal lymph node dissection. Patients with pathological stage II disease can then be observed or treated with chemotherapy per their preference.

EFFICACY OF TREATMENT OPTIONS

> The goal of the therapeutic laparoscopic retroperitoneal lymph node dissection is to limit retroperitoneal relapse. All nodal tissue within the template must be excised, including retroaortic and retrocaval tissue.

The goal of the therapeutic laparoscopic retroperitoneal lymph node dissection is to limit retroperitoneal relapse. All nodal tissue within the template must be excised, including retroaortic and retrocaval tissue.

All treatments of clinical stage I nonseminomatous germ cell are effective (Table 1). As such, the choice for treatment is ultimately dependent on patient preference and

comfort with treatment modalities. Surveillance has the advantage of having no patients unnecessarily treated. The main disadvantage is the three cycles of chemotherapy involved for recurrence, and compliance with the rigorous followup schedule. Primary chemotherapy unnecessarily treats 70% of patients who garner no advantage because they harbor no metastases. These patients are exposed to the long-term toxicity of the chemotherapeutic agents. Open retroperitoneal lymph node dissection has the same disadvantage of over treatment and additionally patients have the lifelong cosmetic disadvantage of the open incision. Furthermore, 30% of patients with metastases will recur and require chemotherapy.

Laparoscopic staging retroperitoneal lymph node dissection can evaluate for metastases with minimal long-term morbidity, but requires two cycles of adjuvant chemotherapy. Therapeutic laparoscopic retroperitoneal lymph node dissection offers all the advantages of open retroperitoneal lymph node dissection without the incision, but studies often include treatment with chemotherapy and randomized studies are lacking.

Unfortunately, high volume centers treating testis cancer have been slow to adopt laparoscopic techniques and as such, comparing the efficacy of open retroperitoneal lymph node dissection to laparoscopic retroperitoneal lymph node dissection is difficult and requires indirect measures. These comparisons are confounded by surgical differences between the major centers performing laparoscopic retroperitoneal lymph node dissection, and by philosophical differences with regard to postoperative chemotherapy.

All laparoscopic retroperitoneal lymph node dissections are not equal. In the Austrian series, laparoscopic retroperitoneal lymph node dissection in the clinical stage I patient is performed as a staging tool, and nodes are not routinely removed posterior to the lumbar vessels. The rationale for performing this more limited retroperitoneal lymph node dissection relies on the lack of an isolated retrocaval or retroaortic positive node based on pathological analyses of the authors' series (7,8). Furthermore, as the procedure is performed as a staging procedure, the goal is to identify patients who require chemotherapy, and then treat those with positive nodes. In the Johns Hopkins experience, the procedure has evolved. Initially, the procedure was aborted if multiple positive nodes were found, because chemotherapy would be instituted in these cases (9). Because technological advances in instrumentation, suturing, and hemostasis have evolved, a traditional approach is the norm. Currently, an exact replication of the open template is performed on all patients with clinical stage I nonseminomatous germ cell, with complete excision of retroaortic and retrocaval tissue, thus rendering the procedure both a staging and therapeutic procedure.

Despite the more complete lymphatic excision of therapeutic laparoscopic retroperitoneal lymph node dissection, it is the philosophy of some medical oncology departments to routinely give two cycles of chemotherapy in all patients with positive nodes at lymph-adenectomy, rather than risk the chance of recurrence and progression and later treatment with a higher dose of chemotherapy. It is unknown if the long-term sequelae with a modified chemotherapy regimen is similar to that seen with traditional three cycles.

From a surgical perspective, laparoscopic retroperitoneal lymph node dissection should duplicate the open template to maintain established oncological principles, particularly if a patient with pathological stage II a disease should choose observation rather than adjuvant treatment.

Use of adjuvant chemotherapy has elicited a major concern: is the laparoscopic retroperitoneal lymph node dissection an adequate "clean-out" of the retroperitoneum or is the chemotherapy masking retroperitoneal nodes that were missed? This question can be answered with another method to compare the open and laparoscopic retroperitoneal lymph node dissection: examination of the patients with pathologic stage I disease. If the laparoscopic retroperitoneal lymph node dissection were inadequate, certainly patients would be misdiagnosed with pathological stage I disease, and the positive lymph nodes in the retroperitoneum would be missed, thus leading to a retroperitoneal recurrence. This supposition has not occurred, because no retroperitoneal recurrences have been reported in our experience or from recent University of Washington data (6,10).

Despite the indirect efficacy of laparoscopic retroperitoneal lymph node dissection, a randomized direct comparison to open retroperitoneal lymph node dissection is theoretically the best approach to establish equal efficacy. Such a comparison has not been performed with other accepted laparoscopic procedures such as tubal ligation, cholecystectomy, gastric fundoplication, adrenalectomy, nephrectomy, or nephroureterectomy.

With these procedures, it has been apparent that the laparoscopic approach differs from the open approach primarily with regard to access of the abdomen, and intra-abdominal manipulations are similar, if not exact. The oncological community has not assessed laparoscopic retroperitoneal lymph node dissection with these same standards, but ultimately, as more centers offer therapeutic laparoscopic retroperitoneal lymph node dissection, the procedure is likely to replace the open procedure as a new standard to treat clinical stage I nonseminomatous germ cell.

COMPLICATIONS OF LAPAROSCOPIC RETROPERITONEAL LYMPH NODE DISSECTION

> The major complication reported during laparoscopic retroperitoneal lymph node dissection is hemorrhage.

The major complication reported during laparoscopic retroperitoneal lymph node dissection is hemorrhage (6,9).

Early in the experience of the procedure hemorrhage necessitated conversion to an open procedure and occasionally blood transfusion. These complications reflect a different era of laparoscopic surgery, in which instrumentation, suturing technology, and hemostatic aids were not available. Currently, techniques have been developed to deal with potential hemorrhage.

> Lymphocele formation is also a complication, more commonly seen in early experience.

Lymphocele formation is also a complication, more commonly seen in early experience. As with open surgery, this can be avoided with careful clipping of lymphatic channels.

> Retrograde ejaculation has been reported at a rate similar to that seen with open retroperitoneal lymph node dissection.

Retrograde ejaculation has been reported at a rate similar to that seen with open retroperitoneal lymph node dissection (6).

POSTCHEMOTHERAPY LAPAROSCOPIC RETROPERITONEAL LYMPH NODE DISSECTION

Postchemotherapy laparoscopic retroperitoneal lymph node dissection is considered a different surgery than the version used for clinical stage I nonseminomatous germ cell. The dissection is more extensive, and more difficult secondary to residual masses and tissue reaction to chemotherapeutic agents. In one series of seven patients, a 42% major complication rate was reported (11). This was the initial series, and involved the learning curve with the procedure. In another series of 68 patients, a 0% complication rate was reported (8). The dissection boundaries in the latter series are unclear. Larger studies with long-term outcomes are needed to evaluate the ultimate efficacy of this approach. Duplication of the open dissection and template is essential.

> Postchemotherapy retroperitoneal lymph node dissection should be attempted only by experienced laparoscopists, and patients should be aware of the possibility of open conversion.

Postchemotherapy retroperitoneal lymph node dissection should be attempted only by experienced laparoscopists, and patients should be aware of the possibility of open conversion.

SUMMARY

- Laparoscopic retroperitoneal lymph node dissection for the treatment of clinical stage I nonseminomatous germ cell has evolved into an excellent alternative to traditional modes of therapy.
- The procedure can replicate the advantages of open retroperitoneal lymph node dissection without the morbidity of a large incision.
- Although all treatment modalities are effective in low stage nonseminomatous germ cell, laparoscopic retroperitoneal lymph node dissection offers a minimally invasive approach to the disease.
- Further studies comparative studies of primary chemotherapy, open retroperitoneal lymph node dissection, and laparoscopic retroperitoneal lymph node dissection are needed from high volume centers to elucidate differences in therapy.

COMMENTARY

Jerome P. Richie
Harvard Medical School, Boston, Massachusetts, U.S.A.

The exceedingly high likelihood of cure for patients with clinical stage I non-seminomatous germ cell tumor dramatically increases the import of potential morbidity, quality of life, and long-term side effects of the treatment regimen. The rigorous follow-up schedule for surveillance and the need for chemotherapy in approximately 25% of patients limit this appealing option to patients with very favorable characteristics. Primary chemotherapy may overtreat many patients and long-term side effects of primary chemotherapy have not been elucidated.

Standard template and nerve-sparing retroperitoneal lymph node dissection has proven efficacy as both a staging and a therapeutic modality, providing important information about retroperitoneal nodal involvement and curing the vast majority of patients without the need for chemotherapy. To date, laparoscopic retroperitoneal lymph node dissection (retroperitoneal lymph node dissection) is a staging modality, but has not proven itself to have therapeutic efficacy. Until longer-term studies can demonstrate that laparoscopic retroperitoneal lymph node dissection is as effective therapeutically as open retroperitoneal lymph node dissection (avoiding the need for chemotherapy postoperatively), laparoscopic retroperitoneal lymph node dissection will still be considered an extension of staging techniques.

Complications of laparoscopic retroperitoneal lymph node dissection, including hemorrhage or chylous ascites, have decreased in incidence in centers of excellence. Nonetheless, because of the relative rarity of patients with low-stage testicular tumor, a steep learning curve may preclude general application of these techniques.

The potential reduction in morbidity, shorter length of stay, and avoidance of a large midline abdominal incision are appealing features of laparoscopic retroperitoneal lymph node dissection, but proof of therapeutic efficacy will be mandatory before this type of procedure can be considered equivalent to open retroperitoneal lymph node dissection.

LAPAROSCOPIC PELVIC LYMPHADENECTOMY FOR PROSTATE AND BLADDER CANCER

Antonio Finelli

Section of Laparoscopic and Minimally Invasive Surgery, University of Toronto, Toronto, Ontario, Canada

INTRODUCTION

Surgery is an effective form of treatment for most localized solid tumors of the genitourinary system. However, lymph node metastases are a significant prognostic factor in urologic malignancy and lymphadenectomy is therapeutic in certain instances. With the advent of laparoscopy, pelvic lymphadenectomy became a popular and frequently performed procedure for staging prostate cancer in the 1990s. Laparoscopy has continued to gain momentum in the management of urologic tumors and laparoscopic radical cystectomy with complete intracorporeal urinary diversion has become a reality. The role of pelvic lymphadenectomy in the management of prostate cancer, as well as bladder cancer, continues to be defined.

PROSTATE CANCER

Current Status of Pelvic Lymph Node Dissection in Disease Management

While there is no consensus in the literature, the most common pelvic lymph node dissection performed for prostate cancer is a limited obturator lymph node dissection (1,2). The obturator space is bound caudally by the pubic bone, cranially by the bifurcation of common iliac artery, laterally by the external iliac vessels and inferiorly by the obturator nerve. Although it is generally believed that the obturator space is the primary landing site of prostate cancer nodal metastasis, anatomical series have demonstrated that the primary landing site may actually be in the internal iliac lymph node chain (3,4). Studies utilizing radioisotope guided dissection have confirmed the heterogeneous nature of prostatic lymph node drainage (5,6).

Historically, prostate cancer series have included a relatively high rate (up to 29%) of patients with pelvic lymph node metastasis (7). However, with stage migration in the prostate specific antigen era, contemporary open radical prostatectomy series have positive lymph node detection rates below 6% (8–10). To further stratify patients at risk for lymph node metastases, low risk and high-risk categories have been defined. Preoperative prostate specific antigen $\leq 10\,\mathrm{ng/mL}$, Gleason Sum ≤ 6, and clinical stage $\leq T_1 c$ is considered low risk whereas, high risk patients have a prostate specific antigen > 10 and/or Gleason ≥ 7 and/or clinical stage $\leq T_2$ (10–12). Since the likelihood of lymph node metastases is low (<2%), pelvic lymph node dissection is often omitted in the low-risk patients.

Recently, there have been studies supporting a more extended pelvic lymph node dissection in the management of prostate cancer (13,14). In a series of 365 patients undergoing extended pelvic lymph node dissection, 88 (24%) of patients had positive lymph nodes (13). Interestingly, of the 88 patients with positive nodes, 51 (58%) had

> Recently, there have been studies supporting a more extended pelvic lymph node dissection in the management of prostate cancer.

nodal metastases along the internal iliac artery. Furthermore, 17 (19%) of the patients had nodal involvement only in this location and thus, it was concluded that a standard limited obturator lymph node dissection would have missed 19% of patients with node positive disease. In a similar study, 203 consecutive patients (103 extended pelvic lymph node dissection and 100 standard lymphadenectomy) were evaluated post radical retropubic prostatectomy (14). The incidence of lymph node metastases was 26% in the extended lymphadenectomy group versus 12% in the standard group ($p < 0.03$). In the extended pelvic lymph node dissection group, 26 patients (42%) had nodal metastases outside the standard template and of these patients, 9 (34%) had lymph nodes positive only outside the standard template. Using a cutoff off prostate specific antigen ≤ 10.5 ng/mL and biopsy obtained Gleason Sum ≤ 6,139 patients (68.5%) would be classified as low risk. If this cohort had not undergone any lymphadenectomy, only four patients would have been missed (false negative rate 2.4%). Thus, the authors of this study concluded that extended lymph node dissection should be performed for highrisk patients only thereby increasing the detection of positive nodes by 14%. Bader et al. (15) presented follow-up data on a series of 92 patients with metastatic nodes at the time of prostatec- tomy. Over a median follow-up of 45 months, 21 patients (23%) had prostate specific antigen recurrence free survival. Whilst this report does not convincingly demonstrate improved survival over an intermediate follow-up, extended pelvic lymph node dissection may benefit a small percentage of patients.

Laparoscopic Technique

Laparoscopic pelvic lymphadenectomy was one of the original laparoscopic urologic procedures described in 1991 (16,17).

Concomitant pelvic lymph node dissection can be performed during either transperitoneal or extraperitoneal laparoscopic radical prostatectomy (18). If the lymphadenectomy is being performed in conjunction with radical prostatectomy, the port placement should be that preferred for laparoscopic prostatectomy. Most commonly, a five-port "fan" or "horseshoe" distribution is used. After pneumoperitoneum is established, 10-mm trocars are placed at the umbilicus and at the lateral edge of the right rectus muscle. A 5-mm port is placed one fingerbreadth medial and cephalad to the anterior superior iliac spine. Two 5-mm ports are then placed in comparable positions on the left side. If a separate staging laparoscopic pelvic lymph node dissection is being performed, a diamond configuration is utilized with 10-mm trocars placed at the umbilicus and 5 cm above the pubic symphysis in the midline. Additional 5-mm ports are placed bilaterally in the midclavicular line near McBurney's point.

Orientation is initially achieved by noting external iliac artery pulsations and the anatomic location of the internal ring. The peritoneum overlying the external iliac artery and/or on the external iliac vein is opened sharply. A combination of blunt and sharp dissection is used to skeletonize the posterior surface of the external iliac vein, dissecting the obturator node packet off the pelvic sidewall in the direction of the pubic bone. Once the obturator nerve is clearly identified along the posterior edge of the lymph node packet, the distal aspect of the nodal packet can be safely clipped and divided at the pubic bone. Throughout the dissection, the obturator nerve is kept in view. The nodal packet is gently dissected and reflected cephalad toward the bifurcation of the common iliac vein. The nodal packet is clipped parallel to the obturator nerve, detached and extracted with an endoscopic spoon biopsy forceps.

Outcomes

More than 20 publications since 1992 have addressed the outcomes of laparoscopic pelvic lymph node dissection (19–26). Historically, laparoscopic pelvic lymph node dissection had been compared to open pelvic lymph node dissection and minilaparotomy pelvic lymph node dissection, but currently staging pelvic lymph node dissection is rarely performed as an independent procedure. Thus, the majority dissections are performed through a midline incision during retropubic prostatectomy or laparoscopically with ports placed in anticipation of performing radical prostatectomy.

In general, the efficacy of laparoscopic pelvic lymph node dissection is comparable to open pelvic lymph node dissection.

Parra et al. (22) demonstrated a comparable yield of lymph nodes (10.7 vs. 11) for laparoscopic and open pelvic lymph node dissection, respectively. Kerbl et al. (20) compared 30 patients undergoing laparoscopic pelvic lymph node dissection with 16 patients undergoing open pelvic lymph node dissection. Laparoscopy was associated with a longer operating time (199 minutes vs. 102 minutes), and a 13% complication rate. Herrell et al. (24) compared laparoscopic pelvic lymph node dissection to open and minilaparotomy pelvic lymph node dissection. The three groups had equivalent staging efficacy, but

<div style="margin-left: sidebar">

Concomitant pelvic lymph node dissection can be performed during either transperitoneal or extraperitoneal laparoscopic radical prostatectomy.

In general, the efficacy of laparoscopic pelvic lymph node dissection is comparable to open pelvic lymph node dissection.

</div>

laparoscopic and minilaparotomy pelvic lymph node dissection were associated with decreased length of hospital stay and complications. Laparoscopic pelvic lymph node dissection required a longer operative time.

Stone et al. (25) compared modified ($N = 150$) with extended laparoscopic pelvic lymph node dissection ($N = 39$). This study revealed the feasibility of laparoscopic extended pelvic lymph node dissection for prostate cancer wherein the obturator, hypogastric, common and external iliac nodes were retrieved. However, the extended group had an increased complication rate, 36% versus 2%. Presently, limited pelvic lymph node dissection for laparoscopic radical prostatectomy adds approximately 30 minutes to the operating time.

The rate of complications associated with laparoscopic pelvic lymph node dissection ranges from 0% to 22% as opposed to 0% to 13% for open pelvic lymph node dissection (19–26). However, these reports were published between 1992 and 1997 and with greater laparoscopic experience, one would anticipate diminished complication rates.

In a series of 100 consecutive laparoscopic pelvic lymph node dissection, the rate of complication was 25% for the first 20 cases and 5% for the subsequent 80 cases (21). Complications in contemporary series compare favorably with prior published open series (27).

> **SUMMARY: PELVIC LYMPH NODE DISSECTION FOR PROSTATE CANCER**
>
> ■ Currently, controversy regarding pelvic lymph node dissection for prostate cancer is focused on the issue of which patients should have a pelvic lymphadenectomy and whether it should be limited or extended, rather than laparoscopic versus open.
> ■ The development of nomograms and preoperative predictive models have aided in identifying low risk patients, decreasing the necessity for unnecessary pelvic lymph node dissection.
> ■ Further studies are required to clarify the exact extent of lymph node dissection in higher risk patients.

BLADDER CANCER

Current Status of Pelvic Lymph Node Dissection in Disease Management

Review of contemporary cystectomy series demonstrates a lymph node positive rate of ~25% (28,29). There is evidence to support the therapeutic role of pelvic lymph node dissection in bladder cancer.

In a large cohort of patients undergoing radical cystectomy and pelvic lymph node dissection, patients with pN+ disease ($N = 244$), experienced 5- and 10-year recurrence-free survival rates of 35% and 34%, respectively (28). Both the anatomic extent of lymphadenectomy (30-32) and the number of nodes involved with metastatic disease are regarded as important independent factors (32-34). Patients with fewer than four lymph nodes involved with metastases fare better than those with five or more positive nodes (33).

Classically, the boundaries of a pelvic lymph node dissection for bladder cancer include the genitofemoral nerve laterally, bladder medially, node of Cloquet distally and the bifurcation of the common iliac artery proximally. Skinner described an extended dissection that includes the lymphatic tissue 2–3 cm above the aortic bifurcation (35).

Although the proximal extent of lymphadenectomy for bladder cancer continues to be debated, all patients undergoing cystectomy with curative intent should have a bilateral pelvic lymph node dissection since bladder tumors metastasize bilaterally even if they are focal and unilateral (36,37).

In an anatomic mapping study of lymph nodes removed during extended pelvic lymph node dissection for bladder cancer, it was demonstrated that in 29 patients who only had metastases to one lymph node, this solitary involved node was never in the presacral, paracaval, interaortocaval or paraaortic areas (37). Furthermore, metastases to the paraaortic, interaortocaval, or paracaval regions only occurred when nine or more lymph nodes from more distal landing zones were positive (37). Thus, the majority of patients with proximal lymph node metastases have more distal disease.

Recently, there has been an attempt to determine the minimum number of lymph nodes that should be removed and examined. An earlier report, demonstrated a cancer-specific survival of 65% versus 51% when 15 lymph nodes or more were removed at cystectomy compared to 15 or less, respectively (31). More recent studies have also found that the number of lymph nodes retrieved, regardless of whether metastases were diagnosed, correlated with survival (32,34). Herr et al. (32) demonstrated improved local control and an overall survival advantage for both pN+ and pN0 patients when more than 11 and 8 lymph nodes were removed, respectively.

There is evidence to support a more extensive lymphadenectomy and thus, patients undergoing laparoscopic radical cystectomy with curative intent should have a meticulous pelvic lymph node dissection with at least 15 lymph nodes removed and examined.

A review of patients undergoing radical cystectomy and pelvic lymph node dissection from the National Cancer Institute Surveillance, Epidemiology and End Results database confirmed the correlation between number of lymph nodes removed and survival (34). The authors concluded that a minimum of 10 to 14 nodes should be examined (34). To further discriminate survival and local control outcomes, the concepts of ratio-based lymph node staging (38) and lymph node density (28) were proposed. A cut-point of 20% correlated with a statistically significant improvement in recurrence-free survival at 10 years. Furthermore, improved survival has been reported in patients with grossly positive nodes undergoing an extended pelvic lymph node dissection (39).

There is evidence to support a more extensive lymphadenectomy and thus, patients undergoing laparoscopic radical cystectomy with curative intent should have a meticulous pelvic lymph node dissection with at least 15 lymph nodes removed and examined.

Laparoscopic Technique

Our technique of laparoscopic radical cystectomy with completely intracorporeal construction of urinary diversion (40) and laparoscopic extended pelvic lymph node dissection have previously been described (41). With the patient in a modified dorsal lithotomy position, a transperitoneal five-port technique is employed. A modification for extended pelvic lymph node dissection involves placing the primary port in a supraumbilical position to facilitate proximal dissection to the aortic bifurcation. Cystectomy is performed initially, followed by pelvic lymph node dissection beginning with the right side. We elect to perform pelvic lymph node dissection after cystectomy in order not to compromise tissue planes.

We elect to perform pelvic lymph node dissection after cystectomy in order not to compromise tissue planes.

The patient is tilted 30° up on the right side and with 30° Trendelenburg. Although we prefer J-hook electrocautery as our primary instrument of dissection, coagulating laparoscopic endoshears with or without bipolar electrocautery is also effective. The lateral border of the dissection is developed medial to the genitofemoral nerve exposing the iliopsoas muscle. The fibroareolar and lymphatic tissue packet is lifted en bloc off the surface of the iliopsoas and swept medially, posterior to the external iliac artery and vein after the tissue anterior to the external iliac artery and vein is individually split longitudinally using J-hook electrocautery. The external iliac vein typically appears flat with standard (15 mmHg) pneumoperitoneum pressures. To enhance visualization of the vein and its edges the pneumoperitoneum pressure can be decreased to 5 mmHg. The obturator lymph node tissue is carefully dissected off the obturator nerve and maintained in continuity with the tissue that had been dissected off the external iliac artery and vein. A large clip is applied distally, and endoshears, are used to release the lymphatic tissue packet from this location.

One of the initial steps in laparoscopic radical cystectomy is dissection and transection of the ureters. The transected ureters are mobilized away and tacked to the sidewall facilitating cephalad dissection along the common iliac artery during pelvic lymph node dissection. The common iliac artery is circumferentially mobilized and retracted with a vessel loop to improve access to the lymphatic tissue in the area immediately distal to the aortic bifurcation. Upon completion of the proximal dissection, the specimen is immediately placed in an impermeable sac. Throughout the dissection, care must be taken to avoid cutting into any enlarged lymph node(s). Lymphadenectomy is similarly performed on the left side, but with the patient now tilted 30° up on that side. For the left-sided pelvic lymph node dissection, the surgeon may stand on the right side of the patient.

Outcomes

Although laparoscopic radical cystectomy has been the discussion of several reports, little attention has been given to the yield and extent of lymphadenectomy. We recently reviewed our technique and results with laparoscopic extended pelvic lymph node dissection (41). Initially, the bifurcation of the common iliac arteries constituted our proximal border (Group I). Commencing August 2002, our dissection included tissue overlying the proximal common iliac artery to the aortic bifurcation (Group II). The extended dissection required an additional 1 to 1.5 hours of operative time. Median number of nodes removed was 3 and 21 for Groups I and II, respectively ($p = 0.001$). Three patients in each group had pN+ disease. During extended pelvic lymph node dissection, an injury to a deep pelvic vein, managed with intracorporeal suturing, resulted in a 200 mL blood loss. Two other patients in this group developed deep venous thrombosis. There were no port site recurrences over a mean follow-up of 11 months (range, 2–43).

> ## SUMMARY: PELVIC LYMPH NODE DISSECTION FOR BLADDER CANCER
>
> - All patients undergoing radical cystectomy with curative intent should have a pelvic lymph node dissection.
> - A minimum of 10 to 14 lymph nodes should be removed and microscopically examined.
> - Although the proximal border of the lymphadenectomy is trending to migrate cephalad, with documented evidence of improved survival as more lymph nodes are removed, the true benefit of an extended dissection has not been demonstrated with well-designed prospective trials.
> - For the time being, albeit a limited experience, laparoscopic extended pelvic lymphadenectomy is feasible and results in nodal yields that are commensurate with current recommendations from conventional open surgical series.
> - Ours is only the initial experience and corroborating data from other centers are necessary before laparoscopic extended pelvic lymph node dissection can be considered to be adequate.

PORT-SITE TUMOR SEEDING AND LOCAL RECURRENCE

Issues of tumor spillage and port site seeding have been raised as concerns regarding the oncologic safety of laparoscopic surgery. Specifically, after pelvic lymphadenectomy, there have been four reported cases of tumor recurrence at a port site (42). Three of the cases occurred after staging lymphadenectomy for bladder cancer (43) and the other after pelvic lymph node dissection for prostate cancer (44). In the cases associated with bladder cancer, the specimens were directly extracted through a port rather than placed in impermeable sacs. Furthermore, the cases were high grade invasive transitional cell carcinoma and associated with other predisposing events such as concomitant transurethral resection of bladder tumor, concomitant bladder dome biopsy, and insertion of a suprapubic tube because of hemorrhage during transurethral resection of bladder tumor and ruptured tumor bearing lymph nodes (43).

Care should be taken to avoid incision into tumor-bearing nodes, especially in the setting of high-grade disease. Also, all lymphatic tissue should be immediately placed in an impermeable sac.

> Care should be taken to avoid incision into tumor-bearing nodes, especially in the setting of high-grade disease. Also, all lymphatic tissue should be immediately placed in an impermeable sac.

> ## SUMMARY
>
> - Currently, limited laparoscopic pelvic lymphadenectomy can be performed with comparable efficiency to open surgery. In the management of prostate cancer there is a vast experience with laparoscopic pelvic lymph node dissection. However, laparoscopic extended pelvic lymph node dissection for bladder cancer is a relatively recent development and further experience will be required to better define its role.
> - In general, surgical times for limited laparoscopic lymphadenectomy are equivalent or longer depending on the procedure and the experience of the surgeon.
> - Pelvic lymph node dissection for staging and prognosis, as is usually the case for prostate cancer, is not as technically demanding as a lymphadenectomy with therapeutic potential. As such, during radical cystectomy with curative intent, an honest effort must be made to perform as meticulous and rigorous an anatomic lymphadenectomy as is carried out with open surgery.
> - We believe that with growing experience and instrument development, laparoscopic extended pelvic lymph node dissection will be performed with equal efficacy to the open procedure.

LAPAROSCOPIC RADICAL CYSTECTOMY (PROSTATE SPARING)

Xavier Cathelineau, Carlos Arroyo, François Rozet, Eric Barret, and Guy Vallancien

Institut Montsouris, Université Pierre et Marie Curie, Paris, France

INTRODUCTION

Radical cystectomy is currently the treatment of choice for invasive bladder cancer and recurrent refractory cases of superficial transitional cell carcinoma (1). However, the procedure influences significantly the quality of life of these patients, especially their sexual and urinary functions. Although current oncological treatments tend to balance the benefits associated with a radical surgery and bladder preservation modalities such as chemotherapy and external beam radiation, cancer control is still inadequate compared to the surgical results (2). With the above concept, partial cystectomy has been described in many centers. However, there is an increased danger of local recurrence and the development of synchronous prostate cancer (3).

We commenced performing prostate-sparing radical cystectomy in selected patients since 1992, in order to improve the functional results while maintaining similar oncological control as compared to radical cystoprostatectomy (4).

The open prostate-sparing cystectomy technique has been modified and used by other teams as well (5–7). Benefiting from experience gained after performing regularly laparoscopic radical prostatectomy, we have developed a laparoscopic approach for this procedure and have done over 30 cases with satisfactory clinical and functional results (8).

> We commenced performing prostate-sparing radical cystectomy in selected patients since 1992, in order to improve the functional results while maintaining similar oncological control as compared to radical cystoprostatectomy.

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

Because of the oncologic risks associated with any surgical technique, especially if it involves a functional and organ-sparing technique, as well as an associated potential higher risk, it cannot be overemphasized that nerve and prostate-sparing cystectomy is not indicated in every patient with invasive bladder cancer requiring a cystectomy. Laparoscopic prostate-sparing radical cystectomy should be reserved for very selected patients that meet not only the regular preoperative criteria, but most importantly strict clinical and laboratory criteria (9).

Because of the oncologic risks associated with performing a prostate-sparing technique, candidates must not suffer any form of erectile dysfunction and must be completely continent; otherwise this procedure offers no benefit.

Concerning the surgical technique, patients should have a complete medical history with physical exam, including digital rectal exam and recent cystoscopy. The laboratory panel must include renal function exams and prostate specific antigen and percentage free prostate specific antigen. Finally, the imaging studies must include a computerized tomography and if possible an intravenous urography.

> Laparoscopic prostate-sparing radical cystectomy should be reserved for very selected patients that meet not only the regular preoperative criteria, but most importantly strict clinical and laboratory criteria.

TABLE 1 ■ Candidate Patients for Laparoscopic Prostate-Sparing Cystectomy Should Comply with the Following Criteria

No brain aneurysm or intracranial tumors
Continent
Potent
Bladder cancer: pTa, pT1, pT2
Tumor located at least 5 mm away from bladder neck
No tumor involvement of the prostatic urethra
No prostate cancer
  Total prostate specific antigen ≤3ng/dL
  Free prostate specific antigen > 12%
  Normal transrectal ultrasound
    If any of these are abnormal then perform transrectal prostate biopsy

The best indications for a prostate-sparing cystectomy are: a potent and continent patient with no contraindications for laparoscopic procedures, with a pTa, pT1 or pT2 bladder tumor that is located far from the bladder neck, with no risk of prostate cancer and no urethral CIS.

TABLE 2 ■ Various Steps Involved in the Laparoscopic Prostate Sparing Cystectomy

Trocar placement
Bilateral pelvic lymphadenectomy
Bilateral ureteric dissection
Vas deferens and seminal vesicle dissection
Opening of the Retzius space
Division of the lateral bladder vascular pedicles
Incision of the anterior surface of the prostate below the bladder neck
Bladder neck closure
Placement of the bladder in an extraction bag
Laparoscopic simple prostatectomy
Extraction of surgical specimens
Open "Z" neo-bladder enterocystoplasty
Uretero—ileal anastomosis and stent placement
Prostato—ileal anastomosis
Drains and Foley catheter placement

Patients with an abnormal digital exam or a prostate specific antigen over 3 ng/mL, or a low percent free prostate specific antigen (<12%) or hypoechoic area on transrectal ultrasound, must undergo a series of prostatic biopsies to exclude prostate cancer.

Finally and most importantly, the bladder tumor characteristics should be strict; such as not being located in or within 10 mm the bladder neck, nor in the prostatic urethra. The histology of the bladder cancer should be transitional cell carcinoma and it must comply with the regular indications for a radical cystectomy and a continent diversion (Table 1).

The best indications for a prostate-sparing cystectomy are: a potent and continent patient with no contraindications for laparoscopic procedures, with a pTa, pT1 or pT2 bladder tumor that is located far from the bladder neck, with no risk of prostate cancer and no urethral carcinoma-in-situ.

Concerning the laparoscopic approach, regular preoperative evaluation, involves excluding absolute anesthetic contraindications for laparoscopic procedures, which also applies to this procedure: intracranial surgical history, brain aneurysm or previous intracranial tumors. There are also some relative anesthetic contraindications that involve respiratory insufficiency such as severe emphysema, severe cardiac insufficiency, and glaucoma. Finally, there are certain patients that will make the procedure more difficult and could be considered, depending on the surgeons experience as relative surgical contraindications, these include: morbid obesity, previous pelvic or abdomen radiotherapy, and history multiple abdominal surgeries.

PREOPERATIVE PREPARATION

Our routine preoperative preparation includes antithrombotic prophylaxis with low-molecular-weight heparin, which is administered subcutaneously the night before surgery and elastic stockings the morning of the surgery. Antibiotic prophylaxis is started during the induction of anaesthesia, and consists of Cefotetan 2 g intravenously. There is no need of bowel preparation before surgery; however, a low residue diet can be recommended five days before surgery. Concerning the skin, the patient's abdomen is not routinely shaved and the patient takes a bath the morning of the surgery with Betadine®.

The surgery is performed under general anesthesia following all the classical anesthesiologic principles. During the induction, Propofol™ (2 mg/kg) is used and transoperative maintenance is done with Desflurane™ or Sevoflorane™ gas, and muscle relaxation by curarization with Atracurium™ (0.5 mg/kg) during the induction and maintained at 0.3 mg/kg/hr. Finally, perioperative analgesia is provided with Sufentanil™.

One important aspect of surgery is patient positioning to avoid the risks associated with a prolonged surgery. The position used is the decubitus position with the lower limbs; the arms strapped along the body so as not to obstruct the surgeon or assistant. Abundant cushioning should be placed to avoid pressure injuries and Velcro straps are applied across the shoulders to maintain the patient's position during the surgery and allow a 30° Trendelenburg tilt, which will be maintained throughout the surgery.

DETAILED LAPAROSCOPIC TECHNIQUE

Prostate-sparing radical cystectomy can be divided into a laparoscopic cystectomy and an open lower urinary tract reconstruction. Each stage can then be further broken down into the following steps (Table 2):

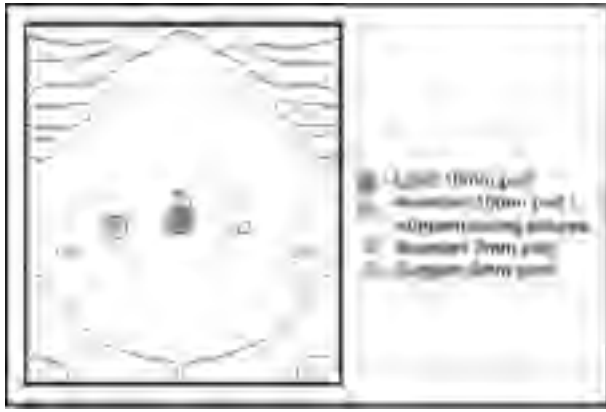
Laparoscopic Cystectomy
Step 1: Placement of Five Trocars Transperitoneally
1. 10 mm trocar is placed in the umbilicus for the introduction of the camera. The surgeon will work on the left of the patient with two 5 mm trocars that are placed above and medial to the iliac spine and another between the lateral and umbilical port. The trocars for the assistant will include a 5 mm trocar that is placed above and medial to the right iliac spine at MacBurney's point and a second 10 mm trocar on the pararectal line between the umbilical and lateral port on the right (Fig. 1).


FIGURE 1 ■ The first trocar position variation involves placement of all the ports as high as possible with respect to the umbilicus, the left side ports are used by the surgeon and the right side by the assistant.
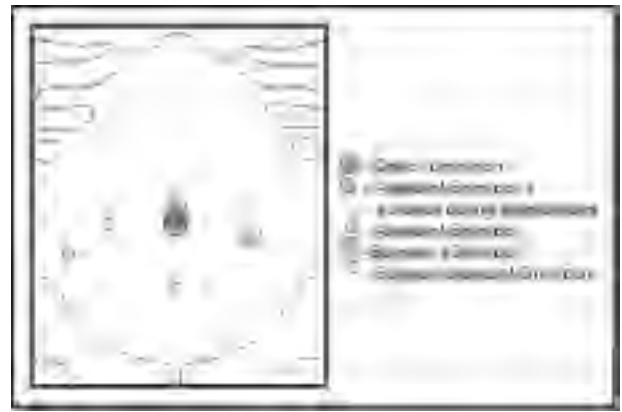

FIGURE 2 ■ The triangular trocar variation involves placement of the surgeon ports on the left side between the umbilical port and the left iliac spine and the other two-thirds of the distance between the umbilical port and the suprapubic rim along the midline.

2. An optional trocar placement involves changing the surgeons trocars using a triangulation position. They are introduced, midway between the umbilical port and left iliac spine and the other two-thirds of the distance between the umbilical port and the suprapubic rim along the midline (Fig. 2).

Step 2: Bilateral Pelvic Lymphadenectomy with Frozen Section Analysis

This is performed along the external iliac vessels, in order to remove all the lymph nodes for frozen section analysis. The limits of the lymph node dissection include the level of the ureter as it crosses the common iliac artery, the genitofemoral nerve laterally and the external iliac and obturator fossa lymph nodes and circumflex iliac vein distally, which comprise the external iliac vessels and obturator fossa.

Step 3: Bilateral Ureteric Dissection

The peritoneal incision used during the lymphadenectomy is extended downward in order to expose and dissect the ureters, which are transacted bilaterally near their entry to the bladder. The distal end of the ureters is sent for frozen section to ensure a healthy surgical margin. Both ureters are ligated with security Hem-O-Lok™ clips.

Step 4: Vas Deferens and Seminal Vesicle Dissection

The vas deferens and seminal vesicles are dissected. The peritoneum is opened along the pouch of Douglas, to gain access to the vas deferens, which are traced deeply, to reach the anterior surface of the seminal vesicles, which are completely liberated from the surrounding anterior aspect of the Denonvillier fascia, allowing their adequate preservation.

Step 5: Opening of the Retzius Space

This is done to free the bladder from the abdominal wall and retropubic space, which will allow an excellent view of the bladder and prostate, making it possible to identify the bladder neck.

Step 6: Division of the Lateral Bladder Pedicles

The lateral bladder pedicles are divided. By retracting medially the bladder wall, the lateral vascular pedicles can be dissected and freed using monopolar and bipolar diathermy.

Step 7: Incision of the Anterior Surface of the Prostate

This is performed at least 5 mm distal to the bladder neck to ensure adequate surgical margins. This incision is completed posteriorly in order to allow the bladder to be separated completely. It is important to perform this incision along the prostatic adenoma, making sure that the bladder neck is completely resected (Fig. 3).

FIGURE 4 ■ Transverse view. The prostate capsule after the simple prostatectomy performed laparoscopically; it is cut below the bladder neck. This allows the preservation of the neurovascular bundles.

Step 8: Bladder Neck Closure

The bladder neck is closed. This must be performed immediately after completing the bladder neck dissection, in order to avoid any possible tumor cell spillage. We routinely do this with an intracorporeal "X" suture with 2-0 Vicryl on a 36 mm needle.

Step 9: Specimen Entrapment

The bladder is then placed in a surgical specimen extraction bag.

Step 10: Laparoscopic Simple Prostatectomy

This removes all of the adenomatous gland and leaves the prostatic urethra "intact" and can be performed with bipolar diathermy or with the harmonic scalpel. The specimen is placed in an Endobag (Fig. 4).

Step 11: Extraction of the Surgical Specimens

Both tissues, the bladder and prostate adenoma, are extracted through a small infraumbilical midline incision.

Step 12: Open Enterocystoplasty

The enterocystoplasty is performed following open surgical principles. A 40 cm ileal segment is isolated and detubularized leaving 3 cm on either end for the ureteroileal anastomosis. The detubularized ileal segment is remodeled using a Z technique into a neobladder (Fig. 5).

Step 13: Ureteroileal Anastomosis

Both ureters are spatulated to allow a side-to-end anastomosis to the nondetubularized ends of the neobladder. Bilateral stents are left on either side for seven days.

Step 14: Prostatoileal Anastomosis

This is performed from the lowest portion of the enteroplasty to the prostatic capsule with interrupted 3/0 Vicryl sutures. The integrity of the anastomosis is confirmed by filling the neobladder with 200 mL of saline.

Step 15: Drains and Foley Catheter Placement

Finally, two suction drains are left in the pelvic cavity and the pouch of Douglas. The Foley catheter is left in the urethra for nine days.

DESCRIPTION OF TECHNICAL MODIFICATIONS

At our center, we modified the surgical technique previously described to render this technique easier to reproduce. Two major modifications include the type of simple

FIGURE 5 ■ Lower urinary tract reconstruction with the "Z" ileal neobladder.

prostatectomy, and the approach for the anastomosis during the lower urinary reconstruction.

In the beginning of our experience we performed a transurethral resection of the prostate extending from the bladder neck to the verumontanum at the beginning of the surgery. Specimens of the prostatic urethra and transition zone were sent in separate containers for frozen section examination before proceeding with the cystectomy. However, currently we have noted that performing a simple prostatectomy after the bladder dissection offers the benefit of the complete prostatic urothelium for histopathologic analysis, and can be done without compromising the surgical results and not increasing significantly the surgical time. However, both options are feasible and the surgeon should select either, according to preference.

The second variation of the technique is the option, after the neobladder construction, of performing the neobladder prostate capsule anastomoses and ureter-neobladder anastomosis laparoscopically by closing the midline incision. We have performed these anastomoses by open and laparoscopic approaches, and have seen that the laparoscopic technique at this stage of the operation does not modify significantly the results and could result in a longer surgical time and a difficult procedure, especially concerning the neobladder-prostate capsule anastomosis (4).

Guazzoni et al. have recently described the laparoscopic approach for a nerve- and seminal-sparing cystectomy, doing one week before the surgery a transurethral resection of the prostate and transectioning the bladder vascular pedicles with Endo-GIA. In our experience, this stapler is not necessary as described in our technique, due to its cost and risk of malfunction, and because we deem bipolar diathermy sufficient (10).

There are no other laparoscopic prostate-sparing techniques described in the literature; however, there have been some techniques applied through an open approach that propose some variations concerning the prostate-sparing dissection planes. These modifications will be described briefly because they are performed by an open technique; however, they could eventually be performed laparoscopically also.

Colombo et al. have reported a similar technique to ours, except for the fact that they perform cystectomy extraperitoneally. After the completion of cystectomy, they open the peritoneum and perform the ileal bladder reconstruction and anastomosis with two semicircular running sutures (11).

TABLE 3 ■ European Groups that Perform Open or Laparoscopic Prostate-Sparing Cystectomy

Meinhardt and Horenblas have performed a technique in which the prostate and seminal vesicles are preserved allowing the neobladder to be anastomosed to the lateral edge of the prostate; however, they do not specify any further details (12).

Ghanem has proposed ligating the anterior prostatic veins and incising the prostate capsule transversely 0.5 cm below the bladder neck, as in retropubic prostatectomy to allow a dissection of the prostatic adenoma attached to the bladder, and continuing a circumferential incision from the anterior transverse incision of the prostatic capsule, to complete the cysto-prostatic-adenomectomy (Table 3) (13).

Spitz et al. described a technique for nonurothelial tumors, and mentioned the variation of an incision of the endopelvic fascia adjacent to the prostate and ligation of the anterior and lateral aspects of the prostate proximal to the puboprostatic ligaments, controlling the dorsal venous complex and the incision of the prostatic stroma at the level of the urethra. This prostate transection is continued posteriorly without compromising the ejaculatory ducts (14).

Center	No. of patients	Continence (%)	Erections (%)
Montsouris	132	100	84
Colombo	41	100	100
Horenblas	39	70	70
Sèbe	34	90	88
Coulange	25	93	86
Meinhardt	24	96	83
Ghanem	4	100	75

All of these open technique variations can be easily applied to the laparoscopic approach; however, the choice of technique depends on the surgeon's personal experience.

TECHNICAL TIPS

- When opening the Retzius space, it is not necessary to open the endopelvic fascia, because the prostate capsule is not manipulated in this technique. Avoiding the incision of the endopelvic fascia ensures that the neurovascular bundles of the prostate are left undisturbed, as well as the surrounding tissues, which being intact serve as support for the prostate.
- During the incision of the bladder vascular pedicle with bipolar diathermy, it is important to take adequate time to ensure that no postoperative bleeding occurs from these vessels.
- The bladder neck can be identified by mild traction on the Foley catheter, which makes evident the prostatovesical junction anteriorly. Another option is to visualize the perivesical fat, which does not extend into the prostate and makes a subtle bladder neck delineation. Finally, if neither of the above is useful, a Benique dilator can be introduced and visualized inside the bladder; however, we must keep in mind that the bladder neck is higher than the tip of the metal dilator.
- To perform the bladder neck incision, it is done along the prostatic adenoma, 10 mm below the bladder neck, ensuring that a complete resection of the bladder neck is performed, thereby diminishing the risk positive margins along the lower portion of the surgical specimen.
- After the bladder is completely liberated, the bladder neck closure must be performed immediately after completing the bladder neck dissection, and introduced into an extraction bag without any excessive pressure on the bladder. All this is done to avoid any possible tumor cell spillage, although the risk is low considering that the bladder has been completely emptied of any remaining urine with the Foley catheter and the ureters have been long since ligated and transected.
- When performing the simple prostatectomy, the distal portion of the incision along the prostatic urethra must not be beyond the verumontanum, in order to avoid any damage to the sphincter.

SPECIFIC MEASURES TAKEN TO AVOID COMPLICATIONS

Complications involved in laparoscopic surgery of the lower urinary tract are mainly the same as those involved with open surgery (15). We describe the transoperative (divided according to the different surgical steps) and postoperative complications.

Perioperative Complications

Perioperative complications are associated with the patient position (such as compartment syndromes and neurologic sequelae secondary to prolonged compression), insufflations (vascular or intestinal injuries), and those associated with intestinal displacement during the laparoscopic stage. These complications can be prevented by carefully positioning the patient with enough cushioning of the dependent areas, by avoiding excessive pressure on the abdominal wall when introducing the insufflation needle, and finally by managing the gastrointestinal tract with blunt instruments and carefully.

Postoperative Complications

Postoperative complications are associated with the different stages of the surgery, and include hematomas resulting from inadequate use of diathermy during dissection, and lymphocele, which is usually rare because the operation is performed transperitoneally and, as such, is reabsorbed by the peritoneum. Wound infections are not due to the intestinal content and should not influence this complication. Neobladder stenosis is rare but can be the result of an incision too low along the prostate or an inadequate anastomosis. Urine leak is due to damage of the tissues in the anastomosis or an inefficient suture, which can be verified transoperatively by filling the neobladder with saline solution. Intestinal fistulae can occur if the entero-entero anastomosis is not carefully performed or there is an ischemic lesion on the ileal wall.

POSTOPERATIVE EVALUATION

The follow-up protocol that we routinely use includes a complete physical exam with digital rectal exam, complete blood analysis with a special interest in urine analysis, serum creatinine, total prostate-specific antigen and free prostate-specific antigen, chest X-rays and computed tomography scan of the abdomen every six months for the first three years, and yearly afterwards. Continence is evaluated using a mailed questionnaire, evaluating their use of protection pads. We define erectile function according to their ability to perform intercourse.

Continence and potency are assessed by the patients (16,17), using mailed questionnaires. Patients are considered continent only when they do not use any pads. They are strictly instructed during the first postoperative year to empty the bladder once or twice at night in order to achieve adequate nighttime continence. Potency is strictly defined as the ability to maintain an unassisted erection sufficient for intercourse. Partial potency is defined as the ability to achieve but not maintain erection long enough for satisfactory intercourse without the use of any device or medications. Patients unable to achieve an erection, as well as those using medications or devices to stimulate erection, are considered as impotent.

RESULTS

During the last 12 years 132 patients have undergone a prostate-sparing cystectomy in our department (4). The first 107 procedures were performed with open approach, and the last 25 using laparoscopic-assisted technique. In our experience, the oncologic and functional results of our laparoscopic series are comparable to that of the open approach series, with the added benefit of a diminished bleeding and less need of postoperative analgesics.

From March 2002 to March 2004, we employed the laparoscopic prostate-sparing technique in 25 patients. The average age was 60 (range, 43–77 years), 20/25 of the patients had a history of smoking as a risk factor. The different pathologic postoperative stages were pT1 = 8, pT2 = 8, pT3 = 8, pT4 = 1 involving the prostate neck (N0, M0). They all had negative surgical margins and no lymph nodes with metastasis. The histopathologic grade was moderate in 6 and high grade in 19. Mean operating time including the neobladder reconstruction was 4.75 hours (range, 3.3–6.3 hours) and mean intraoperative blood loss was 640 cc (range, 200–1500 cc) with transfusion required in six patients. The surgery was successfully completed as described with the laparoscopic and open stages in all of the patients, without any transoperative complications or conversions (Table 4). After performing the neobladder anastomosis laparoscopically in five patients, we did not observe any significant advantage for the surgical technique, and decided to continue performing the neobladder-prostatic anastomosis through the infraumbilical incision by an open technique. Overall, this offers the advantage of preventing any traction on the abdominal wall and hence minimizes postoperative pain. All of our patients were followed up for the first 24 hours in the intensive care unit according to hospital policy without any complications, except for a sinus tachycardia, which resolved without any sequelae. In all, the laparoscopic approach offered diminished bleeding and less postoperative pain.

Among the postoperative complications there was one intestinal suboclusion, one urinary fistula and one pelvic lymphocele. The average follow-up of these patients was 9.7 months (range, 3–27 months). There have been two metastatic progressions (at five and eight months) and one local recurrence (six months after the surgery); the three patients have been submitted to chemotherapy following a methotrexate, vinblastine, adriamycin and cisplatin scheme with good results. All of the patients are alive except for a T3a patient who died seven months after the surgery due to cancer progression. Interestingly, this same patient in the final pathology analysis was reported with a small prostatic adenocarcinoma with a Gleason 3+3 in the resected prostatic adenoma, which was not diagnosed during the frozen section study; he was managed with hormone therapy. Concerning renal function, creatinine levels have been maintained and have not varied significantly (average of 97 mmol/L before and 102 mmol/L after the surgery). This figure also applies to the prostate specific antigen, although a slight decrease was detected after the surgery (from 2 ng/mL before to 0.6 ng/mL after the surgery), which was mainly due to the simple adenomectomy. Finally, concerning functional results, all our patients

---

In our experience, the oncologic and functional results of our laparoscopic series are comparable to that of the open approach series, with the added benefit of a diminished bleeding and less need of postoperative analgesics.

achieved satisfactory daytime and nighttime continence, without using any pad after surgery. Nighttime continence is complete; however, seven patients developed nocturia between one and three per night. No patient has presented with urinary retention, 21 patients (84%) maintained their preoperative sexual potency, and four alluded to a decrease in their erectile function postoperatively. All of our patients have retrograde ejaculation after surgery, which is related to the simple prostatectomy.

DISCUSSION

The current standard of care for muscle invasive and refractory superficial high-grade organ-confined bladder cancer is radical cystoprostatectomy (18). This procedure removes the bladder, prostate, seminal vesicles and vas deferens, and involves a deep pelvic dissection with a significant risk of damage to the pelvic nerves as well as extensive manipulation of the external sphincter (19). This explains why it is associated with a considerable degree of incontinence (5–18%) when a neobladder is constructed and erectile dysfunction (75–80%) (20–22). These functional results explain why more conservative techniques are constantly being explored. The goal is to preserve the urethral sphincter and neurovascular bundles, which will impact on the functional results for these patients (23).

With the above in mind, the laparoscopic prostate-sparing cystectomy was developed at our Institute.

Laparoscopic prostate-sparing cystectomy is associated with the potential risk of developing prostate cancer, carcinoma in situ of the prostatic urethra, transitional cell cancer of the prostatic ducts or glands, and prostatic invasion by bladder cancer, which as a group might influence the oncologic control obtained with this procedure (24).

> Laparoscopic prostate-sparing cystectomy is associated with the potential risk of developing prostate cancer, carcinoma in situ of the prostatic urethra, transitional cell cancer of the prostatic ducts or glands, and prostatic invasion by bladder cancer, which as a group might influence the oncologic control obtained with this procedure.

Risk of Prostate Cancer

Kabalin et al. (25) reported a 38% incidence of occult prostate cancer in cystoprostatectomy specimens but only 1.9% of these had tumors exceeding 0.1 cc in volume. Moreover, their study was performed before the prostate specific antigen era and patients were excluded from their analysis if they had an abnormal digital rectal exam. Our patients were assessed carefully preoperatively to exclude the risk of prostate cancer (26). Patients with an abnormal digital rectal examination, total prostate specific antigen > 3 ng/mL, or percent free prostate specific antigen <12% underwent prostatic biopsies. Preoperatively, frozen sections of the transitional zone were routinely done. These frozen sections were initially of the transurethral resection chips, before the laparoscopic procedure was started; afterwards in our experience, the complete transitional zone was analyzed after the simple prostatectomy in the laparoscopic approach. In our series, two cases were not completed because they had positive frozen section for prostate cancer, and the procedure was completed with a radical cystoprostatectomy. The simple prostatectomy that we currently perform laparoscopically (27) allows complete removal of the transitional zone, improving the reliability of pathologic analysis, which with our strict follow-up protocol of digital rectal examination, and total and free prostate specific antigen every six months, leads to an early detection of any de novo prostate cancer, giving enough time for the patient to be treated successfully with either of the different modalities (external beam radiotherapy, transrectal focused ultrasound, brachytherapy or hormonal treatment). In our experience, two de novo prostate cancers have been diagnosed at three and five years after the prostate-sparing procedure and have been treated successfully, one with external beam radiation and the other by transrectal high intensity energy ultrasound.

Risk of Urethral Carcinoma in Situ and Prostatic Transitional Cell Carcinoma

Matzkin et al. reported a 25% incidence of prostatic transitional cell carcinoma in 86 patients (28). Wood et al. indicated that most of the transitional cell carcinoma seen in cystoprostatectomy specimens was in the prostatic urethra (29). Using our laparoscopic technique, the simple prostatectomy removes completely the prostatic urethra and the transitional zone. Lebret et al. reported no urethral recurrence at 10 years in patients who underwent cystectomy when no tumor was found on frozen section in the prostatic urethra (30,31). Among the 107 patients who underwent open prostate-sparing cystectomy, transitional cell carcinoma recurred in the prostatic fossa in two cases and was managed successfully with transurethral resection. Up to now, no recurrence

has occurred among the last 25 patients who have undergone the laparoscopic prostate-sparing cystectomy with simple prostatectomy.

Prostatic Invasion

Prostatic invasion occurs by carcinoma-in-situ, ductal invasion or stromal invasion (secondary to ductal invasion or primary by direct extravesical tumoral extension). Cookson et al. (32) reported a 15.6% incidence of prostatic invasion by bladder cancer, with an increased risk when carcinomainsitu or multifocality exists (>30%) and decreased risk in absence of carcinomainsitu and multifocality (4.5%). A 5–10 mm safety margin beyond the bladder neck is ensured with our technique. Moreover, frozen section was performed of the prostatic capsule in patients with higher risk tumors, which were close to the trigone.

Oncologic Results

The five years global survival according to the stage are reported Figure 6 and Table 5 for the overall series of 132 patients including open and laparoscopic approach. The five years' recurrence-free survival, isolated local recurrence and distant metastases rates reported (Tables 6 and 7), show comparable data between our series and those published by Studer et al. with 507 patients who underwent radical cystoprostatectomy without any adjuvant or neoadjuvant treatment (33). Stein et al. (34) reported a lower rate of distant metastases (13% for stage = pT2 N0) in 1054 patients who underwent cystoprostatectomy, but 25% of them received adjuvant or neoadjuvant therapies (radiotherapy or chemotherapy).

Benefits of Laparoscopic Approach

The feasibility of the laparoscopic radical cystectomy has been previously described (35–37) and shown to incorporate the advantages offered by minimally invasive surgery with earlier postoperative recovery, less need for pain relief and diminished blood loss. This is confirmed as well in our experience, as well as the fact that while performing the lower urinary tract reconstruction completely intracorporeally can be done,

this does not offer significant advantages for the patient and does increase the surgical difficulty and time.

Functional Results

We have shown in our previously published series (4) of 100 patients who underwent open prostate-sparing cystectomy showed a high rate of continence and maintenance of erectile function. The laparoscopic approach equals these results and those of other published reports, with 100% continence in our series versus 93% in those of Hollowell et al. (38), and 85% preservation of erectile function in our laparoscopic group versus 82% in the open series. These results are so much better than those of the traditional radical cystoprostatectomy (39). The impact on the patient's overall quality of life cannot be overemphasized.

SUMMARY

- There is a growing interest in this surgical procedure, which preserves the prostatic capsule and neurovascular bundles and presents a good option for highly selected patients. It allows a faster recovery of continence and erectile function, although retrograde ejaculation is a limiting factor for fertility potential.
- The laparoscopic technique reproduces the open technique with the added advantage of earlier postoperative recovery and less pain inherent to this approach.
- In order to avoid performing this procedure in cases that require a more radical approach, the need for a careful patient selection for this technique cannot be overemphasized.
- There is still need for longer follow-up and larger series of patients to confirm the overall oncologic outcome. Summarily, the need to ensure the patient's safety is paramount.

INTRODUCTION

Radical cystectomy is the most effective treatment for patients with organ-confined muscle-invasive or recurrent high-grade bladder cancer. The laparoscopic approach to radical cystectomy with urinary diversion is the culmination of many advances in the growing field of minimally invasive urology. However, experience with this technique remains limited. After initial experience in experimental porcine models (1,2), data are now becoming available on small series of completely intracorporeally performed laparoscopic radical cystectomy with a variety of urinary diversions (3–5).

PATIENT SELECTION

Bladder cancer is a potentially lethal disease; the patient's prognosis is partially dictated by the quality of the cystectomy and extent of the lymphadenectomy (6–9). The introduction of the laparoscopic approach with its potential low morbidity profile is, in part, an effort to preserve high quality of care while minimizing the often debilitating effects of cystectomy and permitting more patients the opportunity to undergo this potentially lifesaving procedure. This approach should by no means compromise the oncologic quality of radical cystectomy. Laparoscopic radical cystectomy is still in its early stages, and its long-term advantages and disadvantages are poorly defined. Therefore, patient selection is paramount to a successful laparoscopic radical cystectomy program.

Patients with bulky and locally advanced primary disease are not good candidates for laparoscopic radical cystectomy. Prior pelvic radiation therapy, prior prostate surgery, extensive transperitoneal surgery, and/or low ability to tolerate prolonged pneumoperitoneum (i.e., chronic obstructive pulmonary disease) constitute relative contraindications to laparoscopic radical cystectomy at this time. The laparoscopic approach for the treatment of invasive bladder cancer is promising, and with the accumulated experience its indications will continue to safely expand.

PREOPERATIVE PATIENT PREPARATION

Preoperatively patients receive a mechanical bowel preparation, identical to that for open surgery. Thromboprophylaxis is ensured by sequential compressive devices on both lower extremities and low-molecular-weight heparin administered prior to surgery, then daily afterwards until discharge from the hospital. Thromboprophylaxis is essential given the multiple risk factors, including oncologic surgery, pelvic surgery, laparoscopy, and prolonged operative time. Patients also receive antibiotic prophylaxis.

SURGICAL TECHNIQUE

Patient Positioning

The patient is positioned in a low lithotomy position or a supine position with the lower extremities apart on spreader bars to allow access to the perineum. Both arms are set alongside the body and the patient is secured to the operating table with surgical tape. A right-handed surgeon stands on the patient's left with the assistant on the opposite side; the monitor is placed between the patient's legs, at the surgeon's eye level and as close as necessary (Fig. 1). The operating table is placed in a steep Trendelenburg position during surgery.

Port Placement

The pneumoperitoneum is obtained through a Veress needle and set at a pressure of 12 mmHg. A five to six-port fan-shaped transperitoneal approach is used. First a 12 mm port is inserted supraumbilically and used for the laparoscope. The peritoneal contents are examined for trocar injury and evidence of metastasis, and then the remaining four to five ports are placed under visual control (Fig. 2).

A bilateral pelvic lymphadenectomy is performed either initially or after the cystectomy is completed. The authors' preference is to perform the lymphadenectomy after the cystectomy, prior to specimen extraction in the male, and following specimen extraction in the female (Fig. 3). The lymphadenectomy is often extended to at least the common iliac bifurcation and often to the aortic bifurcation. Laparoscopic bilateral pelvic lymphadenectomy is described elsewhere in this book and will not be covered here Table 1.

LAPAROSCOPIC RADICAL CYSTECTOMY IN THE MALE PATIENT (Table 1)

Posterior Peritoneal Incision (Pouch of Douglas to Ureters)

The sigmoid colon is retracted gently by the assistant, moving any redundant rectum cephalad. In rare cases, a redundant sigmoid colon can be retracted cephalad using a silk

TABLE 1 ■ Surgical Steps of Laparoscopic Radical Cystectomy

	Technical steps
First step	Posterior peritoneal incision to access through the cul-de-sac of Douglas
Second step	Dissection of the ureters
Third step	Control of the posterior vesical pedicle
Fourth step	Anterior approach and development of the Retzius space
Fifth step	Transection of the lateral vesical and prostatic vascular pedicles
Sixth step	Apical dissection, transection, and specimen entrapment
Seventh step	Bilateral pelvic lymph node dissection

FIGURE 3 ■ Pelvis after cystectomy, showing completed right-side pelvic lymphadenectomy and dissection for left-sided pelvic lymphadenectomy.

FIGURE 4 ■ Initial posterior peritoneal incision to access posterior cul-de-sac. The dotted line illustrates planned continued incision of posterior peritoneum overlying the ureter and lateral pedicle.

retraction suture placed through the tenia coli and brought through the skin with a suture passer. The surgeon incises the posterior vesical peritoneum transversally approximately 2 cm above the recess of the pouch of Douglas. This dissection should follow the inferior peritoneal flap; it exposes the outlines of the vesicular complex formed by the vasa deferentia and seminal vesicles. The incision is carried proximally near the lateral pelvic sidewall and to the pelvic brim in order to expose the ureters (Fig. 4).

The seminal vesicular complex is seen through Denonvilliers' fascia. Unlike laparoscopic radical prostatectomy, the vesicular complex is not mobilized but left en-bloc with the bladder. Denonvilliers fascia should be respected at this level and opened lower and closer to the prostate. At that location, Denonvilliers fascia is incised medially and horizontally, bringing into view the prerectal fatty tissue. Dissection is then taken in the plane between the posterior aspect of the prostate and the anterior rectal wall as far as the prostatic apex. This dissection separates the rectum from the posterior and lateral vascular pedicles of the bladder and prostate.

Further Dissection and Transection of the Ureters

The ureters are identified as they cross the iliac vessels and dissected down to the bladder. The ureters are clipped distally (Fig. 5). During this dissection care is taken to leave ample tissue around the ureter and thus preserve its vascular supply. Laparoscopically, it is possible to dissect the ureters closer to the bladder than during open surgery. However, one must be sure to get negative surgical margins. Therefore, once the ureters are divided, the distal ureteral margins are sent for frozen section pathologic analysis with the right and left ureter marked separately. The clips are left on the ureter to allow dilation for later anastomosis. A long stay suture is passed through the distal ureter to facilitate later identification and traction. It is prudent to complete the cephalad ureteral dissection at this point. The limit of ureteral dissection is typically 4–5 cm where it crosses the iliac artery.

FIGURE 5 ■ Transection of right ureter demonstrating clips on either side with stay suture through proximal end.

FIGURE 6 ■ Posterior pedicle dissection showing Endo-GIA on right posterior pedicle with care taken not to transect the distal ureteral stump.

Control of the Posterior Vesical Pedicle

The bladder is pulled anteriorly and the rectum retracted posteriorly. This maneuver exposes the posterior vesical pedicle, which is controlled by either Endo-GIA[a] staplers (vascular 2.5 mm stapler), Harmonic scalpel, surgical clips, bipolar cautery, or a combination (Fig. 6) (4,10,11). After complete transection of the posterior pedicle, the bladder has only lateral, anterior, and apical attachments.

Anterior Approach and Development of the Retzius Space

The bladder is filled with 120–200 mL of saline to help delineate its contours. The peritoneum is opened from one umbilical ligament to the other and the incision is extended upward to include the urachus, which is divided near the umbilicus (Fig. 7). The anterior surface of the bladder is mobilized and the prevesical and preprostatic space entered. The endopelvic fascia exposed is opened, uncovering the levator ani fibers. The latter are bluntly pushed away from the prostate; the puboprostatic ligaments are divided, giving clear access to the dorsal venous complex, which is ligated with 2/0 Vicryl on an SH needle. Transection of the dorsal venous complex is left for the final apical dissection. Once completed, this step provides adequate space for accurate control of the lateral vascular pedicle.

Transection of the Vesical and Prostatic Vascular Pedicle

At this point the bladder is pulled laterally and the rectum posteriorly to expose the lateral pedicle. The vascular control can be performed by either Endo-GIA staplers, harmonic scalpel, surgical clips, bipolar cautery, or a combination (Fig. 8). The unincised peritoneal lining includes the vas deferens, which is secured during the complete transection. If non–nerve-sparing surgery is employed, the transection can simply be taken down to the prostatic apex. If a nerve sparing dissection is planned, the nerves must be teased off the base of the prostate and seminal vesicles as in laparoscopic radical prostatectomy.

Apical Dissection

The bladder is pulled cephalad; the dorsal venous complex is incised in a tangential fashion to avoid iatrogenic incision into the prostate at the apex. Gradually an avascular plane of dissection situated between the dorsal venous complex and the urethra is developed. Alternatively, if a nonorthotopic diversion is planned, one can use the Endo-GIA staplers to control the dorsal venous complex. The proximal aspect of the urethra

FIGURE 8 ■ Lateral pedicle transection with Endo-GIA. Contralateral traction is provided to help delineate the space.

is either clipped or sutured to prevent tumor spillage and the urethra is divided (Fig. 9), freeing the surgical specimen, which will be placed in a laparoscopy bag. The empty pelvis is now prepared for a lymphadenectomy (Fig. 10).

LAPAROSCOPIC RADICAL CYSTECTOMY IN THE FEMALE PATIENT

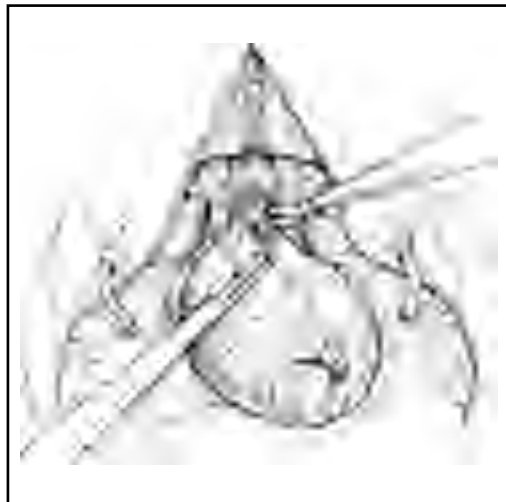
In women, the procedure is very similar to a laparoscopic-assisted vaginal hysterectomy, which our gynecologic colleagues have been performing for some time. Posteriorly, the peritoneum is incised at the level of the rectovesical cul-de-sac and the posterior vaginal wall is mobilized off the rectum. After control and division of the vesical vascular pedicle and the broad ligaments, a sponge stick is inserted in the posterior vaginal cul-de-sac to expose the area of vaginotomy and to help delineate the plane of excision of the anterior vaginal wall. Once freed, the surgical specimen is retrieved through the vaginal vault.


FIGURE 9 ■ Transection of posterior urethra and rectourethralis after securing bladder neck.
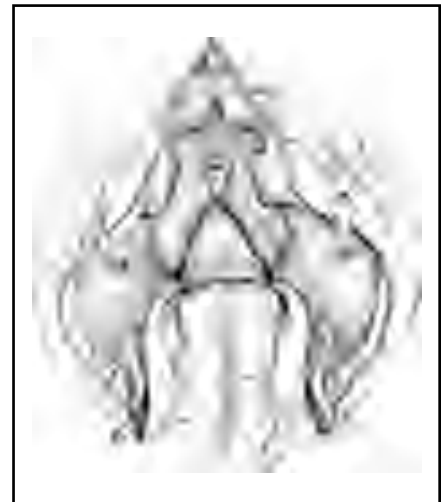

FIGURE 10 ■ View of empty pelvis after cystectomy and prior to pelvic lymphadenectomy.

ROBOT-ASSISTED LAPAROSCOPIC RADICAL CYSTECTOMY

The advent of the robotic technology has allowed many surgeons to translate standard surgical movements to the laparoscopic arena. After initial application in an animal study (12), robot-assisted radical cystectomy has been reported in the clinical setting (13–16). By allowing additional degrees of freedom of movement and a comfortable working position, the robotic assistance provides novice laparoscopy surgeons ease in suturing and knot tying. The general approach to the procedure, however, is the same.

URINARY DIVERSIONS

The urinary diversion may be an ileal conduit, an Indiana pouch, a Camey II performed extracorporally, an orthotopic ileal neobladder with Studer limb, or a rectal sigmoid pouch performed intracorporeally (4,5). These techniques are expertly described elsewhere in the text.

CONCLUSION

The small number of patients in current reported series and the short follow-up precludes any definitive morbidity or oncologic outcome analysis. The feasibility of the procedure has certainly been established. Only detailed analysis and follow-up will determine whether the short-term benefits become greater as more laparoscopic radical cystectomies are performed, and whether they attain the same oncologic efficacy as standard methods.

LAPAROSCOPIC BOWEL SURGERY: GENERAL CONSIDERATIONS

Anthony J. Senagore

Department of Colorectal Surgery, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

Modified use of these resective techniques can be implemented for reservoir construction in urologic procedures.

Data are slowly accumulating supporting the concept that the laparoscopic approach to colectomy offers significant early advantages for the management of most colorectal pathology. Data exist regarding the benefits of laparoscopic management of colon cancer and large polyps, diverticulitis, and inflammatory bowel disease. Modified use of these resective techniques can be implemented for reservoir construction in urologic procedures.

The cost-effectiveness of laparoscopic colectomy is related primarily to reductions in duration of hospitalization and a lower incidence of cardiopulmonary complications that lead to a reduced utilization of postoperative diagnostic and therapeutic investigations (1). The earlier recovery of the patient coupled with an earlier return to normal activity offers other potential cost savings to society at large (2).

Initial concerns with laparoscopic colorectal surgery related to technical difficulty, steeper learning curves, a need for specialized instrumentation and longer operating times. Secondary concerns have developed including increased hospital costs, questions about real improvements in outcome and concerns regarding safety in neoplastic disease (3). These factors have led to the slower dissemination of the technique compared to other advanced laparoscopic procedures such as Nissen fundoplication or splenectomy (4). Recent reports of "fast track" care for colectomy patients have further blurred the distinctions between outcome of laparoscopic and open colectomy because of the perception that length of stay can be dramatically reduced with open surgery. However, the majority of data report shorter duration of hospitalization for laparoscopic colectomy compared to open surgery (5-9).

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

We have taken the approach that laparoscopic colectomy can be broadly applied to colorectal pathology so all patients are considered potential candidates for a laparoscopic approach. However, after initial visualization of the abdominal cavity a determination is quickly made regarding the appropriateness of proceeding. This could be based upon a larger than expected mass or worse than anticipated adhesions. Exclusions from an attempted laparoscopic colectomy are body mass index >35, and prior major abdominal surgeries (exclusive of hysterectomy, cholecystectomy, or appendectomy).

PERIOPERATIVE CARE

All patients receive a mechanical bowel preparation consisting of a clear liquid diet for 24 hours preoperatively and 3 oz of Fleets Phosphosoda™ administered the afternoon

prior to surgery. Intravenous prophylactic cefuroxime 1 g and metronidazole 500 mg one hour prior to the procedure is administered to all nonallergic patients. A urinary catheter is inserted at surgery and removed the following morning. The perioperative care plan includes the following: preemptive analgesia with oral Voltaren[®a] 50 mg the day before surgery; nasogastric tubes and drains are not employed routinely; and analgesia consisting of patient-controlled epidural (bupivacaine/fentanyl) or intravenous morphine for 12 to 18 hours. All patients are offered a full liquid diet as the first meal following surgery. Thereafter, dietary intake is ad libitum with no specific restrictions. Patients are encouraged to ambulate as soon as possible after the procedure, with a minimum of five walks outside the room the first postoperative day. The first postoperative morning patients are converted to oral analgesics that include hydroxycodone (one or two tablets every 6 hours) and Voltaren 50 mg TID. The intravenous catheters are removed the first postoperative morning unless the patient is nauseated or distended. Discharge criteria include the tolerance of three general meals without nausea or vomiting, absence of abdominal distention, adequate oral analgesia, and passage of flatus.

It appears that the combination of a lesser degree of trauma with laparoscopy, early feeding, and aggressive ambulation dramatically reduces the risk of postoperative ileus and allows for early discharge after laparoscopic colectomy.

OPERATIVE TECHNIQUES

Right Colectomy

The operative steps (Table 1) for laparoscopic right colectomy and recommended time for completion are as follows: (5) (i) open insertion of the umbilical port for establishment of pneumoperitoneum and peritoneal inspection (two to five minutes); (ii) placement of a 12 mm port 2 cm medial to the left anterior superior iliac spine, a 5 mm port 2 cm medial to the right anterior superior iliac spine, and a 5 mm port laterally on the left side just rostral to the umbilicus, all under direct vision with pneumoperitoneum (2–10 minutes, if adhesions from prior surgeries require lysis prior to port insertion); (iii) elevation of the right colic pedicle allows dissection beneath the vessels with identification of the origin of the right colic artery and the duodenum (15–20 minutes); (iv) elevation of the right colon and proximal transverse colon off the retroperitoneum (5–10 minutes); (v) release of the hepatic flexure to mid transverse colon (15–20 minutes); (vi) division of the lateral peritoneal reflection and ligament of Treitz (10–15 minutes); (vii) exteriorization of the specimen through a 4 to 6 cm umbilical incision with use of a wound protector (Protractor™[b]) (two to five minutes); and (viii) extracorporeal bowel division and ileocolic anastomosis (5–10 minutes).

If the intended procedure is to mobilize the right colon rather than resect bowel then the following step modifications are used; division of the peritoneum lateral to the colon and medial mobilization of the right colon without ligation of the vessels. The remainder of the procedure is similar as bowel transection and construction of an ileocolic anastomosis is performed extracorporeally in the interest of cost-effectiveness.

Sigmoid/Left Colectomy

The operative steps (Table 2) for laparoscopic colectomy for the sigmoid or left colon and recommended times for completion are: (i) open insertion of the umbilical port for

TABLE 1 ■ Steps for Laparoscopic Right Colectomy

Open insertion of the umbilical port for establishment of pneumoperitoneum
Placement of a 12-mm port 2 cm medial to the left anterior superior iliac spine; a 5-mm port 2 cm medial to the right anterior superior iliac spine; and a 5-mm port laterally on the left side just rostral to the umbilicus
Elevation of the right colic pedicle from the retroperitoneum with ligation of the right colic artery
Elevation of the right colon and proximal transverse colon off the retroperitoneum
Release of the hepatic flexure to mid transverse colon
Division of the lateral peritoneal reflection and ligament of Treitz
Exteriorization of the specimen through a 4 to 6 cm umbilical midline incision
Extracorporeal bowel division and ileocolic anastomosis

TABLE 2 ■ Steps for Laparoscopic Sigmoid/Left Colectomy

Open insertion of the umbilical port for establishment of pneumoperitoneum
Placement of a 12-mm port 2 cm medial to the right anterior superior iliac spine; a 5-mm port 2 cm medial to the left anterior superior iliac spine; and a 5-mm port laterally on the right side just rostral to the umbilicus
Mobilization of the mesosigmoid and mesorectum from the right side for identification of the left ureter and subsequent intracorporeal division of the vessels
Mobilization of the sigmoid and descending colon laterally up to the splenic flexure and medially off Gerota's fascia
Mobilization of the proximal rectum with division of the rectosigmoid junction with a linear endoscopic stapler
Division of the mesorectum at the distal resection site with control of vessels via bipolar cautery or vascular clips
Exteriorization of the specimen through a left lower quadrant muscle splitting incision for specimen resection and anvil placement within the proximal colon
Reestablishment of pneumoperitoneum and circular-stapled colorectal anastomosis

establishment of pneumoperitoneum and peritoneal inspection (two to five minutes); (ii) placement of a 12 mm port 2 cm medial to the right anterior superior iliac spine, a 5 mm port 2 cm medial to the left anterior superior iliac spine, and a 5 mm port laterally on the right side just rostral to the umbilicus, all under direct vision with pneumoperitoneum (two to five minutes); (iii) mobilization of the mesosigmoid and mesorectum from the right side for identification of the left ureter and subsequent intracorporeal division of the vessels (10–20 minutes); (iv) mobilization of the sigmoid and descending colon laterally up to the splenic flexure and medially off Gerota's fascia (10–20 minutes); (v) mobilization of the proximal rectum with division of the rectosigmoid junction with a linear endoscopic stapler (10–12 minutes); (vi) division of the mesorectum at the distal resection site with control of vessels via bipolar cautery or vascular clips (15–25 minutes); (vii) exteriorization of the specimen through a left lower quadrant muscle splitting incision for specimen resection and anvil placement within the proximal colon (15–20 minutes); and (viii) reestablishment of pneumoperitoneum and circular-stapled anastomosis (10–15 minutes). This approach allows the patient to be placed head up for dissection of the flexure at a time when pelvic visualization has already been sacrificed, rather than changing the patient's position during the earlier dissection and losing time with each loss of exposure. If a left colectomy is required then the head up position can be used prior to making the exteriorizing incision that will generally be a short midline at the umbilicus as used for right colectomy (see above). If the sigmoid colon will be used for bladder augmentation or reservoir construction then Step 3 is modified by not dividing the vascular pedicle. The mesenteric mobilization will allow easy reach of the bowel to the pelvis.

Instrumentation for the procedure has been standardized. Reusable ports, graspers, laparoscopic scissors, and cautery (monopolar and bipolar) are used. The fascia at the umbilical port site is approximated around the port via a pursestring suture of 0-polyglycolic acid suture to prevent air leaks. This suture is tied at the end of the case to close the fascial defect. The 12 mm port site is closed with 0-polyglycolic acid suture at the end of the case using a reusable fascial closure instrument. The wound is closed in layers with running 0-polyglycolic acid suture prior to reestablishing pneumoperitoneum. All skin incisions are closed with running subcuticular 4-0 polyglycolic acid suture.

TECHNICAL CAVEAT/TIP

The major pitfalls associated with laparoscopic colectomy are prolonged attempts at performing laparoscopic colectomy despite failure to progress, failure to identify key retroperitoneal structures (particularly the ureter and duodenum), and iatrogenic injuries to viscera.

The steps described above are meant to serve as guidelines for the surgeon to ensure that progress is indeed being made. Failure to identify key structures or to mobilize the bowel safely is an indication that the procedure should be converted to open. The typical conversion rate for major colon resection should be approximately 10%. It is

better to err on the side of safety. Iatrogenic damage to viscera should be a rare event indeed in the hands of an experienced laparoscopic surgeon. Even adherent viscera that must be incised can be repaired laparoscopically; however it is key to observe the operative field at all times to avoid unrecognized damage that then falls out of the visual field. It is also important that the bowel be completely mobilized to allow performance of a tension free anastomosis and to allow the bowel to reach into the pelvis if required for urologic reconstruction.

SUMMARY

- Modified use of colorectal laparoscopic techniques can be employed by urologists for bowel work and reservoir construction.
- Bowel division and reanastomosis is typically performed extracorporeally through a 4 to 6 cm umbilical incision.
- A standardized protocol of preemptive and perigesative analgesia, early feeding, and aggressive ambulation minimizes the risk of postoperative ileus.
- Early in the urologist's experience, teaming up with a laparoscopic colorectal surgeon could allow smooth incorporation of urologic bowel work.

LAPAROSCOPIC URINARY DIVERSION

David Canes, Harrison K. Rhee, and Ingolf Tuerk

Lahey Clinic Medical Center, Institute of Urology, Burlington, Massachusetts, U.S.A.

INTRODUCTION

In an astonishingly short period of time, laparoscopic reconstructive urology has become a feasible option for the experienced laparoscopist. The evolution from purely extirpative laparoscopic procedures to the creation of complex urinary diversions completely intracorporeally has been rapid. As urologists' experience with laparoscopic prostatectomy expanded, the additional control of the vesical pedicles with stapling devices brought laparoscopic radical cystectomy within reach. Subsequent construction of a urinary diversion remains a significant challenge. The past decade has witnessed profound strides in laparoscopic reconstructive urology since 1992 when Parra et al. performed the first laparoscopic cystectomy for recurrent pyocystis in a 27-year-old paraplegic woman who already had an ileocolonic reservoir with a continent stoma created five months earlier. That same year, the first laparoscopic-assisted ileal conduit was reported by Kozminski and Partamian, where a cystectomy was not performed.

Currently, many of the commonly employed urinary diversions have been demonstrated to be technically possible laparoscopically owing to a series of well-designed animal experimental models, followed by clinical experience, increasing facility with intracorporeal suturing techniques, and the continual refinement of laparoscopic instrumentation. The various types of urinary diversions that have been

TABLE 1 ■ Summary of Published Approaches to Selected Urinary Diversions

Cutaneous catheterizable reservoir		✓
Mitrofanoff urinary stoma	✓	✓

Note: A check mark indicates the procedure has been performed either purely laparoscopically or laparoscopic-assisted.

performed laparoscopically can be subdivided into noncontinent urinary diversions (cutaneous ureterostomy, incontinent ileovesicostomy, ileal conduit) and continent urinary diversions (rectosigmoid pouch, catheterizable reservoir, and orthotopic neobladder). Because each of these techniques is in evolution, there is no universally agreed upon technique. Tables 1 and 2 summarize the published approaches to particular urinary diversions to date.

INDICATIONS AND CONTRAINDICATIONS

Following radical cystectomy, and in certain cases for benign conditions, the flow of urine is directed either through a conduit, the so-called noncontinent diversion, or a continent reservoir. The latter includes continent reservoirs with catheterizable stomas in which a low-pressure reservoir is fashioned from a detubularized bowel segment. When the urethra is not involved with cancer, appropriate patients may have a reservoir attached to their native urethra as an orthotopic neobladder. The latter is the gold-standard urinary diversion for patients undergoing radical cystectomy for muscle invasive bladder cancer.

General guidelines for choosing the type of laparoscopic urinary diversion best suited to each patient do not differ from their open surgical indications.

There are technical advantages specific to certain laparoscopic procedures, however, particularly in regards to bowel fixation and ease of suturing. The choice of bowel segment is made with careful consideration of expected metabolic disturbances as they interact with existing medical conditions, as with open surgery.

At all times, sound oncologic principles and the creation of an appropriate urinary diversion suited to the individual patient take precedence. If the surgeon is unable to perform the desired diversion by laparoscopic techniques, open surgery should be employed.

In cases of locally advanced pelvic malignancy, urinary diversion may be indicated without cystectomy. The remainder of patients include those with neurogenic bladder with chronic catheterization, refractory hemorrhagic cystitis, or other conditions in which the bladder may be left in situ while urinary flow is diverted.

Complex reconstructive laparoscopic surgery begins with careful patient selection. In cases where urinary diversion is required following radical cystectomy, exclusion criteria for the cystectomy portion of the procedure will generally dominate the decision process. Common exclusion criteria for laparoscopic surgery in general will apply. Multiple prior abdominal surgeries portend extensive adhesions and usually preclude laparoscopic access; however, on an individual basis, prior surgery is only a relative contraindication. Obesity must also be evaluated in each individual case. For instance, the exact distribution of subcutaneous abdominal fat differs amongst individuals. In cases where the fat is heavily distributed in the lower abdominal and suprapubic regions, excessive traction on trocars to obtain optimal instrument angles may be a limiting factor. As in open surgery, significant obesity may prevent adequate creation of an everted stoma without excessive mesenteric tension. Prior abdominal or pelvic radiation therapy is also a relative contraindication to laparoscopic urinary diversion but may influence the choice of bowel segment.

General guidelines for choosing the type of laparoscopic urinary diversion best suited to each patient do not differ from their open surgical indications.

At all times, sound oncologic principles and the creation of an appropriate urinary diversion suited to the individual patient take precedence. If the surgeon is unable to perform the desired diversion by laparoscopic techniques, open surgery should be employed.

TABLE 2 ■ Important Reports of Laparoscopic Urinary Diversion

Year	Author	n	Case profile	Male/female	Urinary diversion	Specimen retrieval	Complete intracorporeal?	Operative time (hrs)	No. of ports	LOS (day)	Firsts

A: NONCONTINENT URINARY DIVERSIONS

ILEAL CONDUIT

Ileal conduit urinary diversion is commonly employed and has few short-term complications. Initial isolated reports and clinical series describing laparoscopic ileal conduit urinary diversion took advantage of the fact that radical cystectomy specimens are often removed through laparotomy incisions, and therefore used open-assisted or mini-laparotomy techniques.

Kozminski and Partamian performed the first laparoscopic-assisted ileal conduit diversion in 1992. Their procedure did not include a cystectomy. A total of five port sites were used, one of which served as the stoma site. Both ureters were mobilized and transected laparoscopically, whereas isolation of the ileal segment, restoration of small bowel continuity, and bilateral ureteroileal anastomoses were all performed extracorporeally by elevating a small loop of ileum through a port site. The stoma was fashioned last. Operative time was 6 hours and 20 minutes.

Sanchez de Badajoz et al. reported the first laparoscopic combined radical cystectomy and laparoscopic-assisted ileal conduit in 1995 in a 64-year-old woman with high-grade muscle invasive transitional cell carcinoma. Again, an open-assisted approach was used to create the ileal conduit; however, two trocar sites were used to externalize the bowel segment instead of one. The ileal loop was first extracted through an extended right-sided flank incision, where the ileal segment was isolated, bowel continuity was restored, and the ipsilateral ureteroileal anastomosis performed. The contents were then placed back into the peritoneal cavity and brought out a left-sided extended trocar incision for the second ureteroenteric anastomosis. The authors note that their technique requires less mobilized ureteral length, and maintains the ileal segment in a transverse lie. In 1994, the same group reported a case in which no cystectomy was performed for a patient with a solitary left kidney who had previously undergone a partial cystectomy and adjuvant radiotherapy. The single ureteroileal anastomosis was performed through a widened left-sided port site, which also served as the eventual stoma site. Operative time was four hours. Puppo and colleagues reported mini laparotomy at a single stoma site in another four patients following laparoscopically assisted transvaginal radical cystectomy in 1995. In 2002, Peterson and colleagues reported the first case of laparoscopic hand-assisted radical cystectomy with ileal conduit.

They employed four laparoscopic ports and one infraumbilical hand port. Following radical cystectomy, pneumoperitoneum was released and the hand port ring was left in place for skin retraction. The ileal loop was delivered though this incision, and a Wallace ureteroileal anastomosis was subsequently performed. In this particular case, a separate stoma site was created due to an impractical location of their existing right-sided 12-mm port site. Operative time was seven hours, blood loss was 750 mL.

Hemal et al. published their series of 10 patients who underwent laparoscopic radical cystectomy and ileal conduit reconstructed through an infraumbilical incision through which the specimen had been retrieved. A right-sided 12-mm port site was used for the stoma site. Mean operative time was 6.5 hours. They concluded that the extracorporeal reconstruction of the ileal conduit was advantageous in two respects: (1) decreased operative time, and (2) decreased cost, particularly in obviating the need for stapling devices to restore ileal continuity.

Currently, laparoscopic radical cystectomy, bilateral pelvic lymphadenectomy, and ileal conduit can be performed using a mini-lap technique with operative times comparable to open surgery.

Sorcini and Tuerk reported a case in which the operative time was less than five hours. The first two reports of complete intracorporeal techniques for ileal conduit diversion were in 2000 by Potter et al. (without cystectomy) as well as Gill et al. (following radical cystoprostatectomy).

Potter and colleagues performed laparoscopic ileal conduit without cystectomy as a treatment for neurogenic bladder in a 28-year-old man. Five port sites were used, and total operative time was 4.5 hours. With the ileal segment pulled out through the eventual stoma site, a Babcock clamp was negotiated down and through ileotomies, the ureters were pulled into the conduit, and a modified Bernstein anastomosis was performed. The patient had anastomotic edema in the short term, but long-term patency at five years.

Sidebar notes:

Kozminski and Partamian performed the first laparoscopic-assisted ileal conduit diversion in 1992. Their procedure did not include a cystectomy.

Sanchez de Badajoz et al. reported the first laparoscopic combined radical cystectomy and laparoscopic-assisted ileal conduit in 1995 in a 64-year-old woman with high-grade muscle invasive transitional cell carcinoma.

Currently, laparoscopic radical cystectomy, bilateral pelvic lymphadenectomy, and ileal conduit can be performed using a mini-lap technique with operative times comparable to open surgery.

Gill et al. reported the first two cases of completely intracorporeal laparoscopic radical cystoprostatectomy, bilateral pelvic lymphadenectomy, and ileal conduit urinary diversion.

This clinical report was elegantly substantiated first in a porcine model, where the technique was refined in 10 pigs. Preservation of renal function was preserved in surviving animals, and although six animals developed stomal stenosis at the skin, unique healing characteristics of porcine skin were postulated to account for this observation. In their subsequent clinical report in two men, operative times were 11.5 and 10 hours, and blood loss was 1200 and 1000 mL, respectively. A six-port transperitoneal approach was used. The most salient feature of Gill's technique involved initial creation of the stoma, which effectively anchors the external end of the ileal segment, greatly facilitating freehand intracorporeal suturing of the ureteroileal anastomosis. In addition, laparoscopic optical magnification afforded precise mucosa-to-mucosa approximation. Although operative times were lengthy, this important study demonstrated that this complex ablative and reconstructive urologic procedure was feasible laparoscopically. As expected, further experience shortened operative times, and unpublished data mentioned in an accompanying editorial comment suggested that subsequent cases were performed in less than eight hours, and as short as 6.5 hours in one patient.

This was performed in three patients, two with radiation cystitis and one with transitional cell carcinoma. Still early in the learning curve, the mean operative time was 11.5 hours. Mean blood loss was 250 mL. Similar to the technique described by Gill et al., the stoma was created first, and Bricker-type ureteroileal anastomoses were created using the DaVinci robot.

LAP-ASSISTED ILEAL CONDUIT URINARY DIVERSION

At the authors' institution, laparoscopic radical cystoprostatectomy proceeds laparoscopically, while the ileal conduit and stoma are created through a mini laparotomy. Several institutions perform a totally intracorporeal laparoscopic ileal conduit diversion. This technique is described below.

Patient Preparation

Informed consent is obtained with a discussion of risks including but not limited to adjacent organ injury and unrecognized bowel injury. Patients are made aware that safety is paramount, and open conversion may be required for completion of the planned procedure. Patients undergo a full mechanical bowel preparation at home with 4 L of polyethylene glycol one day prior to surgery. Oral antibiotics covering normal intestinal flora are also given. The patient is admitted the morning of surgery. Preoperative antibiotic prophylaxis with a second-generation cephalosporin at induction of anesthesia continues for the first postoperative day. Lower extremity compressive devices are applied. Once general anesthesia is induced, the gastric contents are emptied with a nasogastric tube, which remains in place postoperatively. A 16-French Foley catheter is placed to drain the bladder.

Radical Cystectomy

Radical cystectomy proceeds as described elsewhere. Several specific points deserve attention:

1. *Laparoscopic access*: Pneumoperitoneum is obtained through a standard Veress technique. A primary 10-mm trocar is placed at the umbilicus. An additional four trocars are placed in a fan-shaped distribution. Two 10-mm trocars are placed at the lateral pararectal line 10 cm above the pubic symphysis, and two 5-mm trocars 2–3 cm medial and superior to the anterior-superior iliac spines.
2. *Ureteral dissection*: Ureters are clipped and transected close to their insertion into the bladder. This greatly facilitates subsequent identification and atraumatic laparoscopic manipulation.
3. Two different colored 4-0 Vicryl holding sutures are placed at the distal ends of the ureters.
4. *Vascular pedicle control*: The vascular pedicles of the bladder and prostate are controlled with serial applications of an Endo-GIA laparoscopic stapler.

5. *Specimen retrieval*: Once the bladder is fully excised, it is placed into a laparoscopic retrieval bag. In female patients, the specimen can be retrieved immediately through an opening in the anterior vaginal wall. In male patients, the specimen bag can be placed aside during the next steps of the operation. Once the abdomen is incised for creation of ileal conduit, the specimen can then be removed.

Transposition of Left Ureter

The ureters are dissected for a distance sufficient to reach the proximal end of the loop. Care is taken to preserve periureteral tissue and thus the ureteral vascular supply. The sigmoid colon is retracted superiorly and anteriorly. Blunt dissection is used to develop a tunnel posterior to the sigmoid mesocolon and anterior to the sacrum. The left ureter is passed under the sigmoid colon using the previously placed holding suture. Ureteral length is once again confirmed to assure that both ureters reach the proximal portion of the ileal segment in order to avoid undue tension on the anastomoses. Proximal dissection of the left ureter will provide the further length needed to reach the urinary diversion.

Harvesting Small Bowel

When a right-sided trocar site coincides with the desired stoma site, the trocar site is extended 4.5 cm. When the stoma site is separate from all trocars, a 4.5-cm infraumbilical incision is made. The specimen is retrieved. The color-coded ureteral holding sutures are exteriorized. A 15-cm segment of ileum is selected with care to spare 15–20 cm proximal to the ileocecal junction. The efferent limb should reach the previously marked stoma site without undue tension or mesenteric kinking. The segment of bowel is delivered through the incision and isolated with a GIA stapler by transecting proximally and distally. The mesentery is divided below with care to preserve the major mesenteric vasculature. The isolated segment is dropped posteriorly.

> A previously marked stoma site away from desired trocar sites should not compromise optimal port placement.

A previously marked stoma site away from desired trocar sites should not compromise optimal port placement (Fig. 1).

Restoring Bowel Continuity

The stapled edges of the distal and proximal ileum are removed sharply. Applications of a GIA 55-mm stapler are used to create a side-to-side, functional end-to-end anastomosis along the antimesenteric border of the small bowel. The open end of the anastomosis is then closed using a TA 55-mm stapler. The end staple line is imbricated with interrupted, absorbable suture. The window through the mesentery is then closed with interrupted absorbable suture to prevent internal hernia formation.

Ureteroileal Anastomoses

Gentle traction on the ureteral holding sutures pulls the distal ureters into the operative field. The ureters are gently spatulated for approximately 1 cm. Bilateral ureteral 6-French single "J" stents are passed into the renal pelvis. The ureters are sequentially implanted into the proximal end of the ileal segment in a standard Bricker fashion. The apices are fixed to the bowel using three interrupted 4-0 poliglecaprone sutures. The remainder of the ureteral implantation is performed using a running 4-0 poliglecaprone suture. The proximal end of the ileal conduit is replaced into the abdominal cavity. The ureteral stents are exteriorized through the ileal segment.

Creation of Ileal Stoma

The rectus fascia is partially closed, leaving space through which the conduit passes. The ileal segment is secured to the fascia using interrupted 2-0 polyglactin sutures. The stoma is matured in the standard open fashion.

> In the obese patient, ureteroileal anastomoses performed through an incision may require excessive proximal ureteral mobilization. In these cases, the stoma is matured first, and the ureteroileal anastomoses are performed completely intracorporeally.

Closure and Drains

In the obese patient, ureteroileal anastomoses performed through an incision may require excessive proximal ureteral mobilization. In these cases, the stoma is matured first, and the ureteroileal anastomoses are performed completely intracorporeally.

The ureters and ileal diversion are inspected for any undue tension. Once meticulous hemostasis is assured, a flat Jackson-Pratt drain is placed through a lateral 5-mm trocar site into the small pelvis. The port sites are closed in the usual fashion with fascial closure for all sites 10 mm and greater under direct vision with 0-polyglactin.

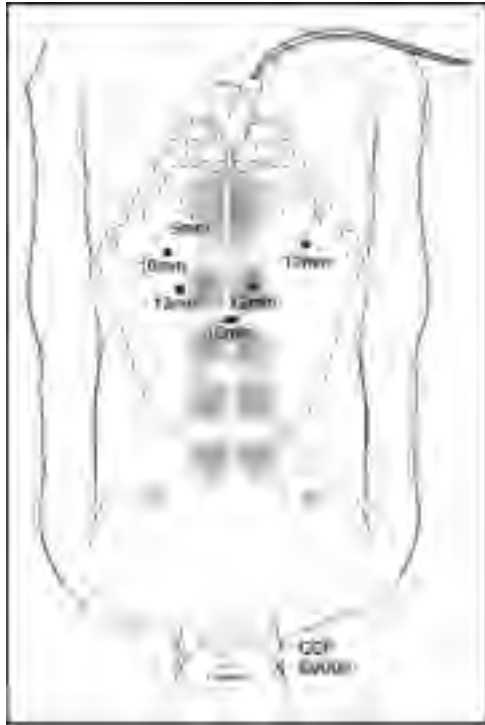
FIGURE 1 ■ Port placement, standard five- or six-port "fan" or "V"-shaped configuration.


FIGURE 2 ■ Stented, bilateral ureteroileal anastomoses and ileal conduit diversion: completion of reconstruction.

Postoperative Period

Postoperative management is as with the comparable open procedure. Patients receive prophylaxis for deep venous thrombosis and ambulation is begun on the first postoperative day. The nasogastric tube is removed once bowel function returns, and the diet is advanced accordingly. The drain is removed once output diminishes. The stents are removed between postoperative days 10 and 12 (as outpatient procedure).

PURE LAPAROSCOPIC ILEAL CONDUIT URINARY DIVERSION

Preoperative preparation and laparoscopic radical cystectomy are performed as described above. The left ureter is transposed to the right side posterior to the sigmoid colon.

Harvesting Small Bowel

A 15-cm segment of ileum is selected with care to spare the distal 15–20 cm proximal to the ileocecal junction. The efferent limb should reach the abdominal wall corresponding to the previously marked stoma site without undue tension or mesenteric kinking. The segment of bowel is isolated with an endoscopic GIA stapler by transecting proximally and distally. The mesentery is divided below these areas with care to preserve the major mesenteric vasculature. Endoscopic staplers, the harmonic scalpel, or serial application of laparoscopic clips can be used to transect the mesentery with complete hemostasis. The isolated segment is dropped posteriorly.

Restoring Bowel Continuity

The stapled edges of the distal and proximal ileum are removed sharply. Applications of an endoscopic GIA stapler are used to create a side-to-side, functional end-to-end anastomosis along the antimesenteric border of the small bowel. The open end of the anastomosis is then closed using an endoscopic TA stapler. The end staple line is imbricated intracorporeally with interrupted, absorbable suture. The window through the mesentery is then closed with interrupted absorbable suture to prevent internal hernia formation.

A previously marked stoma site away from desired trocar sites should not compromise optimal port placement.

Creation of Ileal Stoma

A previously marked stoma site away from desired trocar sites should not compromise optimal port placement (Fig. 1).

The previously marked stoma site is matured in the standard everting fashion. The ileal segment is secured to the fascia using interrupted 2-0 polyglactin sutures.

Ureteroileal Anastomoses

Gentle traction on the ureteral holding sutures pulls the distal ureters to the proximal end of the ileal segment. The ureters are spatulated for approximately 1 cm. Then 6-French single "J" stents are grasped by a laparoscopic right angle clamp, and inserted though the stoma into the conduit lumen. The right angle clamp tents the ileal loop at the desired ileotomy site. A laparoscopic electrosurgical J-hook is used to create the ileotomy and the stent is delivered into the abdominal cavity. The ureters are sequentially implanted in a standard Bricker fashion. The apices are fixed to the bowel using three interrupted 4-0 poliglecaprone sutures. The remainder of the ureteral implantation is performed using a running 4-0 poliglecaprone suture. The stent is passed into the renal pelvis on each side when 80% of the anastomosis is complete (Fig. 2).

Creating the stoma first greatly facilitates intracorporeal suturing of the ureteroileal anastomosis by providing a point of fixation for the ileal segment.

> Creating the stoma first greatly facilitates intracorporeal suturing of the ureteroileal anastomosis by providing a point of fixation for the ileal segment.

Closure and Drains

The ureters and ileal diversion are inspected for any undue tension. The abdominal cavity is irrigated with sterile antibiotic solution. Once meticulous hemostasis is assured, a flat Jackson-Pratt drain is placed through a lateral 5-mm trocar site into the pelvis. The port sites are closed in the usual fashion with fascial closure for all sites 10 mm and greater under direct vision with 0-polyglactin.

Postoperative Period

Postoperative management is as with the comparable open procedure. Patients receive prophylaxis for deep venous thrombosis and ambulation is begun on the first postoperative day. The nasogastric tube is removed once bowel function returns, and the diet is advanced accordingly. The drain is removed once output diminishes. The stents are removed between postoperative days 10 and 12.

Cutaneous Ureterostomy

This technique is covered elsewhere in this book, but is included for the sake of completeness. In patients with advanced bladder cancer or other pelvic malignancy, a palliative urinary diversion such as a cutaneous ureterostomy may be considered as an alternative to percutaneous nephrostomy tube drainage, or where such drainage may be poorly tolerated long term. Patients may be candidates to undergo general anesthesia but comorbidities preclude extensive or prolonged surgery. In other instances, palliative diversion may be advised prior to planned pelvic radiation.

Two studies have reported this procedure laparoscopically. In 1995, Loisides et al. performed a laparoscopic transperitoneal cutaneous ureterostomy on a 59-year-old patient with a solitary functioning kidney. Repeated percutaneous nephrostomy access had exhausted this option, and after successful urinary diversion, dialysis was avoided at 18 months follow-up. In another report, Puppo et al. described their experience with videoendoscopic cutaneous ureterostomy in nine patients, six of which were performed bilaterally. The procedure was performed transperitoneally in five patients, and via a retroperitoneal approach in the remaining four.

Ileovesicostomy

For patients requiring noncontinent urinary diversion with an intact but abnormally functioning bladder, ileovesicostomy is an alternative. Hsu et al. reported a laparoscopic ileovesicostomy performed for a 58-year-old woman with multiple sclerosis and a chronic indwelling catheter. A five-port transperitoneal approach was used. The ileal segment was extruded through an extended infraumbilical port site, harvested, and intestinal continuity was restored extracorporeally. After reintroducing the proximal end into the peritoneal cavity, pneumoperitoneum was re-established and the ileovesical anastomosis was performed from the spatulated ileum to a U-shaped vesicostomy using laparoscopic freehand suturing techniques. A loop stoma was created last, for a total four-hour operative time. Abrahams et al. reported a single case of pure laparoscopic ileovesicostomy in 2003 for a 46-year-old quadriplegic man with neurogenic bladder and recurrent urinary tract infections. Their four-port transperitoneal approach took 4.5 hours. The Endo-GIA stapler was used for ileal segment isolation and restoration of bowel continuity. Freehand suturing was employed for the ileovesical anastomosis; however, there was no bladder or ileal spatulation.

Abrahams and colleagues cite reduced mesenteric tension and bowel manipulation as some of the benefits of pure laparoscopic approach to ileovesicostomy.

> Abrahams and colleagues cite reduced mesenteric tension and bowel manipulation as some of the benefits of pure laparoscopic approach to ileovesicostomy.

B: CONTINENT URINARY DIVERSION

Most patients motivated and healthy enough to undergo an extensive or prolonged laparoscopic procedure will also be those desiring the long-term quality of life benefits of a continent urinary diversion as well as the short-term recovery benefits of a laparoscopic approach.

ORTHOTOPIC NEOBLADDER

From a quality-of-life perspective, orthotopic neobladder is arguably the ideal form of urinary diversion in the appropriate patient. Using either small bowel or sigmoid colon, the orthotopic neobladder is the method of choice for diverting the urine in men and women undergoing radical prostatectomy for muscle invasive transitional cell carcinoma. Increasing facility with the urethroneovesical anastomosis derives directly from experience with laparoscopic radical prostatectomy. The operation is technically demanding and sits on the cutting edge of laparoscopic reconstructive surgery. Kaouk and Gill et al. performed the initial experimental study of laparoscopic orthotopic neobladder in 12 pigs in 2001. They created an ileal neobladder with Studer limb extension, and the entire procedure was performed intracorporeally in all cases. Each of the anastomosis was created with freehand suturing techniques, and none strictured as assessed by both radiographic and postmortem study. Mean operative time was 5.4 hours, with minimal blood loss. Late complications included one port site abscess, and two cases of *Escherichia coli* pyelonephritis causing azotemia in two animals, one of which died at three months.

Gill et al. published the initial two cases of completely intracorporeal laparoscopic radical cystectomy and orthotopic Studer pouch in a 42-year-old woman and 57-year-old man, respectively.

A five-port transperitoneal technique was employed for the cystectomy portion, and a sixth low midline port was added to complete the urinary diversion. Operative times were 8.5 (solitary kidney) and 10.5 hours, respectively, with blood loss from 200 to 400 mL. Specimen retrieval was performed through an extended umbilical port site incision in both cases. Oncologic specimens had pathologically negative margins, and both patients achieved complete daytime continence.

The only other published case of complete intracorporeal orthotopic neobladder following laparoscopic radical cystectomy is from Beecken and colleagues, who performed the procedure with robotic assistance. In this 58-year-old man, a Hautmann ileal neobladder was created, and the entire procedure lasted 8.5 hours. The patient had good oncologic and functional outcomes at five months follow-up.

The remainder of the literature consists of open-assisted approaches to the orthotopic neobladder. Preceded by cadaveric studies, Gaboardi et al. performed a laparoscopic radical cystectomy, pelvic lymphadenectomy, and ileal orthotopic neobladder (U-configuration), in a 72-year-old man for BCG refractory T_1G_3 transitional cell carcinoma. After the cystectomy, specimen was extracted through a 5-cm supraumbilical incision, the ileal segment was isolated extracorporeally, and the neobladder was partially fashioned. They proceeded to perform the ureteroileal and urethroileal anastomoses laparoscopically. Operative time was less than the pure laparoscopic technique previously described, at 7.5 hours. Blood loss was 350 mL and the patient was discharged on postoperative day 7.

Gaboardi et al. made several important observations about combining the advantages of minimally invasive laparoscopy with open surgery, not just with respect to time saved, the ease of bowel transillumination with exteriorization of the ileal segment, and the avoidance of peritoneal soilage during bowel detubularization. Although larger series will be required, the small laparotomy did not seem to negate the advantages of the laparoscopic portion of the procedure.

A report by Abdel-Hakim et al. expanded published experience with a larger series of nine patients who underwent open-assisted laparoscopic orthotopic neobladder following radical cystectomy. Their ileal configuration was a Y-pouch (modified Camey II). The first three patients underwent open ileal exclusion and ileoileal anastomosis via an infraumbilical midline incision. The urethral and ureteral anastomoses were also performed through this incision. As operative times for the cystectomy portion shortened, the extracorporeally prepared Y-pouch was reintroduced for the following six patients, pneumoperitoneum re-established, and the anastomoses were completed laparoscopically. Mean operative time was 8.3 hours. In these patients, a right-sided 12-mm port extension was instead chosen for specimen extraction and neobladder creation.

Similar conclusions have been made regarding the advantages of employing a mini-laparotomy for the reconstruction of the urinary diversion when the primary intracorporeal surgery is robot-assisted.

Menon and colleagues reported 17 patients (14 men, 3 women) who underwent robot-assisted radical cystectomy, with urinary diversion performed through a mini-laparotomy incision. All but three (ileal conduit) had orthotopic neobladders including the W-pouch, double chimney, and T-pouch.

Average operative time for the orthotopic neobladder portion of the procedure was 2.8 hours. The same group later reported robotic radical cystectomy in three more women, two of whom had orthotopic neobladders (W-pouch, T-pouch). The urinary diversion in these two took 190 and 170 minutes. In all 19 cases, isolation of the ileal segment, restoration of bowel continuity, detubularization, and pouch configuration was performed extracorporeally through a limited suprapubic incision.

Finally, as a reminder of the innovative combinations possible amongst techniques, Guazzoni et al. performed an open-assisted orthotopic W-shaped neobladder in three patients. Following laparoscopic cystectomy, bowel exclusion, restoration of bowel continuity, pouch construction, and ureteroileal anastomoses were performed open through a 7-cm periumbilical incision. For the remainder of the procedure, including urethroneovesical anastomosis, this incision was converted to a hand port. Mean operative time was 7.4 hours.

Although the choice of a particular neobladder configuration assumes less importance for an open-assistance technique, the particular choice of ileal pouch assumes greater importance when the reconstruction occurs purely laparoscopically. The Studer neobladder is a practical choice in this regard. This remains an assumption, as Gill et al. and Beecken have reported the only cases of purely laparoscopic orthotopic neobladder (Studer pouch and Hautmann neobladder, respectively).

LAP-ASSISTED ORTHOTOPIC ILEAL NEOBLADDER

At the authors' institution, laparoscopic radical cystoprostatectomy proceeds laparoscopically, while the ileal neobladder is created through a mini laparotomy. Others perform a totally intracorporeal laparoscopic neobladder. This technique is also described.

Patient Preparation

Informed consent is obtained with a discussion of risks including but not limited to adjacent organ injury and unrecognized bowel injury. Patients are made aware that safety is paramount, and open conversion may be required for completion of the planned procedure. Patents undergo a full mechanical bowel preparation with oral antibiotics covering normal intestinal flora on the day prior to surgery. Preoperative antibiotic prophylaxis with an intravenous second-generation cephalosporin is given at induction of anesthesia and continues for the first postoperative day. Lower extremity compressive devices are applied. Once general anesthesia is induced, the gastric contents are emptied with a nasogastric tube, which remains in place postoperatively.

Radical Cystectomy

Radical cystectomy proceeds as described elsewhere. Several specific points deserve attention:

1. *Laparoscopic access*: Pneumoperitoneum is obtained through a standard Veress technique. A primary 10-mm trocar is placed at the umbilicus. An additional four trocars are placed in a fan-shaped distribution. Two 10-mm trocars are placed at the lateral pararectal line 10 cm above the pubic symphysis, and two 5-mm trocars 2–3 cm medial and superior to the anterior-superior iliac spines.
2. *Ureteral dissection*: Ureters are clipped and transected close to their insertion into the bladder. This greatly facilitates subsequent identification and atraumatic laparoscopic manipulation.

3. Two different colored 4-0 Vicryl holding sutures are placed at the distal ends of the ureters.
4. *Vascular pedicle control*: The vascular pedicles of the bladder and prostate are controlled with serial applications of an Endo-GIA laparoscopic stapler.
5. *Specimen retrieval*: Once the bladder is fully excised, it is placed into a laparoscopic retrieval bag. Once the abdomen is incised for creation of neobladder, the specimen can then be removed.

Transposition of Left Ureter

The ureters are dissected proximally for a length sufficient to reach the proximal end of the ileal segment. Care is taken to preserve periureteral tissue and thus the ureteral

vascular supply. The sigmoid colon is retracted superiorly and anteriorly. Blunt dissection is used to develop a tunnel posterior to the sigmoid mesocolon and anterior to the sacrum. The left ureter is passed under the sigmoid colon using the previously placed holding suture. Ureteral length is once again confirmed to assure that both ureters reach the proximal portion of the ileal segment in order to avoid undue tension on the anastomoses.

Harvesting Small Bowel

When a right-sided trocar site coincides with the desired stoma site, the trocar site is extended 4.5 cm. The specimen is retrieved. The color-coded ureteral holding sutures are identified. A 65-cm segment of ileum is selected with care to spare the 15–20 cm proximal to the ileocecal junction. The mid-portion of the segment should reach the urethral stump without undue tension or mesenteric kinking. The segment of bowel is delivered through the incision and isolated with a GIA stapler by transecting proximally and distally. The mesentery is divided below with care to preserve the major mesenteric vasculature. The isolated segment is dropped posteriorly.

Restoring Bowel Continuity

The stapled edges of the distal and proximal ileum are removed sharply. Applications of a GIA 55 mm are used to create a side-to-side, functional end-to-end anastomosis along the antimesenteric border of the small bowel. The open end of the anastomosis is then closed using a TA 55-mm stapler. The end staple line is imbricated with interrupted, absorbable suture. The window through the mesentery is then closed with interrupted absorbable suture to prevent internal hernia formation.

Creation of Neobladder

This portion of the procedure continues extracorporeally. The staple lines are removed and the lumen of the bowel is cleansed using a suction–irrigation device. Care is taken to preserve the proximal 10 cm as a Studer limb. The remainder of the segment is incised along its antimesenteric side using monopolar electrocautery. The posterior plate of the neobladder is created by suturing the medial edges of the detubularized bowel in a running fashion with 2-0 polyglactin such that the bowel forms a "J" configuration.

The anterior plate of the neobladder is closed using another running 2-0 polyglactin suture. The anterior enterotomy is left open for approximately 3 cm at its inferior most portion in order to create the urethroneovesical anastomosis.

The neobladder is reintroduced into the abdominal cavity. The lower midline incision is closed using a 0- polyglactin suture, penumoperitoneum is re-established, and the camera is replaced. The urethroneovesical anastomosis is performed intracorporeally.

Urethroneovesical Anastomosis

The most dependent portion of the detubularized ileum is identified and brought down to the urethral stump. The mesentery is confirmed to be without kinks or undue tension. If addition length is needed, the mesenteric division can be carefully extended.

The anastomosis is started at the 6 o'clock position with two running 2-0 poliglecaprone sutures in a parachute fashion and extended to the 12 o'clock position on either side. The sutures are then tied to each other. Once the anastomosis is finished, a 22-French Foley catheter is placed.

Ureteroneovesical Anastomoses

The following two options are available: (i) Reopen the infraumbilical incision, deliver the Studer limb extracorporeally, and perform the anastomosis in an open fashion. (ii) Particularly in obese patients, bilateral anastomoses are performed completely intracorporeally (see later).

In the former case, gentle traction on the ureteral holding sutures pulls the distal ureters into the operative field. The ureters are spatulated for approximately 1 cm. Bilateral ureteral 6-French single "J" stents are passed into the renal pelvis. The stents are exteriorized through the wall of the neobladder and then through one of the lateral 5 mm port sites. The ureters are sequentially implanted into the proximal portion of the ileal segment in a standard Bricker fashion. The apices are fixed to the bowel using three interrupted 4-0 poliglecaprone sutures. The remainder of the ureteral implantation is performed using a running 4-0 poliglecaprone suture. The Studer limb is replaced into the abdominal cavity. The ureteral stents are drawn through separate ileotomies in the neobladder wall and are exteriorized through the lateral 5 -mm port sites.

Closure and Drains

The ureters and neobladder are inspected in situ. Once meticulous hemostasis is assured, a flat Jackson-Pratt drain is placed through a lateral 5-mm trocar site into the small pelvis. The port sites are closed in the usual fashion with fascial closure for all sites 10 mm and greater under direct vision with 0-polyglactin.

Postoperative Period

Postoperative management is as with the comparable open procedure. Patients receive prophylaxis for deep venous thrombosis and ambulation is begun on the first postoperative day. The nasogastric tube is removed once bowel function returns, and the diet is advanced accordingly. The drain is removed once output diminishes. The stents are removed between postoperative days 10 and 12. The Foley catheter is removed one day after stent removal.

PURE LAPAROSCOPIC ORTHOTOPIC ILEAL NEOBLADDER

Preoperative preparation and laparoscopic radical cystectomy are performed as previously described. The left ureter is transposed to the right side posterior to the sigmoid colon.

Harvesting Small Bowel

A 65-cm segment of ileum is selected with care to spare the distal 15–20 cm proximal to the ileocecal junction. The mid portion of the segment should reach the urethral stump without undue tension or mesenteric kinking. The ileum is isolated with an endoscopic GIA stapler by transecting proximally and distally. The mesentery is divided below these areas with care to preserve the major mesenteric vasculature. Endoscopic staplers, the harmonic scalpel, or serial application of laparoscopic clips can be used to transect the mesentery with complete hemostasis. The isolated segment is dropped posteriorly.

Restoring Bowel Continuity

The stapled edges of the distal and proximal ileum are removed sharply. Applications of an endoscopic GIA stapler are used to create a side-to-side, functional end-to-end anastomosis along the antimesenteric border of the small bowel. The open end of the anastomosis is then closed using an endoscopic TA stapler. The end staple line is imbricated intracorporeally with interrupted, absorbable suture. The mesenteric window through the mesentery is closed with interrupted absorbable suture to prevent internal hernia formation.

Creation of Neobladder

The staple lines are removed and the lumen of the bowel is cleansed using a suction—irrigation device. Care is taken to preserve the proximal 10 cm as a Studer limb. The remaining 55 cm is incised along its antimesenteric side using monopolar electrocautery, endoshears, and/or harmonic scalpel. The posterior plate of the neobladder is created by suturing the medial edges of the detubularized bowel in a running fashion with 2-0 polyglactin such that the bowel forms a "J" configuration (Fig. 3A).

Urethroneovesical Anastomoses

The anterior plate of the neobladder is partially closed using another running 2-0 polyglactin suture. Before completion of the anterior wall, both ileoureteral stents are delivered into the Studer limb and retrieved into the peritoneal cavity through two separate ileotomy incisions at the proposed site of ureteroneovesical anastomoses. The anterior enterotomy is left open at its inferior-most portion in order to create the urethroneovesical anastomosis.

The most dependent portion of the ileal plate is delivered to the urethral stump. The anastomosis is started at the 6 o'clock position with two running 2-0 poliglecaprone sutures in a parachute fashion and extended to the 12 o'clock position on either side. The sutures are then tied to each other. Once the anastomosis is finished, a 22-French Foley catheter is placed (Fig. 3B)

Ureteroneovesical Anastomoses

Gentle traction on the ureteral holding sutures pulls the distal ureters into the operative field. The ureters are spatulated for approximately 1 cm. Bilateral ureteral 6-French single "J" stents are passed into the renal pelvis. The stents are exteriorized through the wall of the neobladder and then through one of the lateral 5-mm port sites. The ureters are sequentially implanted into the proximal portion of the ileal segment in a standard Bricker fashion. The apices are fixed to the bowel using three interrupted 4-0 poliglecaprone

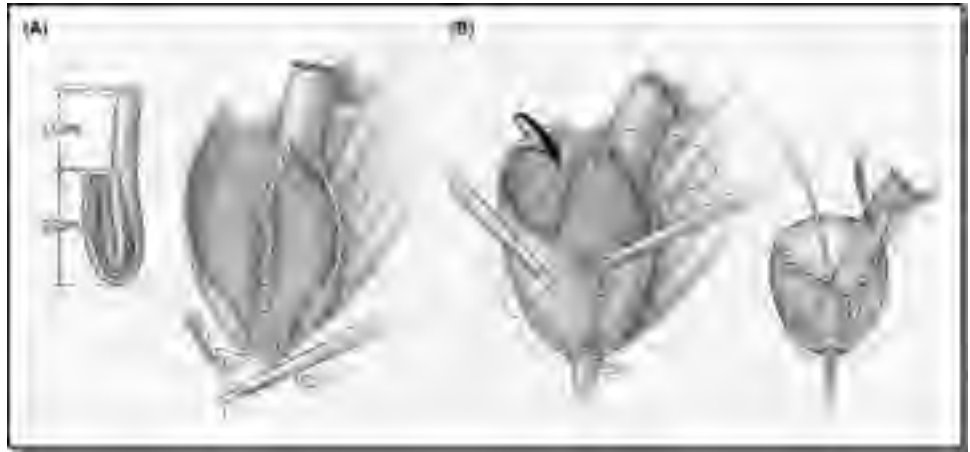
FIGURE 3 ■ (A) Completed posterior neobladder plate and suturing of urethro-neovesical anastomosis. (B) Anterior suture line and completed neobladder with drains.


FIGURE 4 ■ Completed neobladder in the pelvis.
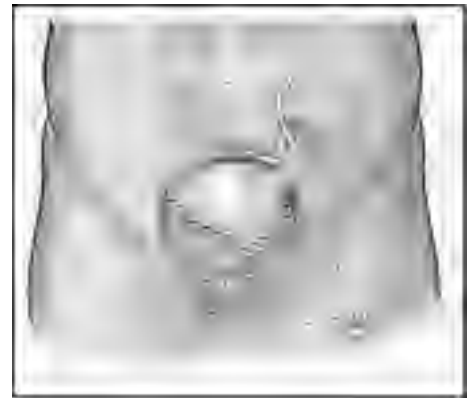


sutures. The remainder of the ureteral implantation is performed using a running 4-0 poliglecaprone suture (Figs. 3B and 4).

Closure and Drains

The ureters and ileal neobladder are inspected in situ for any undue tension. Once meticulous hemostasis is assured, a flat Jackson-Pratt drain is placed through a lateral 5-mm trocar site into the small pelvis. The port sites are closed in the usual fashion with fascial closure for all sites 10 mm and greater under direct vision with 0-polyglactin.

Postoperative Period

Postoperative management is as with the comparable open procedure. Patients receive prophylaxis for deep venous thrombosis and ambulation is begun on the first postoperative day. The nasogastric tube is removed once bowel function returns, and the diet is advanced accordingly. The drain is removed once output diminishes. The stents are removed between postoperative days 10 and 12. The Foley catheter is removed one day following stent removal.

Rectosigmoid Pouch

The rectosigmoid pouch (Mainz Pouch II), first described by Fisch et al. in 1993, is distinct from the largely abandoned ureterosigmoidostomy. Serious hyperchloremic metabolic acidosis, recurrent pyelonephritis, renal calculi, and the development of secondary malignancies at the anastomosis were responsible for aversion to the classic ureterosigmoidostomy. For the Mainz II pouch, the bowel is left in continuity, the colon is detubularized along its antimesenteric border proximal and distal to the rectosigmoid junction, and a pouch is created using a side-to-side anastomosis. The pouch is fixed to the sacral promontory, and a competent anal sphincter provides the continence mechanism. Fisch demonstrated in a series of 47 patients that a low-pressure system is achieved, and all but one patient was continent day and night.

This option is particularly well suited for patients with contraindications to urethral anastomosis, precluding safe creation of an orthotopic neobladder.

The Mainz II pouch is a well-accepted alternative in women in Europe, the Middle East, and North Africa. Contraindications to the rectosigmoid pouch include: (i) incompetent anal sphincter, (ii) distal colonic disease (polyps, diverticuli), (iii) prior radiation, and (iv) planned radiation.

In 2000, Tuerk et al. were the first to report laparoscopic radical cystectomy with rectosigmoid pouch entirely intracorporeally in five patients.

The Mainz II pouch is a well-accepted alternative in women in Europe, the Middle East, and North Africa. Contraindications to the rectosigmoid pouch include: (i) incompetent anal sphincter, (ii) distal colonic disease (polyps, diverticuli), (iii) prior radiation, and (iv) planned radiation.

In a porcine model, Trinchieri et al. described the first experimental laparoscopic construction of a ureterosigmoidostomy. An antirefluxing ureteroileal anastomosis was created along the taenia coli. In 1995, Anderson and colleagues performed laparoscopic rectosigmoid pouch continent urinary diversion in 10 pigs. In this series, pouch creation and bilateral ureteral anastomoses were performed extracorporeally. Mean operative time was 122 minutes, and the pouches performed well (maximal pressure <20 cmH$_2$O, capacity 360 cm^3). They had disappointing results, however, with regard to calculi formation on exposed titanium staple line, as well as ureteroenteric anastomotic strictures. In order to test ureteral anastomotic techniques, the authors performed different techniques on each side. The right ureteral anastomosis used an antirefluxing "dunk" technique where 1 cm of distal ureter is passed though an enterotomy and the ureteral adventitia is tacked to the bowl serosa externally. Postoperatively, 11% of these became obstructed. The left ureter was anastomosed in a simple end to side fashion, and 33% of these stenosed. No stents were used in either case.

Denewer et al. employed the same technique in a clinical series of 10 patients. After completing the cystectomy, an 8 cm infraumbilical mini-laparotomy was used to perform a side-to-side sigmoid pouch (stapling technique) with an intussuscepted antireflux valve. Mean operative time was 160 minutes for the laparoscopic portion and 55 minutes for the continent pouch. The staple line was not assessed postoperatively for stone formation.

In 2000, Tuerk et al. were the first to report laparoscopic radical cystectomy with rectosigmoid pouch entirely intracorporeally in five patients. Mean operative time was 7.4 hours, with average blood loss of 245 mL. All patients were discharged postoperatively by day 10, and all reported complete daytime and night time continence. The pouch was constructed using absorbable suture in lieu of stapling to avoid the risk of staple line stone formation. The distinct advantage of this technique over open-assisted counterparts is transanal specimen retrieval following bowel detubularization, or via the opened vagina in women, avoiding an abdominal incision. Furthermore, the sigmoid and rectum have posterior attachments that keep them still and facilitate laparoscopic suturing. The length of suture lines is also significantly less than for an ileal neobladder.

Concerns over carcinogenesis warrant specific attention in this context. Atta described the preliminary results in 15 patients with a detubularized ureterosigmoidostomy and demonstrated that patients passed urine and feces separately. Although the reservoir described by Atta differs slightly from the Mainz II, in that the detubularization extends to the rectal ampulla and the left colon orifice is fixed in continuity with the posterior wall of the rectal ampulla. However, our clinical experience has shown that many patients with the Mainz II pouch report separate passage of urine and feces as well. The risk of interval development of adenocarcinoma, therefore, is theoretically lower. Surveillance pouchoscopy should still be employed until more data are available.

LAPAROSCOPIC MAINZ II POUCH (SIGMA-RECTUM POUCH)

Patient Preparation

Prior to creation of a rectosigmoid pouch, anal continence should be assured. The sphincteric mechanism is tested by instilling 250 mL of fluid into the rectum. The patient must hold this for 2 to 3 hours. Preoperative sigmoidoscopy is performed to exclude colonic disease including polyposis and diverticulosis. Informed consent is obtained with a discussion of risks including but not limited to adjacent organ injury and unrecognized bowel injury. Patients are made aware that safety is paramount, and open conversion may be required for completion of the planned procedure. Patients undergo a full mechanical bowel preparation and oral antibiotics covering normal intestinal flora are given on the day prior to surgery. Preoperative antibiotic prophylaxis with an intravenous second-generation cephalosporin is given at induction of anesthesia and continues for the first postoperative day. Lower extremity compressive devices are applied. Once general anesthesia is induced, the gastric contents are emptied with a nasogastric tube, which remains in place postoperatively. The legs are gently abducted and a 26-French rectal tube is placed.

Radical Cystectomy

Radical cystectomy proceeds as described elsewhere. Several specific points deserve attention:

1. *Laparoscopic access*: Pneumoperitoneum is obtained through a standard Veress technique. A primary 10-mm trocar is placed at the umbilicus. An additional four trocars are placed in a fan-shaped distribution. Two 10-mm trocars are placed at the lateral pararectal line 10 cm above the pubic symphysis, and two 5-mm trocars 2–3 cm medial and superior to the anterior-superior iliac spines.
2. *Ureteral dissection*: Ureters are clipped and transected close to their insertion into the bladder. This greatly facilitates subsequent identification and atraumatic laparoscopic manipulation.
3. *Vascular pedicle control*: The vascular pedicles of the bladder and prostate are controlled with serial applications of an Endo-GIA laparoscopic stapler.
4. *Specimen retrieval*: Once the bladder is fully excised, it is placed into a laparoscopic retrieval bag. Once the colon is incised for creation of rectosigmoid pouch, the specimen can then be removed through the anus.

Creation of Sigmoid Pouch

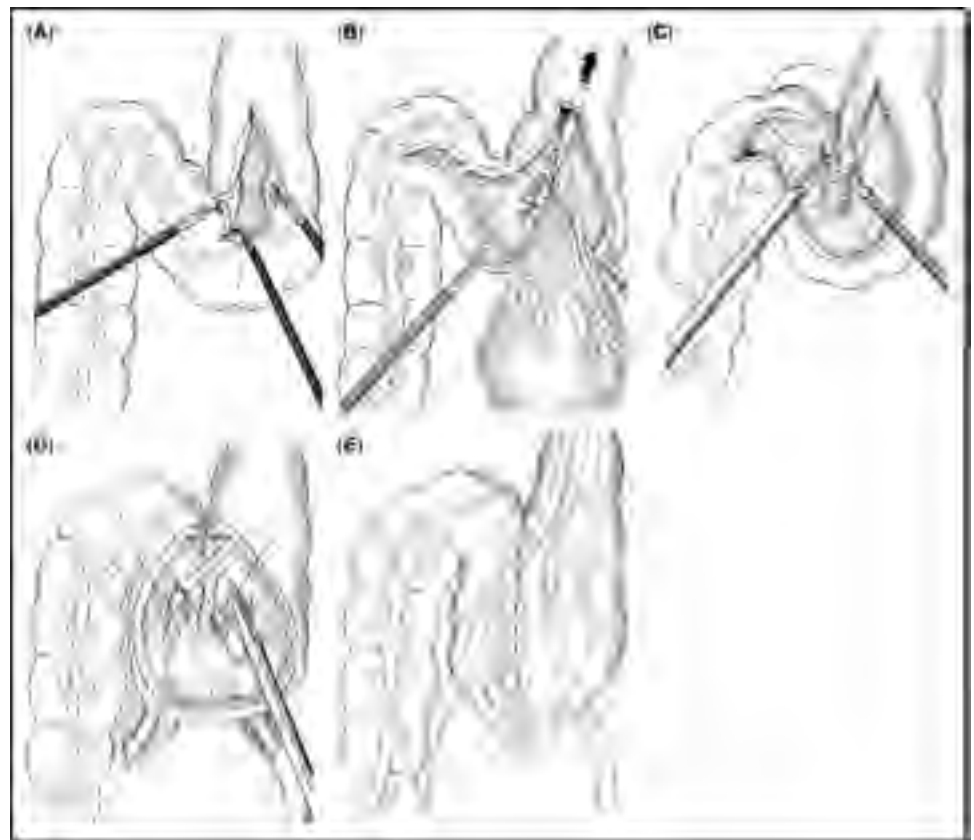
The lateral attachments of the sigmoid colon are dissected free to allow for limited manipulation. The amount of dissection required for the cystectomy portion of the procedure usually allows enough mobility. The sigmoid colon is then incised along its antimesenteric borders using a monopolar hook electrocautery. Individual anatomic variations determine the distal extent of the detubularizing incision. Care is taken to insure that the length of distal incision will correspond to the proximal incision once the pouch is created. The specimen bag is now removed transanally. The posterior walls of the sigmoid colon are anastomosed intracorporeally using a running 3-0 polyglyconate suture. This forms the posterior plate of the pouch.

Native sigmoid fixation facilitates intracorporeal suturing (Fig. 5).

Native sigmoid fixation facilitates intracorporeal suturing.

Ureteral Reimplantation

The ureters are carefully spatulated along their anterior surface for 1 cm. Two incisions are made through the posterior wall of the sigmoid to accommodate the left and right

FIGURE 5 ■ (A) Antimesenteric incision starting at rectosigmoid junction. (B) Transanal specimen retrieval in endoscopy bag. (C) Side-to-side anastomosis of posterior wall of pouch. (D) Submucosal ureteral implantation. (E) Completed ureterosigmoid diversion.


ureters. The incisions are made such that each ureter has approximately 3 cm of length in the pouch for the creation of submucosal tunnels. The submucosal tunnels are created sharply in a superior to inferior fashion. The ureters are pulled through the neo-orifices and secured with a single 4-0 polyglecaprone suture. Eight French monopigtail stents are placed into each ureter and externalized through the anus. The distal margins of each ureter are anastomosed to the sigmoid mucosa using a combination of interrupted and running 4-0 polyglyconate suture. The sigmoid mucosa is then closed over the distal segments of the ureters using running 4-0 polyglyconate suture.

Closure and Drains

The anterior edges of the sigmoid pouch are anastomosed using a running 3-0 polyglyconate suture. The 26 French rectal tube is used to instill 250 mL of sterile normal saline to check for any large leak from the pouch. Figure-of-eight interrupted 3-0 polyglyconate sutures reinforce any areas of leak. Once hemostasis is assured, a single Jackson-Pratt drain is placed into the pelvis through one of the lateral 5-mm trocar sites. Hemostasis is verified, and trocars are removed under direct vision. The port site incisions are closed in the normal fashion with deep fascial sutures for all port sites greater than or equal to 10 mm diameter.

Postoperative Period

Patients receive prophylaxis for deep venous thrombosis, and early ambulation is encouraged. The nasogastric tube is removed once bowel function returns, and diet is then advanced. The Jackson-Pratt drain is removed once output remains minimal. The ureteral stents are removed on postoperative day 8 and the rectal tube is removed on postoperative day 9.

Continent Catheterizable Stomal Reservoirs

When continent catheterizable stomal reservoirs is desired, preoperative preparation and patient selection parallels that of their open counterparts. First and foremost, patients must be motivated and intact cognitively and physically, without restrictions imposed by neurologic injury or neurodegenerative disorders that would impair coordination necessary for clean intermittent catheterization.

Mitrofanoff Urinary Stoma

Many of the reports of appendicovesicostomy urinary diversion are found in the pediatric population, and are comprised largely of lap-assisted procedures affording initial appendiceal and cecal mobilization, followed by lower abdominal incisions for urinary reconstruction. Jordan and Winslow, who performed the procedure in a 15-year-old girl with bilateral ectopic ureteroceles and an obliterated bladder neck, described laparoscopic appendicovesicostomy in 1993. Open assistance was required to fashion the appendiconeocystostomy. Van Savage and Slaughenhoupt later described a similar lap-assisted approach to appendicovesicostomy in three obese women, with laparoscopic mobilization of the appendix and right colon, and a Pfannensteil incision for construction of the urinary diversion. Hedican et al. described the use of laparoscopy in eight patients (mean age, 13.4 years) requiring either an ileal or appendiceal Mitrofanoff, with or without an antegrade continent enema in eight patients with neurogenic bladder and bowel. A lower abdominal incision was used for part of the reconstructive procedure. Cadeddu and Docimo reported a similar series of 11 pediatric patients with neurogenic bladder and bowel in 1999, where laparoscopic-assisted approach was again utilized. A continent urinary diversion was created in seven of these patients through a Pfannenstiel or low midline incision, including appendiceal, tapered ileal, or sigmoid Mitrofanoff urinary stoma positioned at the umbilicus.

The first two completely intracorporeal case reports of laparoscopic appendicovesicostomy were reported almost simultaneously. In April 2004, Pedraza et al. reported their success with the DaVinci robotic system, with a four-port transperitoneal approach. Although total operative time was six hours, the anastomosis took 25 minutes. The patient was discharged on postoperative day 4. One month later, Casale and colleagues reported the feasibility of pure laparoscopic appendicovesicostomy. The case involved a four-year old girl with the VATER malformation and associated neurogenic bladder. A four-port transperitoneal approach was also used; total operative time was 198 minutes, and the patient was discharged home on the third postoperative day.

Other Procedures

Pomel and Castaigne recently reported laparoscopic hand-assisted Miami pouch in a 45-year-old woman following anterior pelvic exenteration. The initial cervical cancer invaded into the bladder. The patient underwent combined chemotherapy and radiation, resulting in total incontinence secondary to a vesicovaginal fistula, with residual local disease. A five-port transperitoneal approach was used, and following anterior pelvic exenteration the right colon, terminal ileum, and cecum were mobilized laparoscopically. The Miami pouch was created though a 4-cm mini laparotomy incision. The ileal conduit portion was sutured to the umbilicus. Total operative time was six hours.

Gill and coworkers reported a laparoscopic radical cystectomy and Indiana pouch urinary diversion with a continent, catheterizable stoma. Orthotopic neobladder was not advised due to prostatic urethral tumor involvement. The pouch was created extracorporeally by exteriorizing the ileocecal segment through a 2–3 cm extension of a right pararectus port incision. In contrast to open-assisted techniques for ileal conduit urinary diversions in which the ureters are commonly delivered through the incision with the bowel segment to perform the anastomosis, the pouch was reintroduced into the abdomen and subsequent ureteroileal anastomoses were performed intracorporeally. The continent stoma was created at the umbilicus. Total operative time was seven hours with 300 mL blood, and the patient was discharged after six days.

> There is little doubt, considering the technical feasibility of a wide range of techniques that have been demonstrated, that the laparoscopic or open-assisted approach will be extended to the many variations of cutaneous continent urinary diversions not mentioned herein.

There is little doubt, considering the technical feasibility of a wide range of techniques that have been demonstrated, that the laparoscopic or open-assisted approach will be extended to the many variations of cutaneous continent urinary diversions not mentioned herein.

FUTURE DIRECTIONS

Considerable progress has taken place in the short time since Parra's simple cystectomy in 1992 to the complex reconstructive laparoscopy of today. Advances in this arena are a true testimony to the logical and elegant progression from the porcine and cadaveric technical models to the initial clinical cases. Small series of laparoscopic urinary diversion have shown acceptable functional outcomes, which need to be substantiated by larger published series with long-term follow-up. We are no longer exploring the feasibility of these complex laparoscopic procedures, but rather refining the techniques in order to decrease operative time.

> The debate between pure laparoscopy and open assistance continues.

The debate between pure laparoscopy and open assistance continues. Those groups who have demonstrated the feasibility of pure laparoscopic techniques have truly pushed the frontiers further than previously imagined. As is often the case, giant leaps hasten the acceptance of small strides. Even if these "laparoscopic-only" approaches do not become common practice, these innovative groups have made the broader community receptive to laparoscopic-assisted approaches, which have become increasingly widespread.

Considering the innovation we have recently witnessed, it is easy to envision that in the near future, laparoscopic reconstructive techniques will catch up to open surgery. Will we then avert the entire debate? In the near future, further experience with free-hand suturing and refined intracorporeal anastomotic and reconstructive suturing technology will allow complex reconstructions to be performed as quickly as with open surgery. Then the choice between open assistance and pure laparoscopy will become one of surgeon preference rather than an issue of technical complexity and decreased operative time. Existing reviews of this topic have recognized that continued refinement of laparoscopic dissolvable staples is one example of a device that would bring us a step further in that direction. Furthermore, robotic surgery has already enhanced the surgeon's performance by simplifying complex maneuvers. Robotic technology therefore holds great promise and potential to effortlessly facilitate the dexterity and flexibility of open surgery. This field will continue to narrow the time gap between open and laparoscopic surgery.

Currently, this technical debate exists within the walls of specialized academic centers. It is clear that the next challenge will be to extend experience into the broader urologic community. In the near future, open-assisted laparoscopic urinary diversion is likely to be the technique of choice to facilitate this transition.

SUMMARY

- The benefits of laparoscopic surgery are well recognized, but few have been subjected to rigorous scientific analysis.
- The theoretical benefits to patients of decreased insensible losses and subsequent early postoperative fluid shifts and fewer instances of ileus as a consequence of less direct bowel manipulation with the laparoscopic approach await scientific substantiation.
- Small clinical series have shown comparable functional and oncologic outcomes for radical cystectomy and urinary diversion between the open and laparoscopic approaches. We eagerly await the results of larger series with long-term follow-up.
- Feasibility of these complex laparoscopic procedures has already been established. Technical refinements are ongoing in order to decrease operative time and increase efficiency.
- The debate between pure laparoscopic and open-assisted procedures to perform urinary diversion continues.

COMMENTARY

John P. Stein

Department of Urology, Keck School of Medicine of the University of Southern California, Los Angeles, California, U.S.A.

This is a well-written, comprehensive chapter on laparoscopy and reconstructive urology as it applies to urinary diversion. As with any laparoscopic technique or application, the astute surgeon recognizes that the laparoscopic approach should mimic the open procedure regarding the basic principles and fundamentals of surgery. The authors maintain this surgical philosophy throughout the chapter. Several important concepts of this chapter regarding laparoscopic urinary diversion must be emphasized.

It appears that laparoscopic urinary diversion is a reasonable option for the "experienced laparoscopist." With improvements in laparoscopic instrumentation

along with increased experience and skill level in intracorporal suturing, a greater number of surgeons will be able to perform laparoscopic forms of urinary diversion. However, it must be emphasized that lower urinary tract reconstruction can even be technically challenging open operations and must not be underestimated, particularly from a laparoscopic perspective. These procedures require an experienced and dedicated laparoscopic surgeon.

The authors appropriately state that a particular surgeon's confidence level with the urinary diversion technique (open or laparoscopic) should not dictate the decision process. Rather, the oncologic principles, patient selection, and patient preference should be the guiding factors. Proper informed consent for all forms of urinary diversion is mandatory. This consent process will collectively allow the patient and physician to make a well-informed decision regarding the form of urinary reconstruction that is best suited for that particular individual.

The ureteral dissection and manipulation is an important step in urinary diversion. The authors comment on atraumatically handling the ureter with holding sutures. This is critical, as the ureter should never be handled with pickups forceps, which could jeopardize the delicate blood supply. Although not specifically addressed in the chapter, the harvesting of the ureter is also an important component. Maintaining the lateral vascular supply emanating from the gonadal vessels is important to prevent ischemia to the distal ureter and will help reduce issues of ureterointestinal strictures. This is particularly important in patients who have received previous radiation therapy to the pelvis.

Regarding the ileal conduit, the authors emphasize on creating the stoma initially which anchors the ileal segment and facilitates intracorporal suturing of the ureterointestinal anastomosis. In addition, the authors that the proximal and distal ends of the ileal conduit are transected with the GIA stapler. However, if there remain exposed staples to the urinary constituents, this may lead to the development of conduit stone formation in the future. It may be best to simply exclude the proximal staple line with an absorbable suture.

I read with great interest on the authors' technique regarding radical cystectomy and orthotopic diversion. Although not specifically mentioned, there is a growing body of data and sound evidence to suggest that a properly performed lymphadenectomy is an important component of the surgical procedure and the long-term outcomes of patients with high-grade, invasive bladder cancer. The consideration of a more extended lymphadenectomy particularly in high-risk patients with bladder cancer is important. Furthermore, from a technical perspective, when performing a radical cystectomy for bladder cancer, care should be taken to avoid spilling any bladder contents during the procedure, which could ultimately lead to tumor spill and possibly a local recurrence, which generally is a lethal event.

The authors provide the background and technical description of laparoscopy-assisted and pure laparoscopic orthotopic neobladder reconstruction. The authors appropriately comment that orthotopic diversion "sits on the cutting-edge of laparoscopic reconstructive surgery." The laparoscopy-assisted technique is facilitated with a minilaparotomy for neobladder construction. It is clear that pure laparoscopic orthotopic reconstruction is technically more challenging and requires an experienced laparoscopist to perform. It may be advisable that surgeons interested in orthotopic laparoscopic urinary diversion start with the laparoscopy-assisted approach prior to embarking on the pure laparoscopic procedures.

The indications and technique of the rectosigmoid urinary diversion are also well described by the authors in this chapter. This form of lower urinary tract reconstruction is more commonly performed in European countries were orthotopic diversion remains controversial in women. It is my belief, however, that in the properly selected female individuals, the orthotopic neobladder is the urinary diversion of choice and provides excellent functional results. It is emphasized that all patients requiring cystectomy should be properly informed of the various forms of lower urinary tract reconstruction.

The future application of laparoscopy and urinary diversion will continue to grow. I believe laparoscopic techniques must attempt to mimic the open techniques with regard to surgical and oncologic principles. With improvements in technique, equipment, and instrumentation, along with the evolution of robotic technology,

I believe this field will continue to grow. Furthermore, it is clear that a greater number of surgeons are performing laparoscopic surgery and, with more experience, some of the more difficult reconstructive procedures will be more commonly performed with this approach. I believe it will be the dedicated laparoscopist who intensely focuses in this surgical approach who will develop the laparoscopic experience and expertise to perform and improve upon the various forms of urinary diversion. The laparoscopic surgeon must have an understanding of the history and general principles of lower urinary tract reconstruction as well as the anatomical approach that is critical to ensuring the optimal clinical and oncologic outcomes in patients requiring urinary diversion. Incredible strides have been made in the field of laparoscopy over the past 15 years and it appears that these improvements will continue to evolve with time in their application to urinary diversion.

COMMENTARY

Urs E. Studer
Department of Urology, University of Bern,
Bern, Switzerland

This is an impressive overview on how fast literally every form of urinary diversion has been performed by dedicated laparoscopic surgeons. While complete intracorporeal construction of urinary diversions have been successfully performed, the procedure may be facilitated either by doing the diversion hand assisted through a minilaparotomy or by exteriorization of the bowel segment used for construction of the reservoir. The use of robotic surgery is another evolving technique that should make the procedures easier for the surgeon and thus shorten the operative time.

In the reports on the feasibility of various forms of laparoscopic urinary diversions, much emphasis is placed on the surgical time. When compared to open surgery, it is generally longer, even in the hands of experienced surgeons. This, however, must not necessarily be a disadvantage. This initial shortcoming was the basis of many forms of innovative research to shorten and facilitate laparoscopic surgery. These techniques will ultimately also facilitate and be used in open surgery. Besides introducing new instruments that had been developed for laparoscopic surgery in open surgery, the advantages of laparoscopic surgery, e.g., decreased tissue trauma, also stimulate the open surgeons to further refine their technique, which ultimately benefits the patient. The current status shows a rapidly evolving technique, with benefits for the patients undergoing laparoscopic urinary diversion, often hand assisted or with a minilaparotomy, not being overwhelming for the moment and being somewhat compensated by a prolonged anesthesia time. These momentary shortcomings, however, are the motor for further improvements, from which, very likely, not only laparoscopic surgery but also robotic surgery and even classical open surgery will further benefit.

The future will be bright, provided the following points are kept in mind:
- The authors' advice in the introduction—that the laparoscopic surgery must be governed by the laws of oncological surgery.
- The patient must receive the type of urinary diversion that fits his/her condition best and not one that is more easily feasible by laparoscopic surgery.
- Errors committed earlier with open surgery should not be repeated. Only spheroidal reservoirs have the best pressure characteristics and the optimal ratio between volume and the (reabsorbing) intestinal mucosa used for its construction. Funnel-shaped outlets for orthotopic bladder substitutes must be avoided to prevent kinking of the reservoir outlet. No antireflux mechanisms with a high probability of complications should be used. Ischemia

and exposure of mesenchymal tissue to urine must be avoided to prevent strictures.

■ The use of laparoscopic techniques should not compromise the long-term results, e.g., by damaging neurovascular bundles or heat damage to sensitive tissues such as anastomotic areas by electrocautery. The best possible functional long-term result counts and not the hospital stay or the operative time.

■ All new developments should focus only on possible long-term patient benefit. Techniques that demand a long learning curve for the surgeon, for which many patients would have to pay with (increased) long-term morbidity, would be unethical.

■ The ultimate goal must be the development of techniques that can not only be performed by artists in the field, but that can also be used by the majority of surgically active urologists.

■ Not everything that is new is necessarily better.

If these points are kept in mind, the future developments in endoscopic surgery will be rapid and convincing. Refinements of robotic surgery should allow some replacement of laparoscopic surgery. While the costs for laparoscopic or robotic surgery are actually of some concern, a drop in costs can be expected as soon as the techniques are widely used. As soon as further developments show the advantages of minimal invasive surgery as convincingly as it had been shown for replacing open (partial) nephrectomy with laparoscopic surgery, this will also become standard procedure for urinary diversion.

LAPAROSCOPIC SURGERY FOR BLADDER CANCER: CURRENT STATUS

Osamu Ukimura and Inderbir S. Gill

Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

Radical cystectomy is the established, standard treatment for patients with organ-confined, muscle-invasive, or recurrent high-grade bladder cancer. The optimal goals of the therapy for bladder cancer can include achieving excellent long-term oncologic outcomes as well as improved quality of life, coupled with the evolved urinary diversion.

The potential advantages of laparoscopic surgery are decreased blood loss, avoidance of certain laparotomy, less postoperative pain, less morbidity, early return to full activity, and better cosmesis. Following recent establishment of laparoscopic upper urinary tract and prostate surgery with a noteworthy decrease in patients' morbidity, a natural progression has been made to applying the laparoscopic technique to bladder surgery. Although the most challenging aspect of laparoscopic surgery for bladder carcinoma is reconstructive procedures, Gill et al. reported initial laparoscopic radical cystectomy with either ileal conduit or orthotopic urinary diversion (Studer pouch), with entire procedure being performed purely intracorporeally, in 2000 and 2001, respectively (1,2). Achieved decrease of blood loss in laparoscopic radical cystectomy (~ 300–400 cc) is considered to be due to clear visualization and delicate hemostatic handling of the bladder pedicles using linear stapling devices, with the tamponade effect afforded by the CO_2 pneumoperitoneum pressure.

Open radical cystectomy with urinary diversion provides accepted oncologic outcomes (Table 1) (3); however, it is a major demanding surgery for patients, involving long postoperative recovery. In the outcomes of the recent largest series in 1054 patients undergoing open radical cystectomy and urinary diversion of conduit ($n = 267$, 25%), ureterosigmoidostomy ($n = 17$, 2%), continent cutaneous ($n = 372$, 35%), or orthotopic ($n = 398$, 38%), with a median follow-up of 10.2 years, there were 27 (3%) perioperative deaths, with a total of 292 (28%) early complications (4). Distant recurrence was reported in 234 patients (22%) and local recurrence in 77 patients (7%). Overall recurrence-free survival at 5 and 10 years was 68% and 66%, respectively. Patients with fewer than five positive lymph nodes, undergoing their proposed extended pelvic iliac lymph node dissection approach, had significantly better survival rates than those with five or more lymph nodes involved ($p = 0.003$) (4).

The laparoscopic radical cystectomy with urinary diversion is a recently emerged surgery, requiring advanced laparoscopic training. As recent growing experiences were published from the major medical centers throughout the world, minimally invasive surgery for bladder carcinoma and urinary diversion reconstruction is gaining acceptance. During the initial part of the learning curve, laparoscopic radical cystectomy should be reserved for nonobese patients with organ-confined, nonbulky bladder cancer without preoperative radiographic and clinical findings of concomitant pelvic lymphadenopathy (1).

As recent growing experiences were published from the major medical centers throughout the world, minimally invasive surgery for bladder carcinoma and urinary diversion reconstruction is gaining acceptance. During the initial part of the learning curve, laparoscopic radical cystectomy should be reserved for nonobese patients with organ-confined, nonbulky bladder cancer without preoperative radiographic and clinical findings of concomitant pelvic lymphadenopathy.

HISTOLOGIC AND EXPERIMENTAL BACKGROUND

In 1992, Parra et al. (5) documented the initial case report of laparoscopic simple cystectomy in female patient suffering from recurrent pyocystis of retained bladder in a 27-year-old paraplegic woman who had already undergone open surgical urinary diversion a few months earlier. The operative time was 130 minutes. The authors described postoperative hospital stay of five days, which was significantly less than that in five similar patients undergoing open cystectomy for vesical empyema in whom the mean hospital stay was 20.6 days. In 1992, Kozminski and Partamian (6) described the first case report of laparoscopically assisted ileal conduit construction, with the bowel anastomosis and both Bricker ureteroileal anastomosis performed extracorporeally through extended port sites. In 1995, Sanchez de Badajoz et al. (7) described the first case of laparoscopic-assisted radical cystectomy with an ileal conduit performed extracorporeally in a 64-year-old woman who had invasive bladder carcinoma. The authors discussed that recuperation was unusually fast and painless, and little postoperative analgesia was required. In 1999, Denewer et al. (8) conducted a series of 10 patients undergoing laparoscopic-assisted cystectomy with open surgical sigmoid pouch, including two patients subjected to primary treatment for bladder tumor, but seven patients to salvage options as well as one to a palliative option after unsuccessful courses of radiotherapy for bladder malignancy.

Although the above reports established laparoscopic feasibility of certain portions of laparoscopic cystectomy or urinary diversion, it was not until 2000 that entire laparoscopic radical cystectomy and completely intracorporeal ileal conduit urinary diversion was employed clinically in two male patients with bladder cancer (1), following a successful pilot study in 10 pigs by Cleveland Clinic (9). Similarly, in author's institution, the completely intracorporeal orthotopic ileal neobladder was initially developed successfully in animal study using 12 pigs (10), followed by clinical application of orthotopic urinary diversion in one man and in one woman, and an Indiana pouch in one man (2).

In 2000, Turk et al. described laproscopic radial prostatectomy with Mainz II pouch entirely intracorporeally also in three men and two women with bladder cancer (11). These reports demonstrated that reconstruction of bowel could be performed with purely intracorporeal freehand suturing techniques.

CLINICAL SERIES

Purely Laparoscopically Completed Orthotopic Ileal Neobladder or Ileal Loop: Cleveland Clinic Experience

Gill et al. reported completely intracorporeal techniques in a manner duplicating open surgical principles can be performed for laparoscopic radical cystectomy with ileal conduit as well as with orthotopic continent urinary diversion (Studer pouch), in 2000 and 2002, respectively (1,2). Specifically, laparoscopic radical cystectomy respects established oncologic principles of wide margin resection in open radical cystectomy, and we have obtained negative margins in all but one of total 33 laparoscopic radical cystectomy performed to date. Mean estimated blood loss was 490 mL. There were no intraoperative complications

---

Sidebar:

Although the above reports established laparoscopic feasibility of certain portions of laparoscopic cystectomy or urinary diversion, it was not until 2000 that entire laparoscopic radical cystectomy and completely intracorporeal ileal conduit urinary diversion was employed clinically in two male patients with bladder cancer, following a successful pilot study in 10 pigs by Cleveland Clinic. Similarly, in author's institution, the completely intracorporeal orthotopic ileal neobladder was initially developed successfully in animal study using 12 pigs, followed by clinical application of orthotopic urinary diversion in one man and in one woman, and an Indiana pouch in one man.

Oncologic outcomes of the initial 22 patients with mean follow-up of 11 months (range 2–43) were that 21 (95%) had negative margin, six (27%) had positive lymph nodes, three (14%) died of distant recurrence, and one local recurrence (4.5%) in case with pT4N2 with lung metastasis (alive, undergoing chemotherapy) was noted.

The median number ($n = 21$) of nodes retrieved in the author's series and anatomical boundaries of the surgical procedure (bilaterally skeletonizing the genitofemoral nerve, external iliac artery, external iliac vein, obturator nerve, hypogastric artery, common iliac artery, and pubic bone) were commensurate with those of current recommendation for open surgery. No patient developed port site or no local recurrence over the short follow-up of 11 months (range, 2–43 months).

The complications of the initial 22 cases of laparoscopic radical cystectomy, all with intracorporeally created urinary diversion, were summarized in six major (27%) and nine minor (41%) complications.

All had negative surgical margins, and an average of 10 lymph nodes (range, 5–16) were removed, resulting in positive lymph nodes in three patients (25%). No patients developed local recurrence. Three (25%) developed systematic disease (two in bone and one in liver and lung) at a median follow-up of 33 months (median time to progression), 22 months; and two (17%, pT3aG3 and pT3aG3N1) of the three patients died of the metastatic disease 15 and 24 months after surgery.

necessary to convert to open. Laparoscopic-magnified image provides excellent mucosa-to-mucosa precision during creation of an orthotopic neobladder, and during urethraileal and ureteroileal anastomosis. Although our initial operative times were around 10 hours, current operative time decreased to 8.5 hours with additional 1.5 hours by extended laparoscopic lymphadenectomy. The cystectomy part of the procedure now comprises approximately two hours.

Oncologic outcomes of the initial 22 patients with mean follow-up of 11 months (range, 2–43) were that 21 (95%) had negative margin, six (27%) had positive lymph nodes, three (14%) died of distant recurrence, and one local recurrence (4.5%) in case with pT4N2 with lung metastasis (alive, undergoing chemotherapy) was noted.

Importantly, radical cystectomy can provide not only an accurate pathological evaluation of the primary bladder cancer but also the assessment of regional lymph nodes involvement. There is increasing evidence to support extensive and meticulous dissection to enhance nodal yield, and oncologic outcomes. Herr et al. (12) reported regarding the impact of numbers of lymph nodes retrieved on outcomes of open radical cystectomy; patients with positive lymph nodes had significantly better survival when greater than 11 lymph nodes were retrieved for examination, and patients with negative lymph nodes had better survival when eight or greater lymph nodes were evaluated. Technique and initial outcomes of laparoscopic extended lymphadenectomy for bladder cancer was reported recently from Cleveland Clinic (13).

The median number ($n = 21$) of nodes retrieved in the author's series and anatomical boundaries of the surgical procedure (bilaterally skeletonizing the genitofemoral nerve, external iliac artery, external iliac vein, obturator nerve, hypogastric artery, common iliac artery, and pubic bone) were commensurate with those of current recommendation for open surgery. No patient developed port site or no local recurrence over the short follow-up of 11 months (range, 2–43 months) (13).

Laparoscopic radical cystectomy is a complex procedure and requires advanced laparoscopic expertise; as such, a critical appraisal of the attendant complications is essential.

The complications of the initial 22 cases of laparoscopic radical cystectomy, all with intracorporeally created urinary diversion, were summarized in six major (27%) and nine minor (41%) complications (13,14).

The major complications, all of which required reoperation, were small bowel obstruction ($n = 3, 14\%$), ureteroileal anastomotic leak ($n = 1, 4.5\%$), urethrovaginal fistula ($n = 1, 4.5\%$), and bowel perforation with delayed death ($n = 1, 4.5\%$). Minor complications were mainly related to prolonged ileus ($n = 6, 28\%$), all of which were conservatively managed, deep venous thrombosis ($n = 2, 9\%$) that was managed by thrombolytics administration, and postoperative bleed ($n = 1, 4.5\%$) that was laparoscopically suture repaired.

Purely Laparoscopically Completed Continent Urinary Diversion: Charite Hospital Experience

The first purely laparoscopically completed continent urinary diversion (rectosigmoid pouch) was reported by Turk et al. in 2001 (11). The authors demonstrated that purely laparoscopic reconstructed rectosigmoid pouch was feasible and safe with the same functional outcomes as after open Mainz II procedure. Recently, among their 20 laparoscopic radical cystectomy series, this group documented the oncologic and functional data of 12 patients undergoing laparoscopic rectosigmoid pouch creation for continent urinary diversion with follow-up for longer than two years (range, 13–42 months, median 33) (15). Median operative time was 485 minutes (range, 365–830); median blood loss was 200 mL (range 190–800); median hospital stay was 15 days (range, 11–30); two patients required reoperation due to persistent leakage of the pouch and rectovaginal fistula, respectively. Unilateral hydronephrosis with loss of the renal function was found in one.

All had negative surgical margins, and an average of 10 lymph nodes (range, 5–16) were removed, resulting in positive lymph nodes in three patients (25%). No patients developed local recurrence. Three (25%) developed systematic disease (two in bone and one in liver and lung) at a median follow-up of 33 months (median time to progression), 22 months; and two (17%, pT3aG3 and pT3aG3N1) of the three patients died of the metastatic disease 15 and 24 months after surgery. All patients were continent during the day. Eleven patients were continent at night, but one was using two or five pads per night.

Laparoscopic-Assisted Laparoscopic Radical Cystectomy

In 2002, Gaboardi et al. (16) introduced the laparoscopic-assisted technique of laparoscopic radical cystectomy with ileal neobladder, in which extracorporeal restoring of intestinal

Source: From Ref. 3.

continuity and partial construction of the posterior plate of ileal neobladder with 25-cm loop was performed through a 5-cm supraumbilical incision that is necessary to remove the surgical specimen. Following closing the supraumbilical incision and recreation of pneumoperitoneum, the urethra-neobladder anastomosis, ureteral anastomosis, and closing of the remained anterior neobladder wall were completed intracorporeally. The authors discussed extracorporeally detubularization of the ileal loop may prevent fecal contamination of the abdominal cavity, and open-assisted ileal-to-ileal anastomosis of the posterior plate with reapproximation of mesenteric margin may prevent intestinal mechanical obstruction.

In their six cases experience of laparoscopic-assisted laparoscopic radical cystectomy with orthotopic ileal neobladder, operative time was reported, 360 to 510 minutes (mean, 425); estimated blood loss, 220 to 440 mL (mean, 311); ileus day, three to five days (mean, 3.7); and hospital stay, seven to nine days (mean, 8.1). All six patients were alive during follow-up of 5 to 15 months (mean, 9.3), however, despite negative surgical margins two (33%) patients (T1N0G3+Cis and T2aN0G2-3) had metastatic diseases at six months after surgery (17).

The authors concluded that laparoscopic-assisted approach contributes to decreased postoperative pain and quicker recovery with similar complication rate to open approach. It should be noted that in this study, the reconstructive portion was performed through a 15-cm low Pfannenstiel incision.

Among total 10 cases of their laparoscopic radical cystectomy series with different urinary diversions, two cases of completely intracorporeally created sigmoid ureterostomy were noted with an operative time of 300 to 390 minutes (Table 2) (3).

In the initial experiences of 11 patients who underwent laparoscopic radical cystectomy and an open-hand sewn ileal conduit from 1999 to 2002, Hemal et al. reported one (9%) case with positive margin and other five (45%) cases of procedure-specific complications (18).

The authors described three intraoperative complications including injury to the external iliac vein ($n = 1$) and a small rectal tear ($n = 2$), all repaired by laparoscopic freehand suturing. Other laparoscopic surgical complications were subcutaneous emphysema ($n = 1$), and hypercarbia ($n = 1$) necessitating conversion to open surgery. The authors discussed that laparoscopic radical cystectomy was associated with complications similar to those seen with other laparoscopic and open surgery procedures, especially during the initial experience.

In 2004, Basillote et al. retrospectively compared perioperative outcomes of radical cystectomy with ileal neobladder between 11 men who underwent open approach and 13 men who underwent laparoscopic-assisted approach (19). The authors suggested laparoscopic approach provided significant decrease in postoperative pain, represented by parenteral morphine equivalent use (mg); open, 144 versus laparoscopy, 61, $p = 0.04$, as well as provided significant quicker recovery, represented by (i) start of oral liquids (days); open, 5 versus laparoscopy, 2.8, $p = 0.004$, (ii) start of oral solids (days); open, 6.1 versus laparoscopy, 4.1, $p = 0.002$, (iii) hospital stay (days); open, 8.4 versus laparoscopy, 5.1, $p = 0.0004$, (iv) lights work back (days); open, 19 versus laparoscopy, 11, $p = 0.0001$, without a significant increase in operative time (open, 7.2 hours vs. laparoscopy 8 hours, $p = 0.5$) and with similar complication rate (open, one major and five minor vs. laparoscopy, four major and two minor).

In the initial experiences of 11 patients who underwent laparoscopic radical cystectomy and an open-hand sewn ileal conduit from 1999 to 2002, Hemal et al. reported one (9%) case with positive margin and other five (45%) cases of procedure-specific complications (18).

As such, an ileal loop or orthotopic neobladder could be completed purely laparoscopically or in an open fashion through an enlarged extraction incision. Proponents of the open-assisted approach refer its decreased operative time for performing the neobladder when compared to the purely intracorporeal procedure. Retrospective or prospective data comparing between intracorporeal and open-assisted approach are not yet available.

Robot-Assisted Laparoscopic Radical Cystectomy

Three-dimensional stereoscopic vision, and multiangled movement with endowrist instruments are advantages for robotic-assisted surgery, although they are cost-intensive tools available in specialized centers alone.

In 2003, the first case report of daVinci-assisted laparoscopic cystectomy with intracorporeally created ileal neobladder (Hautmann) was described by Beecken et al., resulting in operative time of 8.5 hours.

In 2003, the first case report of daVinci-assisted laparoscopic cystectomy with intracorporeally created ileal neobladder (Hautmann) was described by Beecken et al., resulting in operative time of 8.5 hours (20).

The feasibility of robot-assisted laparoscopic cystectomy with intracorporeal created ileal conduit was reported in two men and one woman by Balaji et al., although mean operative time was more than 10 hours (691 minutes); mean estimated blood loss,

250 mL; and hospital stay, 7.3 days (21). Menon et al. reported technical feasibility of nerve-sparing robot-assisted radical cystectomy with extracorporeally created urinary diversion in 14 men and 3 women (22). Mean blood loss was less than 150 mL, and operative time for robotic radical cystectomy, extracorporeal ileal conduit, and extracorporeal orthotopic neobladder were 140, 120, and 168 minutes, respectively, although 13 (76%) patients had associated bilharziasis, with significant periureteric, perivesicular, and perivesical scarring. The functional and oncological data in this series were awaited.

The authors concluded that laparoscopic-assisted approach contributes to decreased postoperative pain and quicker recovery with similar complication rate to open approach. It should be noted that in this study, the reconstructive portion was performed through a 15-cm low Pfannenstiel incision.

Hand-Assisted Laparoscopic Radical Cystectomy

The first case report of hand-assisted laparoscopic radical cystectomy with ileal conduit was described by Peterson et al. in 2002 (23). Operative time was seven hours with 750 mL of blood loss. McGinnis et al. described the first series of seven patients undergoing hand-assisted laparoscopic radical cystectomy and ileal conduit. Mean operative time was 7.6 hours, blood loss was 420 mL, and hospital stay was 4.6 days (24). In 2004, Taylor et al. documented nonrandomized comparison between hand-assisted laparoscopic radical cystectomy and open cystectomy in eight cases each (25).

The author reported significant difference was observed only in the mean postoperative parenteral analgesia administration; hand-assisted, 31 mg versus open, 149 mg ($p = 0.01$); however, no statistical differences in others, including (i) operative time; hand-assisted, 403 minutes versus open, 420 minutes ($p = 0.7$), (ii) blood loss; hand-assisted, 637 mL versus open, 957 mL ($p = 0.2$), (iii) hospital stay; hand-assisted, 6.4 days versus open, 9.8 days ($p = 0.06$), (iv) regular diet; hand-assisted, 4.5 days versus 7.9 days ($p = 0.05$).

Prostate-Sparing Laparoscopic Radical Cystectomy

Prostate- and seminal-sparing cystectomy may be an option in young patients whose preservation of urinary continence and sexual potency are fundamental (26). In carefully selected patients, this procedure was proposed in open surgically resulting in more than 90% of patients being potent, while nearly all are totally continent, with no additional oncologic risk. In 2003, Guazzoni et al. reported the initial three cases of laparoscopic nerve- and seminal-sparing cystectomy with extracorporeally created orthotopic ileal neobladder (27). The operative time was 410 to 480 minutes, blood loss was 150–300 mL, and hospital stay was eight to nine days. All three patients were fully continent and had normal sexual functions at three months after surgery.

Cathelineau et al. reported the largest experience with laparoscopic radical cystectomy in 84 patients, including cystoprostatectomy in 31, and prostate-sparing cystectomy in 40 (28).

All patients had negative surgical margins. Pathologic staging comprised pTa-pT1 {13}, pT2 {59}, pT3 {11}, and pT4 {1}, and tumor grades were grade 1 {1}, grade 2 {13}, and grade 3 {17}. Seven patients had positive lymph nodes; numbers of retrieved nodes were not reported. Median surgical time was 4.3 hours; a median blood loss was 550 cc; median hospital stay was 12 days, with requiring parenteral narcotics for 24 hours postoperatively in 58% of patients. Urinary diversion was reconstructed extracorporeally with orthotopic bladder in 51 and ileal conduit in 33 patients. Postoperative complications were reported in 15 patients, including urinary tract infection {8}, pelvic hematoma {3}, urinary fistula {2}, pulmonary embolism {1}, and pyelonephritis {1}.

At an average follow up of 18 months (range 1–44 months), all 84 patients were alive at last follow up, and 83% were disease-free without any evidence of trocar or extraction site seeding. Eight patients developed metastatic disease, and five developed local recurrence.

INTERNATIONAL REGISTRY AND FUTURE DIRECTION

There is no current universally established approach for the reconstructive component of this surgery. Indication for choosing the type of laparoscopic urinary diversion that is best suited to a patient is not different from that of open surgery.

To define the laparoscopic radical cystectomy can be a viable alternative to standard open radical cystectomy, careful prospective and long-term evaluation of oncologic and functional outcomes will be necessary. Recently created International Registry for Laparoscopic Radical Cystectomy has been established by Gill and coworkers to facili-

Margin notes:

The author reported significant difference was observed only in the mean postoperative parenteral analgesia administration; hand-assisted, 31 mg versus open, 149 mg ($p = 0.01$); however, no statistical differences in others, including (i) operative time; hand-assisted, 403 minutes versus open, 420 minutes ($p = 0.7$), (ii) blood loss; hand-assisted, 637 mL versus open, 957 mL ($p = 0.2$), (iii) hospital stay; hand-assisted, 6.4 days versus open, 9.8 days ($p = 0.06$), (iv) regular diet; hand-assisted, 4.5 days versus 7.9 days ($p = 0.05$).

Cathelineau et al. reported the largest experience with laparoscopic radical cystectomy in 84 patients, including cystoprostatectomy in 31, and prostate-sparing cystectomy in 40.

At an average follow up of 18 months (range 1–44 months), all 84 patients were alive at last follow up, and 83% were disease-free without any evidence of trocar or extraction site seeding. Eight patients developed metastatic disease, and five developed local recurrence.

To define the laparoscopic radical cystectomy can be a viable alternative to standard open radical cystectomy, careful prospective and long-term evaluation of oncologic and functional outcomes will be necessary. Recently created International Registry for Laparoscopic Radical Cystectomy has been established by Gill and coworkers to facilitate development of this emerging field in a cohesive manner by optimizing operative techniques, establishing standardized critical care postoperative pathways, and prospectively collecting oncologic, functional, and quality-of-life outcomes data.

Complications were reported intraoperatively in 25 (8%), postoperatively in 75 (24%), and in a delayed fashion in 49 (16%). Positive surgical margins were in 11 patients (4%). In mean follow-up of 18 months (range 0.5–68) among 292 patients (95%) with available information, the overall and cancer-specific survival was 80% and 94%, respectively. There were local recurrences in 20 patients (7%), systemic recurrences in 20 patients (7%), and no port site recurrences.

In the future, laparoscopic radical cystectomy will evolve into a technically optimal combination, with intracorporeal performance of the radical cystectomy, including extended pelvic lymphadenectomy, ureteral mobilization, and selection of the appropriate bowel segment. Majority of the reconstructive procedures, creation of the bowel reservoir, and ureterointestinal anastomoses are likely to be performed extracorporeally through a minilaparotomy. In patients undergoing orthotopic reconstruction, the urethroenteric anastomosis will then be completed intracorporeally.

tate development of this emerging field in a cohesive manner by optimizing operative techniques, establishing standardized critical care postoperative pathways, and prospectively collecting oncologic, functional, and quality-of-life outcomes data (3).

The International Registry database involved nine international centers with published experience in laparoscopic radical cystectomy of at least 10 cases. From December 1999 to July 2005, 308 patients underwent laparoscopic radical cystectomy in 244 males and 64 females with a mean age of 65 years old. Preoperatively, concomitant carcinoma in situ was in 18%, and preoperative computed tomography indicated pelvic lymphadenopathy in 3% and perivesical fat involvement in 8%. Laparoscopic radical cystectomy procedures included cystoprostatectomy (69%), prostate-sparing cystectomy (11%), female anterior pelvic exenteration (14%), and female radical cystectomy (6%). Pelvic lymphadenectomy was performed in 91% of the patients (the mean number of lymph nodes nine, ranged 2–36), revealing nodal involvement on pathology in 52 patients (17%). The types of urinary diversion included orthotopic neobladder (56%) and ileal conduit (38%), which were reconstructed extracorporeally in 89% and intracorporeally in 11%. Mean operating room time was 6.3 hours {1.6–13.8}, and blood loss was 660 cc {50–5000} with 10 patients electively converted to open surgery because of extensive tumor.

Complications were reported intraoperatively in 25 (8%), postoperatively in 75 (24%), and in a delayed fashion in 49 (16%). Positive surgical margins were in 11 patients (4%). In mean follow-up of 18 months (range 0.5–68) among 292 patients (95%) with available information, the overall and cancer-specific survival was 80% and 94%, respectively. There were local recurrences in 20 patients (7%), systemic recurrences in 20 patients (7%), and no port site recurrences.

Because the most technically challenging of laparoscopic radical cystectomy is the reconstructive urinary diversion, the majority of centers preferably perform the urinary diversion extracorporeally through a minilaparotomy incision. Published literatures reported that perioperative outcomes of extracorporeal versus intracorporeal reconstruction of urinary diversion are likely very similar, albeit with shorter operative times and less requirement of advanced laparoscopic skills in the extracorporeal technique.

In the future, laparoscopic radical cystectomy will evolve into a technically optimal combination, with intracorporeal performance of the radical cystectomy, including extended pelvic lymphadenectomy, ureteral mobilization, and selection of the appropriate bowel segment. Majority of the reconstructive procedures, creation of the bowel reservoir, and ureterointestinal anastomoses are likely to be performed extracorporeally through a minilaparotomy. In patients undergoing orthotopic reconstruction, the urethroenteric anastomosis will then be completed intracorporeally.

SUMMARY

- Minimally invasive surgery for bladder cancer and urinary diversion is increasingly gaining acceptance at select institutions across the world.
- Long-term oncologic outcomes of laparoscopic radical cystectomy are limited; however, the currently available perioperative and short-term oncologic outcomes are encouraging.
- Laparoscopic radical cystectomy should include extended pelvic lymphadenectomy mirroring the template of open surgery.
- Laparoscopic approach contributes to decreased postoperative pain and quicker recovery with similar complication rate to open surgery.
- Reconstructive creation of the bowel reservoir and ureterointestinal anastomoses are preferably performed extracorporeally through a minilaparotomy, and then, in patients undergoing orthotopic reconstruction, the urethroenteric anastomosis is completed intracorporeally.
- An international registry of laparoscopic radical cystectomy has been established by the author to facilitate development of this emerging field in a cohesive manner to optimize operative techniques, establishing standardized critical care postoperative pathways, and prospectively collecting oncologic, functional, and quality-of-life outcomes data.

TRANSPERITONEAL LAPAROSCOPIC RADICAL PROSTATECTOMY: TECHNICAL VARIATIONS, ONCOLOGIC AND FUNCTIONAL RESULTS, AND TRAINING

Jens J. Rassweiler, Tibet Erdogru, Marto Sugiono, Marzel Hrutza, and Dogu Teber

Department of Urology, SLK Heilbronn Hospital, Heilbronn, Germany

THE HISTORY OF LAPAROSCOPIC RADICAL PROSTATECTOMY

The goals of laparoscopic radical prostatectomy, as in retropubic radical prostatectomy, are lifelong oncologic control of localized prostate carcinoma while maintaining continence and potency functions with minimizing of operative morbidity that contribute to a global quality of life.

Transperitoneal laparoscopic radical prostatectomy with ascending approach was first performed by Schuessler et al. (1) and presented in 1992. However, the technical difficulties did not allow widespread application of this procedure. An initial series with nine patients was published in 1997 by the same authors, but they concluded that the procedure was not feasible due to the excessive operation time and multiple technical difficulties (2). The authors stated "laparoscopic radical prostatectomy is not efficacious alternative to open radical prostatectomy as curative treatment of clinically localized prostate cancer."

Subsequently, Rabboy et al. (3) successfully performed laparoscopic radical prostatectomy with an extraperitoneal access in two patients. In 1993, Kavoussi et al. (4) performed laparoscopic approach to the seminal vesicles as a helpful tool during perineal radical prostatectomy or when treating primary seminal vesicle pathologic conditions. Following the technical modifications of Gaston with a similar transperitoneal dissection of the seminal vesicles in December 1997, Guillonneau and Vallancien promoted

this procedure based on the same principle and published the "Montsouris technique" in 1998 with 40 patients (5). Subsequently, another center from Paris (Creteil) committed to the similar technique and both centers were able to report more competitive operation times of 3–4 hours after considerable experience (6,7). In 1999, Rassweiler et al. developed the transperitoneal ascending laparoscopic technique similar to the classic anatomic radical prostatectomy in 1999 and published this technique as the "Heilbronn technique" with 100 patients (8). Basically, this approach consists of an ascending part, with early division of the urethra and posterolateral dissection of the prostate, followed by the incision of the bladder neck and dissection of the cranial part of the seminal vesicles and vasa deferentia (8).

In 2001, Bollens et al. (9) published a standardized technique of extraperitoneal laparoscopic radical prostatectomy shifting from their initial experience with the transperitoneal approach. These authors emphasized that the main reasons for the extraperitoneal approach were the comparability with the open counterpart (i.e., retropubic descending radical prostatectomy) and potential disadvantages of the transperitoneal route associated with the risk of bowel injury or peritonitis in case of urine extravasation. Laparoscopic radical prostatectomy has become a worldwide accepted alternative to open surgery at centers of expertise using different modifications (Table 1).

In the meantime, several studies have been published about perioperative morbidity or the impact of technical modifications on short-term results; however, there are only few reports concerning the long-term functional and oncological outcome. This is mainly related to the fact that only a limited number of centers of expertise (i.e., Bordeaux, Paris-Montsouris, Paris-Creteil, Heilbronn, Berlin, Bruxelles, and Cleveland) might be able to present such results with an adequate follow-up. With the evolution in laparoscopic technology and proficiency, laparoscopic radical prostatectomy is now useful not only with its surgical outcomes but also with the oncologic and functional results (11). Laparoscopy can be considered feasible if it improves operative and postoperative morbidity and allows a better preservation of periprostatic vascular, muscular, and neurovascular structures by providing better visualization and optical magnification. Nowadays, transperitoneal laparoscopic radical prostatectomy has been increasingly accepted providing similar function and oncologic results as open radical prostatectomy (12–14).

INDICATIONS OF LAPAROSCOPIC RADICAL PROSTATECTOMY

The indications for the radical laparoscopic prostatectomy are the same as that for the open procedures including treatment of men with localized prostate carcinoma and a life expectancy of 10 years or more.

> Laparoscopic radical prostatectomy has become a worldwide accepted alternative to open surgery at centers of expertise using different modifications.

> The indications for the radical laparoscopic prostatectomy are the same as that for the open procedure including treatment of men with localized prostate carcinoma and a life expectancy of 10 years or more.

TABLE 1 ■ History and Technical Modifications of Laparoscopic Radical Prostatectomy

Author	Comment
Schuessler et al. (1)	The first reported case underwent laparoscopic radical prostatectomy
Kavoussi et al. (4)	Laparoscopic approach to seminal vesicles for its diseases and perineal radical prostatectomy with dissection of these structures
Schuessler et al. (2)	Laparoscopic radical prostatectomy is not alternative to open counterpart due to technical difficulty and longer operation time
Rabboy et al. (3)	Feasible to perform extraperitoneal laparoscopic radical prostatectomy with 2 cases
Gaston (1997) (10)	The model of retrovesical dissection of seminal vesicles and vas deferens was first proposed
Guilloeneau and Vallancien (7)	As a feasible alternative, Transperitoneal laparoscopic radical prostatectomy was promoted as the "Montsouris technique" based on the same principle previously described by Gaston
Abbou et al. (6)	At another center in Paris, the "Creteil" technique committed to a similar technique of transperitoneal laparoscopic radical prostatectomy
Rassweiler et al. (8)	Described as the "Heilbronn technique", basically consists of an ascending part which is similar to the open counterpart
Bollens et al. (9)	A standardized technique of extraperitoneal laparoscopic radical prostatectomy shifting from their initial experience with the transperitoneal approach

The goal must be eradication of the disease. There is no rigid age limit for radical prostatectomy and a patient should not be deprived of this procedure based on age alone. Due to the lengthy course of prostate cancer, the age and comorbid conditions of the patient are the most important determinants of the benefits of treatment.

The clinical stage has influence in the outcomes of the radical prostatectomy, together with the Gleason score and the preoperative prostate-specific antigen. The Gleason score is an important prognostic factor, but it cannot be used to determine prognosis or to justify management. Also prostate-specific antigen cannot definitively distinguish the stage of the cancer in an individual patient and should not be used alone as a contraindication to definitive treatment. The final decision must be taken with the consent of the patient after the explanation of likelihood of success and complications of each procedure.

SPECIFIC CONTRAINDICATIONS

There is no specific contraindication for laparoscopic surgical approach for localized prostate cancer apart from open surgery. There are four absolute contraindications not only for laparoscopic radical prostatectomy but also for the other laparoscopic surgical approaches: abdominal wall infection, generalized peritonitis, bowel obstruction, and an uncorrected coagulopathy (15).

Problematic Conditions
In obese patients, creation of access might be more difficult while the body habitus of the patient usually does not influence the laparoscopic approach to pelvic region. The thickness of the abdominal wall diminishes the available length of the trocars and consequently the ability to reach deeply situated structures with the instruments.

Previous abdominal surgery or radiotherapy sometimes leads to parietal or intestinal adhesions, which may represent increase risks during access to the Retzius' space.

Periprostatic fibrosis increases the difficulty of dissecting the prostate, particularly its posterior wall. This situation is often observed after neoadjuvant hormonal therapy, repeated transrectal biopsies, previous inflammation of prostate, and finally transurethral resection of the prostate or open adenomectomy of prostate. However, even the patient following external radiotherapy (i.e., salvage prostatectomy) has been treated laparoscopically (16).

LAPAROSCOPIC TRANSPERITONEAL ASCENDING RADICAL PROSTATECTOMY (THE HEILBRONN TECHNIQUE)

The principal goal of the Heilbronn technique (ascending-laparoscopic radical prostectomy) was to transfer as much of the technical steps of the well-established and perfected classic retropubic radical prostatectomy to the laparoscopic armamentarium.

Armamentarium
We use standard equipment for laparoscopy, including high-flow insufflator, xenon-light source, three-chip charge compled device camera, and a high-frequency generator for mono- and bipoar coagulation. A voice-controlled robot is utilized to maneuver the telescope (Table 2). A rectal balloon is used for rectal identifications. The retracting forceps are kept in place by a mechanical articulated arm (Martin arm). The main parts of the operation are carried out by use of a bipolar forceps and Metzenbaum endoscissors. Endoscopic suturing is performed with a fine needle holder providing a scissors-like handle. A special endo-peanut-sponge holder is used for bladder retraction. For vascular control, we use 10-mm clip-applicator, and for nerve-sparing technique, we use a 5-mm clip-applicator. We also use an applier for placement of lockable polyurethane clips (Hem-O-Lok). For the urethral stump, we use a special designed open tip 20-French bougie.

Patient Preparation
The patient is put in deflected supine position with the arms at the sides and the legs adducted. Additionally, a 30-degree Trendelenburg decline supported with inflatable balloon pillow was placed under the patient's buttocks, which displaces the bowel cephalad by gravity. The abdomen is shaved from the costal margins to the pubic bone. A rectal balloon catheter is placed and inflated with 70 cm^3. Before trocar placement, a 16-French Foley catheter is inserted under sterile conditions and blocked with 15 cm^3 saline. The procedure can be divided into several important steps.

Trocar Placement

We use a W-shaped arrangement of the trocars with insertion of the first trocar (12 mm) periumbilical minilaparotomy (Hasson technique). This port is used for the laparoscope and later for retrieving of the specimen. The other four trocars (2 × 10 and 2 × 5 mm) are placed under endoscopic control after establishing the pneumoperitoneum (maximum pressure 15 mmHg, maximum flow 30 mL). The abdomen is inspected for trocar injury, bleeding, and adhesions. Anatomic landmarks to observe are the Foley balloon in the bladder, obliterated urachus (median umbilical ligament) in the midline, the two obliterated umbilical ligaments (medial umbilical ligament), and the vasa deferentia.

Access to Retzius Space

Following the inspection of the abdomen, we divide the urachus and the both umbilical ligaments using monopolar endoscissor and bipolar endodissector, followed by incision of the peritoneum to the internal inguinal rings laterally. Traversing the light prepubic areolar tissue of the space of Retzius using sharp and blunt dissection exposing the pubic bone caudally as the first landmark and the external iliac vessels laterally, freeing the bladder from its anterior attachments. Then a sixth port (5-mm) is placed in the right lower abdomen through which a grasping forceps is used to pull the urachus and dome of the bladder cranially. After that, the pelvic lymphadenectomy is carried out depending on the prostate-specific antigen (>10 ng/mL) and Gleason score (>6).

Santorini Plexus Control and Transection

First, the bladder is retracted cranially with a forceps grasping at the urachus (VI trocar 5-mm, caudally to the right). The fatty tissue overlying the endopelvic fascia has to be resected or swept cephalad and lateral. An endo-peanut-sponge holder is used to push the prostate medially, exposing the endopelvic fascia. The point of incision is where the fascia is transparent, revealing the underlying levator ani musculature, lateral to the arcus tendineus fascia pelvis because the lateral branches of the dorsal venous complex are directly beneath it. The incision in the endopelvic fascia is then carefully extended in an anteromedial direction toward the puboprostatic (or pubovesical) ligaments (17). This incision, allowing access to the levator ani muscles arching lateral, is carried distally up to lateral most puboprostatic ligament. If necessary, the small veins around the puboprostatic ligaments may be safely cauterized with bipolar forceps. With the puboprostatic ligaments transected, the superficial branch of the dorsal vein is readily apparent in the midline over the bladder neck. The adherent levator ani muscle is gently detached from the prostate, followed by transection of the puboprostatic ligaments (pubovesical ligament). The Santorini plexus is adequately controlled by two stitches caudally and one at the base of prostate for the back flow, using endoscopic suturing technique (17-mm Vicryl MH 2/0). The needle is passed from the right to the left side and should be situated so that the curve of the needle follows the curves of the symphysis pubis. The dorsal vein complex is first coagulated with bipolar forceps then divided cranial to the two distal stitches due to the coagulation-induced shrinkage of the tissue. With slight cranial traction on the prostate, the coagulated veins and the surrounding fibromuscular fatty tissue retract on both sides.

Tips and Tricks

The angle between the needle and the needle holder should be 100 degrees. The dorsal vein complex is transected proximal to the caudal stitches. The optimal retraction of the prostatic apex is accomplished by the use of 120-degree endodissector (10-mm), with the blunt tips up to avoid injuries in the bladder. Minor bleeding (i.e., back bleeding from the prostate, lateral branches of deep dorsal vein complex) can be controlled by bipolar coagulations.

Apical Dissection

The approach to the apex of the prostate is determined by the decision of proceeding with nerve-sparing or nonnerve-sparing technique.

Following division of the Santorini plexus, both neurovascular bundles are exposed lateral to the rectum by blunt dissection.

The approach to the apex of the prostate is determined by a decision to proceed with nerve-sparing or with the nonnerve-sparing technique.

The criteria for carrying out nerve-sparing technique are listed in Table 3.

Nonnerve-Sparing Technique

After transection of the dorsal vein complex, the anterior striated sphincteric urethral complex is demonstrated. The fibers of this complex at the apex are horseshoe shaped and

TABLE 3 ■ Criteria for Carrying Out Nerve Sparing

Clinical stage	Role in nerve-sparing
T1	When prostate-specific antigen is relatively low and the number of positive biopsies or the extent of biopsy involvement is limited
T2a	A contralateral nerve-sparing procedure can be proposed
T2b	A nerve-sparing attempt can result in positive surgical margins and give rise to local failure

form a tubular, striated sphincter surrounding the membranous urethra (18). The urethral sphincter is incised using bipolar forceps and endoscissor exposing the smooth muscle of the urethra. Under the gentle cranial traction of the prostate, anterior rotation of the apex of the prostate occurs and the prostatourethral junction is illustrated where the anterior wall of urethra is incised sharply (no electrocoagulation). The anterior wall of urethra is incised at the level of the prostatic apex (i.e., veru montanum), trying to preserve a maximal length of the stump. After urethra transection the Foley catheter is ligated at the urethral meatus, cut and pulled inside the abdomen to achieve retraction of the gland cranially, using grasping forceps (VI Trocar). The 20-French bougie is inserted to facilitate the cutting of the urethral posterior wall. It is important not to divide the rectourethralis muscle, which fixates the urethral stump dorsally. The prostate apex is dissected gently from the rectum and the distal prostatic pedicles are clipped using 10-mm Hem-O-Lok clips.

Because, the verumontanum is considered as the beginning of the distal continence zone, the urethral transection should be performed at or just distal to the veru. Sometimes the apical prostate overlaps the urethra beyond the verumontanum with urethral transection at or beyond the apex, and the patient can expect a period of incontinence that exceeds what could be achieved if the transection had been made just distal to the verumontanum (17).

The dissection of the urethra should be performed as near as possible to the apex of the prostate before incision is carried out.

The dissection of the urethra should be performed as near as possible to the apex of the prostate before incision is carried out. The Foley catheter is ligated at the urethral meatus cut and pulled inside the abdomen to achieve retraction of the gland cranially, using a grasper (sixth port). The 20-French bougie is placed to assist in the division of the posterior urethral wall. This maneuver is facilitated by the use of 120-degree endodissector to retract the prostate (Fig. 6).

Because the apex of the prostate and rectal ampulla are in close proximity, rectal injuries during radical laparoscopic prostatectomy commonly occur at this location.

Because the apex of the prostate and rectal ampulla are in close proximity, rectal injuries during radical laparoscopic prostatectomy commonly occur at this location.

The apex of the prostate is dissected gently from the rectum using right angle forceps and suction device. The neurovascular bundle areas are clipped using 10-mm Hem-O-Lok clips and incised, releasing the posterolateral attachments of the prostate, while the midline is dissected bluntly.

Nerve-Sparing Technique

The nerves are microscopic in size; their anatomic location can be estimated by using the capsular vessels as a landmark. The neurovascular bundles are located in the posterolateral side of the prostate, inside a triangle formed by the lateral pelvic fascia (lateral wall), prostatic fascia (medial wall), and the anterior layer of the Denonvilliers' fascia (base) (19). Near the apex, the neurovascular bundle travels at 5 and 7 o'clock positions. The lateral pelvic fascia is incised prior to the incision of the urethra. Displacing the prostate on its side exposes the lateral surface of the prostate. A right angle clamp is inserted under the lateral pelvic fascia beginning at the bladder neck extending distal towards the apex of the prostate, detaching the area of neurovascular bundle from the posterolateral border of the prostate and dissecting gently from the apical part of the prostate. All the prostatic branches from the neurovascular bundle are controlled step by step using 5-mm titanium clips. We avoid the use of bipolar or monopolar coagulation in the bundles area.

We avoid the use of bipolar or monopolar coagulation in the bundles area.

The urethra is incised as in nonnerve-sparing technique but when the striated sphincter is divided closer to the apex of the prostate, there is risk that the neurovascular bundle may be damaged. As the neurovascular bundle approaches the apex of the prostate, it is often fixed medially beneath the striated sphincter by an apical vessel. For this reason, the lateral edges of the sphincter should be divided only down to the lateral edge of the smooth muscle of the urethra and not any further posteriorly (not close to the apex of the prostate) (18).

Bladder Neck Incision
After detaching the prostate from the rectum, the gland is gently pulled ventrally by applying traction on the intra-abdominal Foley catheter. The balloon helps to identify the vesicoprostatic comissure.

Non-Bladder Neck-Sparing Technique
Starting at the prostate–vesical junction, the anterior wall of the bladder neck is incised using bipolar coagulation and endoscissors, with the balloon becoming visible. Now the balloon is deflated by cutting the suture at the end of the catheter so that it can be now used as a loop-like retractor. The posterior bladder neck wall is incised, and via retrovesicle access both vasa deferentia and seminal vesicles are dissected following by the incision of the overlying Denonvilliers' fascia.

Bladder Neck-Sparing Technique
Before the division of the bladder neck, the attachments between the bladder and the prostate are incised anteriorly and laterally, thus opening the retrovesicle space and exposing the cranial pedicles, vasa deferentia, and seminal vesicles. Following transaction of these structures between clips, the only part attaching the bladder with the prostate is the bladder neck that is finally divided.

Division of Cranial Pedicles and Seminal Vesicle Dissection
Both lateral pedicles are divided stepwise starting to divide the superficial portions of pedicle and then the deeper portions using two or three lockable 10-mm Hem-O-Lok clips to secure it. In case of a nonnerve-sparing technique, the clips are placed proximally, while in the nerve-sparing technique they are placed close to the base of the prostate. After division of both proximal pedicles each vas deferens is transected. Finally, the seminal vesicles are completely isolated and divided after clipping their vasculature. In the nerve-sparing technique, the dissection of the tips of the seminal vesicles is performed carefully to avoid injuries in the neurovascular bundles. The specimen is then entrapped in the self-opening extraction bag.

Urethrovesical Anastomosis
To perform the urethrovesical anastomosis, the right-medial port IV (for the needle holder) and the left lateral port I (for endo-dissector or second needle holder) are used to achieve an optimal angle between the instruments (30–35 degrees). During this part, we insert the bougie for optimal exposure of the urethra. If it is necessary, the bladder is retracted cranially by a grasper inserted via left medial port. We start with a 17-cm suture at 6 o'clock taking the posterior urethra together with the rectourethralis muscle (Fig. 12). The telescope is inserted deep in the pelvis with the 30-degree angle looking upward. Subsequently, two further stitches are made at 5 and 3 o'clock followed by two stitches at 7 and 9 o'clock starting with the bladder side and then the urethral side. All stitches are performed using intracorporeal knotting technique and tension-free stitches. Thus, all sutures are tied outside the urethral lumen. Choreographed sequence and hand positions are summarized in Table 4.

Reconstruction of the Bladder Neck
After insertion of a 20-French Foley catheter with Tiemann tip, the anterior reconstruction of the bladder neck is performed with two or three interrupted sutures (15-cm Vicryl 3/0, SH needle). Subsequently, the anterior part of the anastomosis is closed over the indwelling catheter. Next, the Santorini vascular complex is reapproximated to the bladder neck to reduce tension on the anastomosis. Posterior bladder neck reconstruction is necessary when the orifices are very close (less than 5 mm) to the resection line (i.e., in case of a large midlobe). In critical case, the 20-French bougie with working channel allows to insert of a guide wire (0.038 inch) into the bladder and a central perforated 20-French silicone Foley catheter can be placed safely over the guidewire.

Specimen Retrieval
After placing the drainage tube via the port IV under vision and affixing it to the skin, the prostate is extracted within the organ bag via the umbilical incision (site of trocar I). For this purpose, the rectus fascia is incised according to the size of the gland. The entire specimen then is sent to the pathologist for staging of the disease.

All steps are summarized in Table 5.

TABLE 4 ■ Choreographed Sequence and Planning of Interrupted Vesi-Courethral Anastomosis During the Heilbronn Technique

Stitch sequence	Location	Plan	Which hand
1	6 o'clock	Outside-in on the urethra	Right hand, forehand stitch
		Inside-out on the bladder neck	Right hand, forehand stitch
2	5 o'clock	Outside-in on the bladder neck	Right hand, forehand stitch
		Inside-out on the urethra	Left hand, forehand stitch

		Inside-out on the urethra	Right hand, forehand stitch
6	12 o'clock (triangle suture)	Outside-in on the bladder neck (right side)	Right hand, forehand stitch
		Inside-out on the urethra	Right hand, backhand stitch
		Outside-in on the bladder neck (left side)	Left hand, forehand stitch
		Inside-out on the bladder neck (right side)	Left hand, forehand stitch

LAPAROSCOPIC TRANSPERITONEAL DESCENDING RADICAL PROSTATECTOMY (THE MONTSOURIS TECHNIQUE)

Trocar Positioning

After a transverse infraumblical incision of 1–2 cm, a Veress needle is introduced into the peritoneal cavity and insufflation started after the safety maneuvers, without exceeding a pressure of 12 mmHg. After establishing pneumoperitoneum, a 10-mm trocar is inserted into the umbilicus for passage of the laparoscope. Four other trocars are placed

TABLE 5 ■ Laparoscopic Radical Prostatectomy with the Heilbronn Technique—Technical Steps of the Procedure

1. Trocar placement	A "W"-shaped arrangement of the trocars with insertion of the first trocar following infraumbilical Hasson technique. A sixth 5-mm port was inserted in the right lower abdomen after creating Retzius' space
2. Exposure of Retzius' space	By high transection of the urachus and both lateral umbilical ligaments
3. Incision of endopelvic fascia and control of dorsal vein complex	Following incision of the endopelvic fascia, partial transection of puboprostatic ligaments and placement of back flow stitch, the dorsal vein complex is double-sutured with grasping of the needle at a 100-degree angle to the branches of the needle holder
4. Transection for urethra and nerve sparing (if required)	The urethra is incised at the level of apex, the periprostatic fascia is incised laterally, and the neurovascular bundles are exposed and dissected from the apical part of the prostate
5. Incision of bladder neck	The circumferential attachments between the bladder and the prostate are incised using bipolar and endoscissor after pulling ventrally of the apex
6. Division of cranial pedicles and dissection of seminal vesicles	Stepwise two or three lockable 10-mm polyurethane clips. After division of both vasa deferentia, finally the seminal vesicles are completely isolated and divided with clipping their vasculature
7. Urethrovesical anastomosis	Using the right-medial port IV (for the needle holder) and the left lateral port I (for endodissector) for an angle between the instruments (30–35 degrees). The anastomosis is performed by consecutive six interrupted suturing
8. Retriving the specimen	After placing of drainage tube via port IV under vision and fixed to the skin, now the prostate is extracted within the organ bag via peri the umbilical incision (site of trocar I)

into peritoneal cavity: a 5-mm trocar in the left iliac fossa midway between the left anterior-superior iliac spine and umbilicus, a midline 5-mm trocar between the umbilicus and symphysis pubis, a 5-mm trocar at the level of umbilicus localized at the lateral margin of the right rectus abdominis muscle, and for introduction of the needles and the entrapment sac a second 10-mm trocar in the right iliac fossa at McBurney's point. According to Guillonneau and Vallencien's standardized technique, the Montsouris technique is performed in seven steps (Table 6).

Posterior Approach

Step 1: Posterior Dissection of the Prostate
Dissection of the Seminal Vesicles
The retrovesical cul-de-sac is inspected and the first landmarks are the vas deferens behind the pertoneum and transverse semicircular peritoneal folds at the inferoposterior aspects of the bladder on both sides.

> The more superior of these peritoneal folds represents the approximate location of the ureters and should be avoided. The more inferior fold, nearly at the depth of the peritoneal reflection, is created by the meeting of the vasa deferentia in the midline, with the seminal vesicles lying just lateral.

The more superior of these peritoneal folds represents the approximate location of the ureters and should be avoided. The more inferior fold, nearly at the depth of the peritoneal reflection, is created by the meeting of the vasa deferentia in the midline, with the seminal vesicles lying just lateral.

As described by Abbou et al. (6) and Gill et al. (20), the sigmoid colon can be retracted cephalad with a stitch passed through an appendix epiploicae and brought out directly through the anterior abdominal wall and skin. Using electrosurgical endoshears a transverse peritoneotomy along the inferior peritoneal fold is created at the level of the second inferior peritoneal fold to reach the vas deferens and seminal vesicles. The vas deferens is cauterized or clipped and transected. At this point, the surgeon must be aware of the deferential artery that runs posterior along to the ductus and close to the seminal vesicle. This artery should be selectively coagulated and divided. Dissection and cephalad traction of the vas allows access to the ipsilateral seminal vesicles, which is mobilized circumferentially. The tip of the seminal vesicle, supplied by the vesicular artery, is located in close proximity to the neurovascular bundle. Excessive electrocautery in this area should be avoided in case of nerve-sparing technique.

TABLE 6 ■ Laparoscopic Radical Prostatectomy with the Montsouris Technique—Technical Steps of the Procedure

1. *Posterior dissection of the prostate*:	
Vas deferens and seminal vesicle dissection	A transverse peritoneotomy along the inferior fold is created at the retrovesical cul-de-sac to reach the vas deferens and seminal vesicles, which are mobilized following their arteries selectively coagulated and divided.
Opening Denonvilliers' fascia	The Denonvilliers' fascia is horizontally incised to expose the prerectal fatty tissue and to allow rectoprostatic cleavage to be extended downward until the levator ani muscles are reached.
2. *Anterior approach*:	
Development of space of Retzius	After making an inverted U-shaped incision, the urachus was divided. An avascular plane is developed on either side of the bladder and dissection is continued anterior and caudal as far as pubic bone.
Incision of endopelvic fascia	After the prostate is retracted to the contralateral and placing the ipsilateral endopelvic fascia on stretch, the fascia is incised on its line of reflection.
Ligation of the dorsal venous complex of Santorini	After placement of back flow stitch, the dorsal vein complex is double-sutured with grasping of the needle in a 100-degree angle to the branches of the needle holder.
3. *Bladder neck transection*	After incising, the fibrous fasica dissection is continued by following the detrusor muscle fibers where there is an avascular plane between the prostate and bladder until exposing the balloon of Foley catheter.
4. *Dissection of the lateral surfaces of the prostate*	The lateral pedicle then is meticulously and slowly divided close to the lateral border of the prostate using clip application and cold cutting.
5. Apical dissection of the prostate	
Section of the venous complex	Incision of venous complex is performed by first coagulating with bipolar forceps and then incising tangentially to avoid incision of the anterior surface of the prostate.
Incision of the *urethra*	The anterolateral urethral wall is incised with a cold knife or scissors. After the tip of urethral metal bougie is delivered through the anterior urethrotomy for exposing the posterior wall, the posterior wall of the urethra is incised similarly.
Incision of the rectourethral muscle	With gentle traction to the prostate superior, rectourethral muscle appears as the final attachment of the prostate and is then incised.
6. Urethrovesical anastomosis	Four sutures are placed at 4,8,2, and 10 o'clock positions and tied outside the lumen.
7. Eat from the abdominal cavity	Incisions are left open and a Drain introduced into the pelvis.

Opening Denonvilliers' Fascia

An important part of the posterior dissection represents the incision of Denonvilliers' fascia, which facilitates the dissection of the prostatic pedicles by taking the rectum away from the pedicles after bladder neck incision. To make the exposure easier, the bilateral completely mobilized seminal vesicles and vas deferens are retracted anteriorly and rectum is retracted posteriorly, thereby placing Denonvilliers' fascia on tension. A shallow incision is made and visualization of yellow perirectal fat confirms to entry into the correct plane between prostate and the rectum.

Step 2: Anterior Approach: Bladder Dissection

Development of Space of Retzius

Bladder dissection starts with an inverted U-shaped incision, lateral to the bladder contour but medial to medial umbilical ligament, which is extended inferior to the vas and superior to the abdominal wall. The horizontal part of the U-incision is located high on the undersurface of the anterior abdominal wall, cephalad to the dome of the bladder. An avascular plane is developed on either side of the bladder and dissection is continued anterior and caudal as far as pubic bone. At the end of this step, in the midline in the vicinity of the puboprostatic ligaments, a small pad of fat remains including superficial dorsal vein, which is thoroughly coagulated with bipolar electrocautery and transected.

After incision of endopelvic fascia, the dorsal venous complex of Santorini is ligated in the above-described way, similar to the Heilbronn technique following a back bleeding stitch placed across the anterior surface of the prostate using a similar needle. The tails of the back bleeding stitch are cut somewhat long because this suture is helpful during subsequent dissection at the bladder neck, as a locking grasping forceps can be fixed to the tags emanating from the suture knot that allows upward traction of the stitch later during the procedure.

Step 3: Bladder Neck Transection

The bladder is retracted cephalad holding from the long end of back flow stitch, thereby placing the anterior bladder neck on traction. To identify the bladder neck the anterior prevesical fat is retracted superior causing a faint outline of the prostatic vesical plane. After incising the fibrous fasica, dissection is continued by following the detrusor muscle fibers where there is an avascular plane between the prostate and bladder. The anterior wall is incised to expose the balloon of Foley catheter. The catheter balloon is deflated and catheter is pulled up into the abdomen to expose the lateral and posterior urethral walls, which are incised. The bladder neck is carefully preserved with the ureteral orifices far from region of dissection. The anterior layer of Denonvilliers' fascia is incised to enter the previously dissected retrovesical plane. The ductus deferens and seminal vesicles now are delivered through this opening and placed on anterior traction. The remainder of the attachments between the bladder and prostate are divided with electrocautery, maintaining hemostasis. The endpoint of the dissection bilaterally is the lateral pedicle of the prostate, which is anatomically identified by presence of yellowish perivesical fat.

Step 4: Dissection of the Lateral Surfaces of the Prostate

In the antegrade laparoscopic procedure the pedicles are exposed before being incised. A thin fat plane separates the prostatic vascular pedicles from the posterolateral neurovascular bundles. The pedicle is characterized by well-visualized arteries and veins.

At this stage of the technique, different strategies are performed depending on nonnerve-sparing versus nerve-sparing procedures.

Nonnerve Sparing

Bipolar coagulation, harmonic scalpel, or vascular clips (i.e., Hem-O-Lok clips) can be employed to transect the lateral pedicles widely. The ipsilateral seminal vesicle and ductus deferens are retracted anteriorly, placing the adjacent lateral pedicle on traction. Vascular clips or even an endo is consecutively placed across the lateral pedicle, away from and cephalad to the base of the prostate. After employing the clips or stapler, the lateral border of the prostate and neurovascular bundle from the perirectal fat is detached, thereby achieving a wide margin of excision. A similar maneuver is performed on the contralateral side, leaving the prostate attached only at the apex.

Nerve Sparing
Nerve sparing is performed in an antegrade fashion. The ipsilateral seminal vesicle and ductus deferens are retracted anteriorly, placing the lateral pedicle on traction. The lateral pedicle then is meticulously and slowly divided close to the lateral border of the prostate using clip application and cold cutting. To avoid thermal damage to the neurovascular bundle, the surgeon should avoid use of bipolar electrocautery. After division of the cranial pedicles dissection enters a pericapsular fatty space, that contains the neurovascular bundles, which must be preserved by lateral incision of a thin visceral fascia that covers the peribundle fat lateral and medial incision of the lateral edges of Denonvilliers' fascia. These incisions expose the neurovascular bundles and capsular arteries lateral, rising vertically into the prostate that must be clipped with 5-mm metal clips without coagulation to decrease the risk of thermal lesions. Dissection must be extended to the point where the bundles enter the pelvic muscular floor, which is posterolateral from the urethra.

Step 5: Apical Dissection of the Prostate
Division of the Venous Complex
Incision of venous complex is performed following additional bipolar coagulation and then incising tangentially to avoid incision of the anterior surface of the prostate.

An avascular plane of dissection separating the urethra from the venous complex must be found underneath the venous complex. This plane allows complete identification of the prostate limits and urethra.

Some authors prefer introducing a metal bougie into the urethra to facilitate the apical dissection and improve tactile perception of the urethral wall.

Incision of the Urethra
The anterolateral urethral wall is incised with a cold knife or scissors and the tip of previously introduced urethral metal bougie is delivered through the anterior urethrotomy to open the urethral lumen and expose the posterior wall. The posterior wall of the urethra is incised similarly with the endoscissors under traction.

Incision of the Rectourethral Muscle
Rectourethral muscle appears relatively attenuated with this approach and represents the final attachment of the prostate. Division of the rectourethral muscle close to the prostate completely frees the specimen. The excised prostate is entrapped immediately in an endobag, which is temporarily positioned in the upper abdomen.

Step 6: Urethrovesical Anastomosis
According to the authors with expertise in this technique, the preferred length of suture should equal 1.5 lengths of a laparoscopic trocar, working with two needle holders. Anastomosis is performed with interrupted 3-0 or 2-0 Vicryl on a No. 26 or UR-6 needle and all sutures are tied intracorporeally. The metal bougie with a depressed tip helps guide the needle into the urethra and the metal bougie can also help by allowing the needle to slide along the catheter. The first suture is placed at the 5 o'clock position, running inside out on the urethra (right hand, forehand). The second suture is placed at the 7 o'clock position, running inside out on the urethra (right hand, forehand) and outside in on the bladder neck (right hand, forehand). The two sutures are tied inside the urethral lumen. Then four sutures are symmetrically placed at the 4, 8, 2, and 10 o'clock positions, and tied outside the lumen similar to the Heilbronn technique.

Step 7: Exiting the Abdominal Cavity
Peritoneal incisions are left open and a drain is introduced into the pelvis through the lowest left port. Abdominal pressure is lowered to 5 mmHg to check for venous bleeding and trocar sites. The previously entrapped specimen is extracted through McBurney's incision.

TECHNICAL VARIATIONS

Trocar Positioning
In the Montsouris technique, the authors from Paris prefer the insertion of Veress needle to achieve pneumoperitoneum before placement of the first two 10-mm trocars.

> An avascular plane of dissection separating the urethra from the venous complex must be found underneath the venous complex. This plane allows complete identification of the prostate limits and urethra.

In contrast, in the Heilbronn and Creteil experiences, the authors prefer to place the first trocar (12 -mm) using an open Hasson technique at the infraumbilical location (6,21).

Position of the trocars is different in the Montsouris, Creteil, and Cleveland experience in spite of the same technique (7,20,22).

Montsouris Technique

After creating pneumoperitoneum with a Veress needle, a 10-mm trocar is inserted infraumbilically. The second 10-mm trocar is inserted at McBurney's point, to which the CO_2 line is connected. A 5-mm trocar is placed superomedial to the second trocar on the right pararectal line at the level of umbilicus. A 5-mm trocar is inserted in the left iliac fossa midway between the anterior-superior iliac spine and umbilicus. Finally, a midline 5-mm trocar is placed between the umbilicus and the symphysis pubis.

Creteil Modification

The Creteil technique comprises a 12-mm trocar at the infraumbilical location (open Hasson technique); a second 12-mm trocar, near to the lateral margin of the rectus sheath and just below the umbilicus on the surgeon's side; a 10-mm trocar, lateral to the rectus and just below the umbilicus on the assistant's side; and two 5-mm trocars on each side at the level of the anterior-superior iliac spine, just lateral to the epigastric vessels.

Cleveland Modification

The Cleveland variation includes a 12-mm trocar at the infraumbilical location; 10-mm trocars (as port 2 and 3) are on either side of the midline, positioned lateral to the rectus muscle bilaterally and approximately two fingers breadths inferior to the level of the umbilicus; and 5-mm trocars (as port 4 and 5) on either side in the left iliac fossa midway between the anterosuperior iliac spine and umbilicus.

Heilbronn Technique

The Heilbronn technique includes a 12-mm trocar at the infraumbilical location (open Hasson technique); 10-mm trocars (as port 3 and 4) on either side of the midline, positioned lateral to the rectus muscle bilaterally and approximately two fingers breadths inferior to the level of the umbilicus; 5-mm trocars (as port 2 and 5) on the either side of the anterior axillar line at the level of umbilicus; and a sixth 5-mm port in the right lower abdomen following access to the Retzius' space by high transection of the urachus and both lateral umbilical ligaments are employed.

Access in Laparoscopic Radical Prostatectomy

Laparoscopic radical prostatectomy represents a continuously evolving technique with no more than 6000 patients treated in Europe. As in the open retropubic approach different technical modifications have been introduced. Principally four different approaches can be distinguished: (i) transperitoneal descending prostatectomy with initial dissection of the seminal vesicles (Montsouris technique), (ii) transperitoneal ascending prostatectomy (Heilbronn technique), (iii) extraperitoneal descending technique (Brussels technique), and (iv) extraperitoneal ascending technique (modified Heilbronn technique).

Recently, comparable surgical results between extraperitoneal and transperitoneal laparoscopic radical prostatectomy have been published by experienced centers (23–25). However, there was no consensus: some authors (24,26) emphasized the advantages of the extraperitoneal approach (i.e., no bowel lesion, ileus, and peritonitis) and concluded that this technique is superior to the transperitoneal access. Other authors (25) could not find significant differences between both techniques and stated this as a "false debate."

According to the authors' experience comparing transperitoneal and extraperitoneal laparoscopic radical prostatectomy, there was no significant difference between extraperitoneal and transperitoneal approaches using the Heilbronn technique regarding all important parameters (27). In addition to the preference and experience of the individual surgeon, previous abdominal surgery, gross obesity, and requirement of simultaneous inguinal hernia repair may be considered as selective indications for extraperitoneal laparoscopic radical prostatectomy (Table 7).

Control of Vascular Structures

Adequate hemostasis is one of the most important prerequisites of the procedure. For this purpose, several techniques have to be mastered. Minor bleeders are controlled by

use of the bipolar forceps/dissector. We prefer the use of a bipolar dissector because it offers all functions of a normal dissector (i.e., grasping and retraction of tissue). The generator power should not increase 50 W to avoid secondary thermal lesions that could lead to a rectourethral fistula.

Especially on the side of prostatic pedicle control, several different instruments are preferred in different centers of excellence as listed below (6,7,20,28,29):

- Heilbronn technique: Bipolar endodissector combined with Hemo-O-Lok vascular clips.
- Cleveland technique: Endo-GIA vascular staplers (white color, 3.5 mm and gray color, 2.5 mm) for nonnerve-sparing approach; Hemo-O-Lok clips for nerve-sparing approach.
- Montsorius and Creteil techniques: Bipolar endodissector combined with Hemo-O-Lok vascular clips.
- Berlin technique: Ultrasonic endoscissor.

Anastomosis

In the Creteil technique, main difference is that these authors use a single circumferential running suture for urethra-vesical anastomosis instead of interrupted sutures (30). A starting knot is performed at the 3 o'clock position outside-in fashion forehand with the right needle holder on the bladder neck and inside-out on the urethra. The short tail of the suture is not cut because it will serve to knot the running suture when it is completed. The posterior half of the running suture consists of 4 to 5 needle passages. After performing the anterior half of the running sutures, anastomosis is completed by knotting at the 3 o'clock.

Recently, van Velthoven et al. (31) described a technique for facilitating the urethrovesical anastomosis. Two 6-inch sutures (3-0 Vicryl with SH or UR-5 needle) are tied together at their tail ends and delivered into the operative field by way of a 12-mm port. The running sutures is initiated by placing both needles outside-in through the bladder neck and inside-out on the urethra, one needle at the 5:30 position and the other needle at the 6:30 position. A running suture is completed from the 6:30 to the 12:00 o'clock position and from the 5:30 to the 12:00 o'clock position, at the end of which a single intracorporeal tie is completed.

As described previously, in Heilbronn technique (Table 4), the authors are used to outside knotting for all stitches, whereas the Cleveland and Montsouris groups prefer inside knotting at 5 and 7 o'clock (7,20).

TABLE 7 ■ Advantages and Disadvantages of Both Accesses and Techniques

Extraperitoneal LRP	Transperitoneal LRP	Descending approach	Ascending approach
Advantages		*Advantages*	
No contact with bowel	Larger room	Less bleeding	Similarity of open counterpart

RESULTS

Perioperative Outcomes

Guillonneau and Vallancien used transperitoneal access to the seminal vesicles followed by a descending radical prostatectomy starting the dissection at the bladder neck (7). The Heilbronn technique was designed to copy the standardized technique of open anatomic radical prostatectomy starting with an ascending part controlling Santorini's plexus, dividing the urethra and the distal pedicles followed by a descending part with transection of the bladder neck and transvesical access to the seminal vesicles (29). Corresponding to the experience with open surgery, the descending technique initially offers the advantage of less blood loss because of the earlier control of the proximal prostatic pedicles and the late transection of the dorsal vein complex. However, we could demonstrate that with evolution of our technique and increasing experience, we were able to decrease significantly our transfusion rate (Tables 8 and 9). In our opinion, the ascending technique offers some advantages over the descending technique, such as early identification and detachment of the neurovascular bundle and optimal exposure of the bladder neck, the seminal vesicles, and prostatic pedicles.

As with other laparoscopic procedures (i.e., radical nephrectomy), initially the operating time was significantly longer ranging from 4 to 5.4 hours in the first series. If one renews all of our 1010 cases, the operating time continuously decreased, down to 3.5 hours (2.2–5.4 hours) in our last 100 cases. For the open radical prostatectomy, Scardino's group reported a mean operating time of three hours during the period 1990–1994 decreasing from 3.6 hours in the first to 2.8 hours in the last year of his study. This means that they could reduce their operating time during four years performing 472 cases by 47 minutes or 21.7% of the initial time. With our 1010 patients, we needed a five-year period (1999–2004) for a 100-minute reduction of the operating time including pelvic lymph node dissection from 5.2 to 3.5 hours corresponding to 32.1% of the initial time. This is similar to the experience of the French centers. Therefore, it can be anticipated that a further reduction of operating time will occur in all laparoscopic series of experienced centers, which will also increase the financial benefit of the operation (Table 9).

The most relevant advantages of laparoscopic radical prostatectomy should be documented in a decrease of associated morbidity and shorter convalescence compared to open surgery (Table 10).

There is no doubt that these questions can only be answered definitively by a prospective randomized study. However, the comparison of early results of

> The most relevant advantages of laparoscopic radical prostatectomy should be documented in a decrease of associated morbidity and shorter convalescence compared to open surgery.

laparoscopy to recent data of experienced centers already documents considerable differences with respect to the rates of early and late complications in favor of laparoscopic radical prostatectomy. These differences are caused mainly by the lower rate of anastomotic, thromboembolic, and wound-related complications after endoscopy. Additionally, if the initial development phase, and the learning curve of laparoscopic radical prostatectomy, are taken into consideration, these differences may become even more pronounced.

Pathological Assessment of Follow-Up

Cure of the treated localized prostate cancer represents the first goal of radical prostatectomy as mentioned in the first part of this chapter. Because of the limited follow-up, laparoscopic radical prostatectomy can only provide short-term results. All of the few published series report only on a three-year progression-free survival (Table 11). On the other hand, the evaluation of the oncologic outcome of recent technical modifications of open radical prostatectomy can only be based on a similar follow-up. Since the overall results of the different series mainly depend on the case selection (i.e., with or without adjuvant radiation or antiandrogen therapy), we have

Rassweiler et al. (present series)	1500	22.5	5.9		34.2	50.8	58.7	16.0	9.6

analyzed the current literature with a stratification according to the pathologic stage (pT2 vs. pT3).

For an objective evaluation of the positive margins, the specimen should be inked with two different colors for each lobe and examined with gross sections according to the Stanford protocol (41). In our routine follow-up protocol, the prostate-specific antigen was determined on the 10th postoperative day, after three weeks, and then every three months. If not performed in our laboratory, the data were obtained by telephone contact or transmitted via fax from the referring urologist. In the studies of the literature, patients were usually followed every three months in the first year, and every six months until year 5 (42–45).

> We could not detect a significant difference when comparing the rate of positive margins after open or laparoscopic radical prostatectomy, neither for pT2 stages (2.1–16.4% vs. 7.4–21.9%) nor for pT3 tumors (26.4–67.7% vs. 31.1–45.7%).

We could not detect a significant difference when comparing the rate of positive margins after open or laparoscopic radical prostatectomy, neither for pT2 stages (2.1–16.4% vs. 7.4–21.9%) nor for pT3 tumors (26.4–67.7% vs. 31.1–45.7%).

However, there is a remarkable range in the different series. A recent paper found a higher positive margin rate (34% vs. 19%) after laparoscopic radical prostatectomy among junior surgeons compared to experienced surgeons (39). In our recently published comparative study, the overall rate of positive margins (SM+) did not differ significantly (28.7% vs. 21.0% vs. 23.7%) in the open versus the early and late laparoscopic groups (37). Similarly, no significant difference in the rates of positive surgical margin with 16.9% and 20% has been reported between biopsy grade and clinical stage-matched laparoscopic and open radical prostatectomy (46). However, there was significant difference in location at apex with 5.1% vs. 11.7% ($p < 0.05$) and multiple positive margin locations with 0% versus 8.3%. On the other hand, Katz et al. (47) were able to reduce the rate of positive margins continuously after technical changes of laparoscopic radical prostatectomy.

> Wide resection of the bladder neck and cutting the puboprostatic ligaments decreased bladder neck and apical positive margins. In accordance to our own observation, nerve preservation did not increase the incidence of positive margins.

Wide resection of the bladder neck and cutting the puboprostatic ligaments decreased bladder neck and apical positive margins (47). In accordance to our own observation, nerve preservation did not increase the incidence of positive margins.

Prostate specific antigen relapse, defined as increase of serum levels more than 0.2 ng/mL, was observed in 4.1–11.0% of pT2 stages and 12.0–43.2% of pT3 tumors three years after laparoscopic radical prostatectomy (Table 11). In our first 500 patients followed up for five years, the overall progression-free survival rate was 82.5%, while prostate specific antigen-relapse rates were 15.8%, 19.2%, and 45.5% for pT2, pT3a, and pT3c/4, respectively (Table 12). As mentioned before, only a few centers are able to provide such results. Oncologic studies after open prostatectomy usually present a longer follow-up ranging from five to 15 years. When we have analyzed the Kaplan–Meier curves of the respective studies to calculate three years' results, this revealed similar results for open radical prostatectomy (pT2: 3.7–15%; pT3: 14.7–33.1%) compared to the laparoscopic group (14). The data about clinical progression could not be compared because of the different follow-up and presentation.

> Current data indicate that the oncologic outcome after laparoscopic radical prostatectomy will not differ from open surgery. Most importantly, recent studies could not detect any specific oncologic risk related to the laparoscopic technique, such as port site metastases.

Current data indicate that the oncologic outcome after laparoscopic radical prostatectomy will not differ from open surgery. Most importantly, recent studies could not detect any specific oncologic risk related to the laparoscopic technique, such as port site metastases (48).

In summary, we did not detect any significant differences with respect to positive margins and short-term PSA recurrence comparing laparoscopic versus open radical prostatectomy. Of course, we have to wait for the long-term results of laparoscopy. However, until now there are no results indicating specific risk factors or deterioration of the oncologic outcome in comparison with open surgery.

Functional Assessments and Outcomes

Urinary incontinence and erectile dysfunction are the two most frequent and most disabling functional sequelae.

Recovery of Continence

The quality of continence after any technique of radical prostatectomy (i.e., retropubic, perineal, laparoscopic) is difficult to assess, as reflected by the marked variability of incontinence rates reported in the literature. This is related to three main factors: definition of continence, modalities of evaluation, and follow-up.

The definition of continence varies considerably from one pad study to another: total absence of protection (i.e., no pad) or use of a maximum of one pad (i.e., safety pad). Others distinguish between diurnal and nocturnal continence. Geary et al. (49) reported that 80.1% of patients did not require any protection, while Eastham et al. (50), considering patients who required a maximum of one pad daily to be continent, reported a rate of 91%. It might not be extremely relevant for the quality of life of the patients to wear a safety pad (i.e., to be "socially dry"), and some patients may still use one despite having reached already complete continence.

In most laparoscopic and open studies (Table 13), full continence was defined as no need of any pads during normal daily activity (i.e., work, exercise, walking), no urine leak with cough or sneeze. Minimal stress incontinence was defined as occasional urine leak (i.e., when exercising, with cough or sneeze) necessitating no more than three pads per day and no urine leak during night. Moderate stress incontinence was defined as urine leak during the day under normal activity requiring more than three pads, and no urine leak during night. Severe stress incontinence was defined as urine leak during the day and night representing a serious problem for the patient.

The modalities of evaluation also differ considerably: clinical interview by the surgeon, interview by another doctor not involved in the surgery, self-administered questionnaire. The method of data collection is essential to obtain perfectly objective information. Again an increase by 10–15% of incontinence rates has to be calculated, when using a questionnaire (36,59,60). Evidently, the general application of a validated questionnaire (i.e., Interrehand Continence Society-Male Questionnaire) would facilitate comparison of the various results reported in the literature (61). It has to be emphasized that in most of the laparoscopic studies a questionnaire was applied. In our center, all patients who do not return the questionnaire are interviewed by colleagues not involved in the surgery. Additionally, the time to full continence is documented for each patient.

Finally, the follow-up frequently differs from one series to another. Although about half of the patients can achieve full continence within the first three months and

> The definition of continence varies considerably from one study to another. Such different definitions usually contribute to a difference of about 10% in continence rates.

most are dry at one year, some patients can still recover for up to two years (Table 14) with significant impact on their quality of life. Thereafter, improvement of urinary function is unlikely to occur.

Furthermore, independently of the technique, the main predisposing factor for postoperative incontinence appears to be greater than 70 years (49,52,53,61). The respective roles of other factors, such as stage of disease, associated diseases (i.e. diabetes, polyneuropathia, smoking), postoperative extravasation, or anastomotic stricture are also discussed (49,50,63).

Apart from this, some authors, again independent from the approach, consider that certain technical modifications appear to facilitate preservation of continence: quality of apical dissection, preservation of puboprostatic ligaments, preservation of bladder neck or the neurovascular bundle (55,63–65). The impact of such surgical modifications on postoperative continence is evident but very difficult to evaluate.

There is no doubt that in this millennium every "radical prostatecomist"—be it an open surgeon or a laparoscopist—tries to perform a most delicate apical dissection with maximal preservation of the circumferential rhabdosphincter muscles and minimal damage to its surrounding structure. On the other hand, all further technical proposals, such as preservation of the bladder neck or puboprostatic ligaments, preservation of the intrapelvic branch of the pudendal nerve, reconstruction of the rectourethralis muscle or facial retrourethral structures are still under debate, mainly because the initially described quicker time to total continence turned out not to be constantly reproducible (55,63–65).

TABLE 14 ■ Laparoscopic Radical Prostatectomy: Development of Continence (Compared with Open Radical Prostatectomy)

[a]Follow-up at 18 months.
Abbreviation: NA, not available.

In summary, there are no significant differences between the laparoscopic or open approach, neither with respect to overall 12 months continence (60–94% vs. 61–98%) nor regarding the three months continence (51–63% vs. 62–69%), as postulated by some authors.

Conclusively, it is not the approach but the experience of the surgeon that remains one of the most essential factors to improve the recovery of continence.

The most successful tool to evaluate erectile dysfunction proved to be the abridged, five-item version of the International Index of Erectile Function.

In summary, there are no significant differences between the laparoscopic or open approach, neither with respect to overall 12 months continence (60–94% vs. 61–98%) nor regarding the three months continence (51–63% vs. 62–69%), as postulated by some authors.

Based on the actual results, laparoscopic surgery enables the transformation of all technical variations proposed for open radical prostatectomy, but despite all efforts could not yet significantly improve early continence rates in comparison to open surgery (49,50,53–55,62–65).

Conclusively, it is not the approach but the experience of the surgeon that remains one of the most essential factors to improve the recovery of continence. The cases of later recovery of continence are mainly attributed to associated factors such as age or concomitant morbidity of the patient.

Recovery of Sexual Potency

As for continence, objective evaluation of postoperative erectile dysfunction encounters a number of difficulties:

1. Absence of a consensual definition of sexual potency in the studies
2. Various methods of evaluation
3. Difficulties of evaluation
4. Variable follow-up

The definition of sexual potency varies according to the adopted criteria, such as erection without intercourse (i.e., return of erection) or erection firm enough for intercourse. Moreover, the frequency as well as quality of sexual activity has been recorded (66).

The most successful tool to evaluate erectile dysfunction proved to be the abridged, five-item version of the International Index of Erectile Function (67).

Hara et al. were able to demonstrate its applicability when comparing the quality of life after open and laparoscopic radical prostatectomy. They found a significant impairment of sexual function by surgery with no difference between the laparoscopic or open approach (68). Additionally, the quality of erection should be classified according the international classification (E1-5) distinguishing between tumescence (E2-3) and rigidity (E4-5).

The methods of evaluation of sexual potency are also very heterogeneous including clinical interview by the surgeon, interview by another physician, or a self-administered questionnaire (Table 15). The additional use of oral, intraurethral, or intracorporeal therapy of erectile dysfunction, particularly in the early postoperative phase (i.e., intracorporeal injection therapy to expedite recovery of erection) makes it difficult to compare the various series. In laparoscopic radical prostatectomy with the

Heilbronn technique, our results of erectile response during sexual intercourse with or without using intracavernosal injection in patients who underwent bilateral and unilateral nerve sparing are given in Table 16. Moreover, in contrast to urinary continence, spontaneous sexual potency is difficult to assess objectively (65). Rigiscan studies may provide insight into the organic basis of postradical prostatectomy erectile dysfunction, but are not yet a routine part of evaluation (71).

Follow-up again represents an important parameter in this evaluation. While a large number of series have demonstrated the possibility of late recovery, most studies are limited to a relatively short follow-up. There is a consensus that the assessment of recovery of sexual function requires a follow-up of at least 18 months (71). According to this, Litwin et al. (72) found little additional recovery in the sexual domains after 18–24 months. Although the nerves are optimally preserved during nerve-sparing surgery, they usually are damaged by direct trauma or by stretch injury during intraoperative retraction. This is reflected again by the study of Hara et al. (68), showing a significant impairment of sexual life by surgery without any difference between laparoscopy and open prostatectomy. These damaged nerves need time to heal. Restoration of the neuron occurs from the point of injury to the target organ at a rate of 1 mm per day.

Like for recovery of continence, several authors have published some technical steps that may improve the results of nerve-sparing surgery, such as the use of water-jet dissection, the early detachment of the neurovascular bundle before division of the urethra to avoid any traction on the neurovascular bundle or monopolar coagulation close to the bundles and the tip of the seminal vesicles, and the preservation of the accessory pudendal arteries (70,73–75).

Other factors influencing the operative results have also been considered: the quality of erections before surgery, patient's age, and the type of surgery. It is very important whether the surgeon is able to preserve both or only one neurovascular bundle. In our previously published review, we focused mainly on the results of bilateral nerve sparing (Table 15). The long-term outcome of sural nerve-grafting (which has also been realized laparoscopically) still remains an open question (70–73). All comparative analyses should also focus on the selection of patients (i.e., less than 65 years, potent, with sexual interest, low-stage, low-grade tumor) in the different series. Some authors postulate that nerve-sparing surgery should only be limited to patients aged less than 60 or even 55 years (76).

In summary, there are no significant differences between the laparoscopic or open approach concerning the recovery of potency (34–67% vs. 31–79%), if one excludes the selected series of Walsh with a mean age of 57 years (Table 15).

Again, laparoscopic surgery enables the transformation of all technical variations proposed for open radical prostatectomy, but despite all efforts could not yet significantly improve potency rates in comparison to open surgery. Conclusively, not the approach but the experience of the surgeon still remains one of the most essential factors to improve the recovery of potency. The cases of failed recovery of potency are mainly attributed to associated factors such as age or concomitant morbidity of the patient.

Early outcomes have indicated that once the learning curve is established, transperitoneal laparoscopic radical prostatectomy is at least equivalent to open radical prostatectomy in terms of early oncological outcomes continence and potency rates, and operation times.

> In summary, there are no significant differences between the laparoscopic or open approach concerning the recovery of potency (34–67% vs. 31–79%), if one excludes the selected series of Walsh with a mean age of 57 years.

TRAINING

Training for Vascular Control and Reconstructive Parts of Laparoscopic Radical Prostatectomy

In spite of the increasing number of laparoscopic operations performed worldwide, the issue of how to teach and train laparoscopy has not been solved. In our opinion, today's residents should be exposed to standardized training programs in laparoscopy from the beginning of their residency so that they gain experience in laparoscopic surgery and open surgery both. Training by experienced laparoscopic surgeons will enable residents to deal with intraoperative complications laparoscopically without the need for conversion to open surgery. We believe that urologic surgeons who wish to practice laparoscopic surgery and who have not been exposed to laparoscopic surgery should get their training in a laparoscopic center. Because of the long learning curve, especially for reconstructive laparoscopy, this training period should be at least several months before being able to practice reconstructive laparoscopy. For this purpose, the standardized Heilbronn laparoscopic training program is described.

Training Program

In a closed pelvic trainer, six different models were used to simulate and exercise reconstructive procedures. In step I, we used a two-row construction of four pins. In each row the middle pins had ring heads, the lateral pins had L-shaped hooks. This model allowed to practice hand–eye coordination under two-dimensional vision. In steps II and III, suturing and knotting activities were performed using a chicken leg to imitate human tissue (the different incisions and positions of the chicken leg allowed practice in changing angles of the needle, as needed in intracorporeal suturing). A bone and soft tissue model (chicken leg) was used in step IV; the bone part made it necessary to pass the needle above the bone through the soft tissue in the fashion that the needle was used to perform the stitch ligating the Dorsal-vein complex. In step V, we used a tubular structure (20 Chr. silicone catheter) to exercise interrupted sutures at the edges in 3, 5, 6, 7, 9, and 11 o'clock positions. In step VI, a urethrovesical anastomosis was simulated in a porcine bladder model. The anastomosis was performed the same way as in our laparoscopic prostatectomy starting with the 6 o'clock stitch and continuing clockwise. The pelvic trainer was used in combination with a standard two-dimensional video technology. Suturing was performed with a needle holder and an endodissect using 3-0 Vicryl suture filaments (15 to 17 cm). Only curved needles were used (RB needles) in our operating room for performing the urethrovesical anastomosis.

We used a defined standard position of the instruments (distance between trocars 12 cm, intracorporeal instrument length 25 cm, angle between the instruments and the horizontal line 55 degrees, middle position of the object, middle camera position, diameter of 25 cm available for motion of the instruments, angle between the instruments <45 degrees) (77).

Definition of Task Goals

Expert laparoscopic surgeons in our hospital (defined as those who performed advanced laparoscopic procedures, i.e., pyeloplasty, radical prostatectomy, radical cystectomy, and retroperitoneal lymph node dissection), developed the various stages of the training program in order to define the expert level time for each stage. The average time of the results for each step were multiplied by the factor 2 and defined as task goals (double expert time) for the participants. Due to this, the time frames 3, 15, 15, 10, 20, and 30 minutes for step I, II, III, IV, V, and VI, respectively, have become the student's goal to reach before proceeding to the next stage.

Each training session time had to be recorded to calculate the needed time for reaching the expert level in each stage and for completing the entire program. As mentioned previously, the training program is planned to expose the participant gradually to more and more advanced tasks in laparoscopy. After reaching the expert skill level, which will be proved by a standardized test, they will be able to proceed to the next step until being able to participate in laparoscopic operations (Table 17).

Influence of the Program to Reconstructive Dexterity

A complete stitch contains two parts, the suturing part and the knotting part. Due to the two-dimension vision the inverted manipulation is the suturing part; especially the right positioning of the needle into the needle holder is a challenging procedure.

TABLE 17 ■ Model, Purpose of Each Step, and Required Time in Laparoscopic Training

	Model	Purpose	Time (min)
Step I	Two-row pin construction	Hand–eye coordination under two-dimensional vision passing a rubber band through the pins	3
Step II	Chicken leg: linear incision	Simple linear cutting, suturing, and knotting	15
Step III	Chicken leg: curved incision	Curved cutting, suturing (with changing angels of the needle) and knotting	15
Step IV	Chicken leg: dorsal-vein complex-simulation	Suturing with a pronation movement of the needle imitating the dorsal-vein complex stitch	10
Step V	Tubular structure	Circular suturing and knotting	20
Step VI	Porcine urethra	Urethrovesical anastomosis	30

Therefore, two parts of the program were examined more accurately concerning the influence of training to increase reconstructive capability.

Step IV (dorsal-vein complex simulation) and the 6 o'clock stitch (step V) were analyzed regarding the suturing and knotting parts. There was a significant decrease in total time required for a single stitch before and after the training. Training of reconstructive procedures decreased the total time by 55.7% for step IV (mean, 18 vs. 7.5 minutes) and by 52% for the 6 o'clock stitch (mean, 206 vs. 102.5 seconds). The mean time required for a single 6 o'clock stitch was 206 seconds before training and 102.5 seconds after training ($p \leq 005$). The same applied to the needed time to succeed step IV (before training 18 minutes and after finishing the program 7.5 minutes, $p \leq 0.05$).

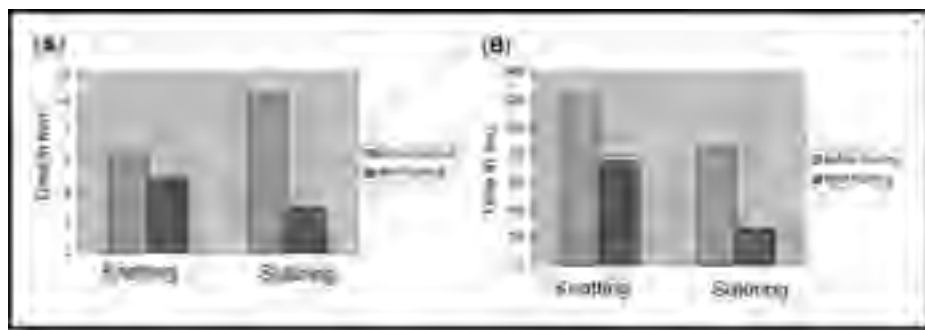
The time for the suturing part (especially the ideal positioning of the needle) could be decreased in step IV by 72.2%, whereas the improvement of the knotting part was 34.3% (Fig. 1A and B). Accordingly, in the 6 o'clock stitch, the suturing part decreased by 66.3%, the knotting part only by 38.2% (78).

Our study (78) showed that, after passing the training program, all trainees decreased the time for succeeding each task compared to their baseline. Due to this, all participants were able to perform a safe urethrovesical anastomosis reproducible in less than 30 minutes at the end of the program. The mean time for reaching this level required 40 hours of practice. In this context, it might be interesting to note that the time for an urethrovesical anastomosis in the clinical setting (laparoscopic radical prostatectomy) ranges between 2 and 40 minutes.

> Results of our study indicate that the especially challenging parts of reconstructive laparoscopy, such as intracorporeal suturing with the right angle of the needle in relation to the model and the needle holder, can be learned by using specially designed tasks.

Results of our study indicate that the especially challenging parts of reconstructive laparoscopy, such as intracorporeal suturing with the right angle of the needle in relation to the model and the needle holder, can be learned by using specially designed tasks.

This preclinical part of our training program is followed by clinical training in the operating rooms, including the first and second assistance and performing different parts of each laparoscopic procedure under supervision. This training runs at least three and up to 12 months.

FIGURE 1 ■ **(A)** Comparison of mean required time (separately for suturing and knotting) performing step IV (Dorsal-vein complex-simulation). Influence of training on suturing and knotting performance. **(B)** Comparison of mean required time (separately for suturing and knotting) performing the 6 o'clock stitch (step V). Influence of training on suturing and knotting performance.


SUMMARY

- The goals of laparoscopic radical prostatectomy, as in retropubic radical prostatectomy, are lifelong oncologic control of localized prostate carcinoma while minimizing operative morbidity, maintaining continence, and preserving potency.
- Laparoscopic radical prostatectomy has become a worldwide accepted alternative to open surgery.
- The indications for radical laparoscopic prostatectomy are the same as that for the open procedure including treatment of men with localized prostate carcinoma and life expectancy of 10 years or more.
- Compared to open surgery, the most relevant advantages of laparoscopic radical prostatectomy are decreased morbidity and shorter convalescence.
- The authors could not detect a significant difference when comparing the rate of positive margins after open or laparoscopic radical prostatectomy, either for pT2 or for pT3 stage tumors.
- Wide resection of the bladder neck and cutting the puboprostatic ligaments decreased bladder neck and apical positive margins (47). Nerve preservation does not increase the incidence of positive margins.
- Oncologic outcome after laparoscopic radical prostatectomy will not differ from open surgery. No specific oncologic risk such as port site metastases correlates to the laparoscopic technique.
- There are no significant differences between the laparoscopic and open approach either with respect to overall 12 months continence or regarding the three months continence.
- There are no significant differences between the laparoscopic and open approach as regards recovery of potency.
- Early outcomes have indicated that once the learning curve is established, transperitoneal laparoscopic radical prostatectomy is at least equivalent to open radical prostatectomy in terms of operation times, early oncologic outcomes, and continence and potency rates.

COMMENTARY

Guy Vallancien
Institut Montsouris, Université Pierre et Marie Curie, Paris, France

The paper presented by Jens Rassweiler and the group at Heilbron is an excellent review on the state of the art of transperitoneal laparoscopic radical prostatectomy. The author gives accurate results of the different techniques for this procedure.

As Rassweiler highlights, it is difficult to provide an accurate measure of potency and successful sexual intercourse in this patient population. It is, indeed, impossible to compare results between academic groups. Accurate results of sexual function and urinary incontinence can only be obtained if an academic group evaluates another group's patient population by the International Continence Society questionnaire and the IIEF5 questionnaire. Furthermore, to help minimize any potential bias, only questionnaires filled in at the patient's home should be used to evaluate these outcomes. Nevertheless,

potency results are improving every year. These improvements are the result of both bilateral nerve sparing and oral phosphodiesterase-5 inhibitor therapy started a few days after surgery.

Laparoscopy, despite its technical difficulty, material investment, and longer operating times, provides patients with less pain and a rapid recovery. These are the reasons surgeons learn to be laparoscopists. In urology, we have no validated outcome measures to compare open versus laparoscopic prostatectomy. However, an excellent clinical observation can be made. With open surgery, our patients are unable to mobilize without a pillow on their abdomen and someone to help them. They cannot laugh or cough without pain. After laparoscopy, however, when you knock at the door, the patient gets up from his chair, and with a large smile comes to greet and congratulate you.

As for technical training, it is important that young surgeons understand that a laparoscopic prostatectomy should not be attempted after participating in a postgraduate course and watching the operation on video. Laparoscopic skills can only be acquired at a significant laparoscopic center where these procedures are performed on a daily basis. The young surgeon needs to practice for hours to master knot tying and suturing. These skills can be acquired on cadavers, animal models, or the pelvitrainer. Only then will he or she have the skills to operate successfully on patients. Furthermore, in my opinion, a successful laparoscopic prostatectomy requires only scissors, two graspers, two bipolars, and one aspirator. There is no need for additional instruments.

As for the future of urologic surgery, I expect within the next 10 years, most surgeries will be done laparoscopically. This movement will be driven by the next generation of urologists who have understood the benefits of laparoscopy and its future in urologic surgery and who are ready to make the commitment to excellent surgical training.

LAPAROSCOPIC RADICAL PROSTATECTOMY: EXTRAPERITONEAL TECHNIQUE

INTRODUCTION

Following the pioneering work of Schuessler et al. (1), laparoscopic radical prostatectomy was propagated mainly using transperitoneal approach (2–4). Most laparoscopic centers, including ours, considered that primary access to the seminal vesicles was the key step of this technique (2–5). However, some concern has been voiced because this technique transformed a traditionally extraperitoneal procedure (open retropubic or perineal radical prostatectomy) into a transperitoneal one, with unique potential complications (6–8).

In 1997, Raboy et al., (9) described a modification of this procedure, the extraperitoneal approach, which was later developed by Bollens et al. (10,11).

Following Bollens et al.'s experience, we started performing laparoscopic radical prostatectomy in 1998 using the transperitoneal approach, and we switched to the extraperitoneal approach since 2002 (10,11). Other teams embarked in this approach since then (8,12).

Our preliminary results with extraperitoneal technique convinced us to further develop this approach, abandoning the transperitoneal technique (13). Between February 2002 and May 2004, we performed more than 300 laparoscopic radical prostatectomy via this extraperitoneal approach. Herein, we describe our standardized extraperitoneal laparoscopic radical prostatectomy step by step.

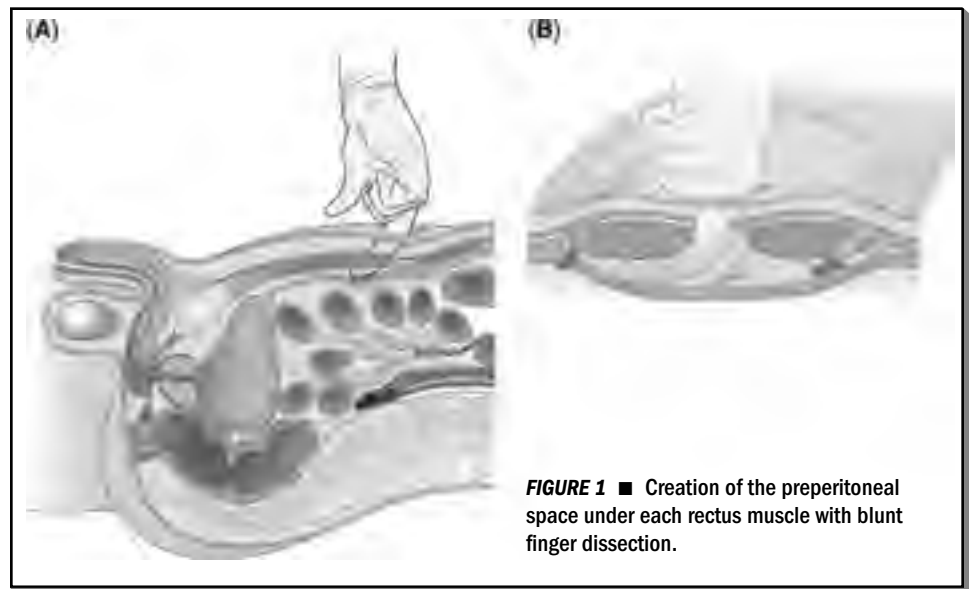
OPERATIVE TECHNIQUE

Patient Positioning

The patient is placed in dorsal decubitus with well-protected arms extended along the body. The legs are placed in a slight abduction to permit digital rectal examination during the procedure. After undergoing a standard iodine skin preparation, the patient is sterilely draped and a 20 French Foley catheter is inserted into the bladder. The surgeon stands on the left side of the patient and two assistants on the other side.

Step 1: Access to the Preperitoneal Space

A midline 3 cm incision is made transversally 1 cm inferior to the umbilicus. The subcutaneous tissue is divided down to the anterior rectus fascia. The anterior rectus fascia is then incised transversally to identify the inner borders of the rectus muscles separated by the linea alba. The index finger is introduced medially under the rectus muscle and along the posterior rectus sheath (Fig. 1). A blunt finger dissection is performed to create a space extending superiorly from the level of the skin incision to the lateral border of the rectus muscle. This space is limited caudally by the arcuate line of Douglas, posteriorly by the posterior rectus sheath, anteriorly by the posterior fibers of the rectus muscle and medially by the linea alba (Fig. 2). The same step is performed on the other side. At this stage, two spaces are created under each rectus muscle and separated by the linea alba.

FIGURE 1 ■ Creation of the preperitoneal space under each rectus muscle with blunt finger dissection.


The linea alba is then incised in contact with the anterior rectus fascia (Fig. 3). The disruption of linea alba is continued by the index finger as far as possible toward the symphysis pubis. At the end of the blunt finger dissection, a large preperitoneal space is created.

Step 2: Trocar Placement

Trocars No. 1 and No. 2 are inserted under digital guidance laterally to the rectus muscles (Fig. 4). A Hasson canula (Bluntport[®a]) is inserted into the initial subumbilical incision and secured with stay sutures (trocar No. 3). Insufflation is initially performed at 18 mmHg. A conventional 0° laparoscope is placed in trocar No. 3.

Under laparoscopic vision, the incision of the linea alba is completed to the symphysis pubis. The Retzius space is opened and the prevesical space is developed laterally. The anterior aspect of the bladder, the pubic arch and the external iliac vessels are visualized. Development of the preperitoneal space is then performed laterally to the epigastric vessels, easily identified on the posterior aspect of the rectus muscles (Fig. 5). On both sides, the space is completed between the spermatic cord and the epigastric vessels in contact with the abdominal wall. The peritoneum is forced back. Under vision, trocars No. 4 and No. 5 are inserted in the iliac fossa 3 cm inside the anterior

FIGURE 2 ■ End of finger dissection: index finger can move in a large preperitoneal space.

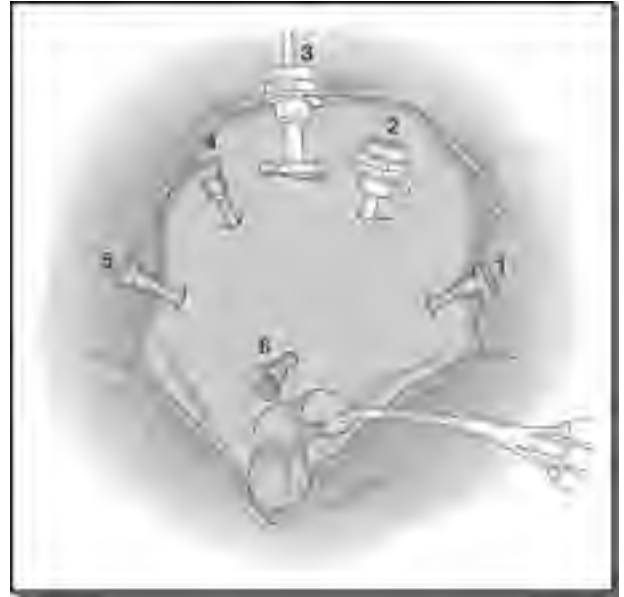

FIGURE 4 ■ Trocar positioning: No. 1, No. 4, No. 5, and No. 6: 5-mm trocars; No. 2: 12 mm (Versaport®[b]); No. 3: 12-mm trocar (Bluntport).

superior iliac spine (Fig. 4). Insufflation pressure is lowered to 12 mmHg and table is set in a 20° Trendelenburg position.

The two previous steps, i.e., space creation and trocar insertion, can be performed more efficiently and quickly using the balloon-trocar. As such, the initial incision and the digital dissection between the rectus muscles and their posterior sheath are done the same way as described above. Then, the balloon-trocar is inserted on the left side; the tip of the trocar is directed toward the anterior superior iliac spine, and the balloon is inflated with approximately 3 L of air. Under laparoscopic control, the symphysis pubis, the epigastric vessels, and the spermatic cord are clearly seen. The same maneuver is repeated on the right side. Then, a 12-mm trocar is placed through the umbilical incision and the secondary trocars are inserted under laparoscopic control after insufflation.

FIGURE 5 ■ Development of the extraperitoneal space laterally to the epigastric vessels.

[b]U.S. Surgical Corp., Norwalk, CT.

Step 3: Pelvic Lymph Node Dissection

Pelvic lymphadenectomy is performed if indicated. The technique is identical to pelvic lymphadenectomy performed during radical retropubic prostatectomy, with identical anatomical landmarks. The dissection of the inner border of the external iliac vein is bilaterally extended from the pubic arch to the vas deferens.

An accessory obturator vein is often found near the pubic arch, which may either be preserved or divided between hemostatic clips.

All tissues medial to the external iliac vein are dissected. The vein is then retracted laterally and dissection is completed to visualize the lateral wall of the pelvis. More posteriorly, the obturator nerve is exposed. The strip of lymph node tissue, starting distally with the lymph node of Cloquet is divided between clips in contact with the pubic arch. The lymphatic tissue with obturator nodes is then pulled upward with a locking grasper. The proximal dissection is performed as far as possible in order to include hypogastric nodes. An endoscopic bag is passed through trocar No. 2. The two specimens are placed in the bag and sent for frozen section analysis.

Step 4: Incision of the Endopelvic Fascia and Dissection of Santorini's Plexus

The fatty tissue is swept cephalad and lateral from the endopelvic fascia and from the anterior surface of the prostate. At this point, the superficial dorsal vein is coagulated and divided. On both sides, the endopelvic fascia is incised toward the puboprostatic ligaments laterally to its line of reflection. The levator muscle attachments are peeled off the prostate and the apical dissection is performed to identify Santorini's plexus. The puboprostatic ligaments are then divided in contact with pubic arch to facilitate dissection of the Santorini's plexus. The apical dissection is then started to identify the posterior limits of the plexus and the urethra.

Step 5: Transection and Preservation of the Bladder Neck

The bladder neck is identified by palpation of the supple bladder in comparison to the solid prostate. A second suture is passed and secured around the superficial tissue at the base of the prostate, and a long tail is left for retraction. A sixth trocar is inserted (Fig. 4) and a toothed grasper is placed on the stitch for upward traction of the bladder neck (Fig. 6). The anterior aspect of the bladder neck is incised at the limit between the muscular fibers of the detrusor and the prostatic capsule. When the bladder is opened, the catheter balloon is deflated, and the catheter pulled out through the opening. The grasper is now placed on the tip of the catheter. Counter traction is achieved by securing the catheter with a Kelly clamp placed just beyond the urethral meatus. In this manner, the assistant exposes the posterior edge of the prostate and the posterior bladder neck.

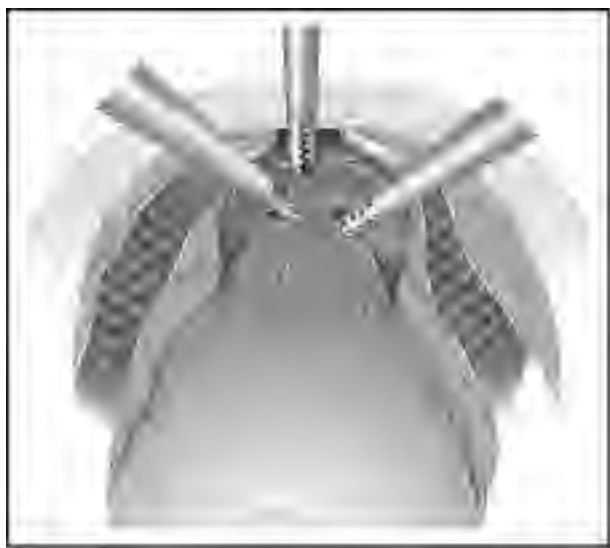
Transection of the bladder neck is completed. A locking grasper is placed on the posterior bladder neck, which is retracted cephalad, exposing the anterior layer of Denonvilliers' fascia (Fig. 7).


FIGURE 6 ■ Suspension of the base of the prostate and section of the anterior bladder neck.

FIGURE 7 ■ Division of the posterior bladder neck from the anterior layer of Denonvilliers' fascia, which is incised transversally.

Step 6: Dissection of Seminal Vesicles

The anterior layer of the Denonvilliers' fascia is incised transversally to allow the visualization *of* the vasa deferentia (Fig. 7). The vasa deferentia are dissected, clipped, and divided. The vascular pedicle for each structure is selectively clipped and sectioned. After division of each vas deferens, upward traction on the distal portion of the vas allows exposure of the seminal vesicles. Two large arteries supplying each seminal vesicle from the lateral side are typically identified. These are clipped and divided in a position immediately adjacent to the seminal vesicles. As dissected, each seminal vesicle is grasped and pulled anteriorly (Fig. 8). With anterior traction on the seminal vesicles, the prostatic pedicles are exposed.

Step 7: Transection of Prostatic Pedicles and Preservation of Neurovascular Bundles

To optimize transection of prostatic pedicles and neurovascular bundle preservation, the visceral prostatic fascia and the lateral edge of the posterior Denonvilliers' fascia are incised in contact with prostatic capsule. Incision of the posterior layer of Denonvilliers' fascia reveals prerectal fat and provides a safe plane of dissection (Fig. 9). Hemostasis of prostatic pedicles is performed near the bundles with clips, and near the prostatic capsule with bipolar electrocautery. The plane between the neurovascular bundles and prostatic capsule is opened after transection of the pedicles. Small capsular arteries, which are divided in a position immediately adjacent to the prostatic capsule after being controlled with clips, are the last attachments of the bundles. Dissection is extended to the prostatic apex. The vasa deferentia and the seminal vesicles are grasped and retracted anteriorly. Incision of posterior Denonvilliers' fascia is completed medially and dissection of the prostatorectal plane is performed into the rectourethral muscle behind the prostate.

Step 8: Section of Santorini's Plexus and Section of Urethra

One assistant grasps and retracts the suture at the base of the prostate cephalad to put the apex on tension. The margin between the urethra and dorsal vein complex is identified and a figure-eight stitch is placed around the Santorini's plexus. The plexus is sectioned perpendicularly. The plane between the plexus and the urethra is then developed caudally in an oblique manner. The anterior urethral wall is incised and the Foley catheter is visualized (Fig. 10). The catheter is pushed through the anterior urethrotomy to open the urethral lumen and expose the posterior wall. The assistant retracts and rotates the prostate successively to each side and places the suction tip under the rectourethralis muscle and above the rectum. This maneuver allows a good exposure of the posterior lip of the prostatic apex, optimizing the section of posterior urethral wall and rectourethralis muscle and reducing the risk of positive posterior margins. After incising the urethra and the rectourethralis muscle, the freed prostate is placed in an endoscopic bag. The specimen is extracted through the slightly enlarged infraumbilical port site.

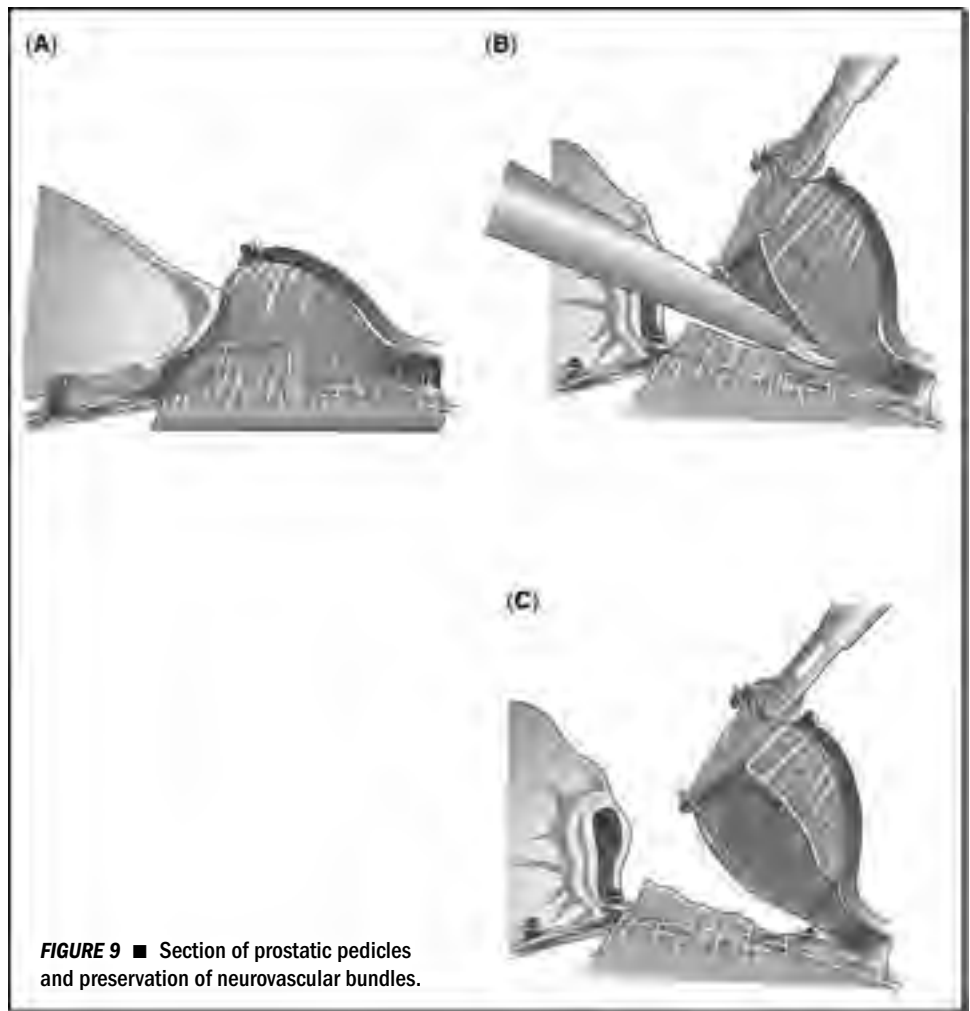
FIGURE 8 ■ Exposition of the prostatic pedicles.


FIGURE 9 ■ Section of prostatic pedicles and preservation of neurovascular bundles.

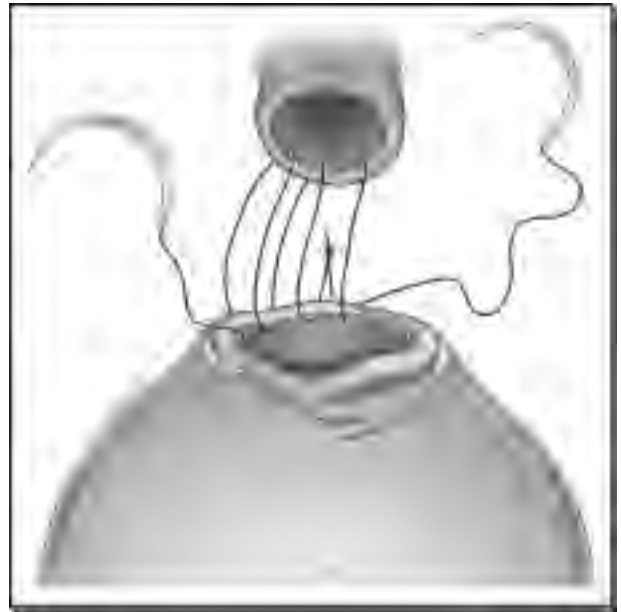
Step 9: Vesicourethral Reconstruction

The Hasson canula is replaced. A posterior tennis racket reconstruction may be necessary in case of associated large prostatic hyperplasia or previous transurethral resection of the prostate. The urethrovesical anastomosis is performed adopting the method originally described by Van Velthoven et al. (14). The running suture is prepared by knotting together two 3-0 Vicryl 5/8 sutures of a total length of 14 cm. The first running suture is initiated by placing a stitch outside in through the bladder neck and inside out on the urethra at the 4 o'clock position. Another needle is passed outside in through the bladder neck at the 3 o'clock position. The knot is blocked behind the bladder neck and the needle is

FIGURE 10 ■ Section of the urethra.

FIGURE 11 ■ Vesicourethral reconstruction: needle passages of the posterior anastomosis.


placed on the right side of the operative field. The other running suture is initiated by placing a stitch symmetrical to the first at the 5 o'clock position. The posterior lip of the bladder is left 2 cm apart from the urethral posterior wall. The posterior anastomosis is completed with four needle passages outside in on the bladder and inside out on the urethra, from the right to the left (Fig. 11). Upon completion of these passages, each suture is gently pulled on an alternating basis to approximate the bladder neck to the urethra. A Foley catheter is then placed into the bladder. The anterior anastomosis is then performed by placing the first suture outside in on the bladder and inside out on the urethra, from the right to the left. At the 10 o'clock position, the two running sutures are knotted on the outside of the bladder. Inadvertent inclusion of the Foley catheter into the anastomotic running suture should be ruled out prior to inflation of the balloon. Leakage from the urethrovesical anastomosis is ruled out by filling the bladder with 120 mL saline solution.

Step 10: Closure
A small suction drain is inserted through the left lateral port site and placed in the Retzius space near the anastomosis. The anterior rectus fascia is closed. Skin incisions are closed and sterile dressings are applied.

DISCUSSION

Development of laparoscopic radical prostatectomy started with the experience with transperitoneal laparoscopic access to the prostate and seminal vesicles employed by a few surgeons (2,5,15). In fact, transperitoneal laparoscopic radical prostatectomy was successfully introduced in routine clinical practice in France following the pioneering work of Gaston and Piéchaud in 1998 (unpublished series). This approach became predominant worldwide and is currently considered the gold standard of laparoscopic prostatectomy. However, other teams have shown that primary transperitoneal incision of the Douglas pouch is not essential for the dissection of seminal vesicles. Rassweiler et al. (4) proposed a technical alternative by approaching the Retzius space directly through a transperitoneal access and reproducing the retrograde technique described by Walsh. Raboy et al. performed the seminal dissection after transection of the bladder neck using a purely preperitoneal approach (9).

Creation of a preperitoneal working space was initially described to perform laparoscopic inguinal hernia repair (16). Later, access to the preperitoneal space has been used for many other laparoscopic procedures including pelvic lymph node dissection, bladder neck suspension, varicocelectomy, and more recently, radical prostatectomy (9,16).

The creation of a preperitoneal space is standardized and represents a minimally invasive approach to the prostate.

We developed a technique with initial blunt finger dissection, which is a fast, safe, and a less costly alternative to the balloon technique (16). Performing this dissection anterior to the posterior rectus sheath minimize the risk of inadvertent entry into the peritoneal cavity.

The creation of a preperitoneal space is standardized and represents a minimally invasive approach to the prostate.

Trocar geometry is similar to that previously described in transperitoneal laparoscopic radical prostatectomy but a sixth trocar can be introduced during initial space creation.

Prostate dissection is performed in a traditional anterograde fashion and allows preservation of the neurovascular bundles.

All crucial elements of our previously described transperitoneal technique of laparoscopic radical prostatectomy (17) are reproduced and only a few technical points have been modified since we switched to the extraperitoneal approach.

Trocar geometry is similar to that previously described in transperitoneal laparoscopic radical prostatectomy but a sixth trocar can be introduced during initial space creation. This 5-mm suprapubic trocar does not result in any additional morbidity but we have found it useful when mobilizing the prostate (Fig. 4).

Prostate dissection is performed in a traditional anterograde fashion and allows preservation of the neurovascular bundles. During this step, we prefer to use clips rather than any kind of thermal energy to achieve hemostasis.

Based on our favorable experience with vesicourethral reconstruction performed using two hemicircumferential running sutures (18), we recently adopted the technical modification proposed by Van Velthoven et al. (14). Such latter technique requires only one intracorporeal knot instead of three, and simplifies the control of the posterior half of the anastomosis since all the posterior stitches are placed prior to approximating the bladder neck to the urethra.

PURELY EXTRAPERITONEAL APPROACH

PROS
- Reduces risk of intraperitoneal injuries during laparoscopic access.
- Laparoscopic preperitoneal access renders bowel adherences due to previous abdominal surgery a technical nonissues.
- Potentially decreased incidence of postoperative ileus and pain.

CONS
- Previous inguinal herniorrhaphy with mesh increase the complexity of prevesical space development. Pelvic lymphadenectomy is often impossible in these cases.
- Smaller working space.

In a comparison between extraperitoneal and transperitoneal laparoscopic radical prostatectomy at our center, measures of perioperative morbidity (postoperative pain, time to full diet) were more favorable when using the extraperitoneal technique (13). During transperitoneal laparoscopic radical prostatectomy, some urine and blood inevitably enter the peritoneal cavity, potentially causing at least some degree of chemical peritonitis. Persistent urine in the suction drain can be present for more than six days due to anastomotic leakage in 10% to 17.2% of patients (19–21). In transperitoneal laparoscopic series, prolonged ileus attributed to anastomotic leak was reported in 2.8% to 8.6% of cases (6,21). In another large series of transperitoneal laparoscopic radical prostatectomy, secondary anastomotic leakage in combination with acute pain, acute urinary retention, and peritoneal irritation syndrome occurred after catheter removal in 2% of patients (19). Ileus, anastomotic leak, and hemoperitoneum are all classified as group II by Clavien for laparoscopic surgery (19,22). Grade II complications are defined as "potentially life threatening but without residual disability."

Establishing the complexity and technical difficulty of a surgical intervention is mostly a subjective exercise. However, indirect data suggest that, in certain institutions, the extraperitoneal approach may provide a simplification of laparoscopic prostatectomy. Currently, only a few studies comparing transperitoneal versus extraperitoneal laparoscopic radical prostatectomy are available in the literature (13,23).

The initial results of extraperitoneal laparoscopic radical prostatectomy in terms of oncologic cure and preservation of continence and potency are similar to those of transperitoneal laparoscopic radical prostatectomy (10,13,24). Extraperitoneal laparoscopic radical prostatectomy seems to be reproducible, with possibly a shorter operative time by 10 to 54 minutes (13,23,25). These advantages gain importance in an academic center like ours, especially because teaching laparoscopic radical prostatectomy is a complex process requiring a large number of cases (>50) to reach the plateau of learning curve (26). Nevertheless, attempts to decrease operative time and perioperative morbidity should not outrival the oncologic principles. To objectively determine the relative benefits of the transperitoneal and extraperitoneal approaches, a prospective comparison is awaited.

Attempts to decrease operative time and perioperative morbidity should not outrival the oncologic principles.

CONCLUSION

Laparoscopic radical prostatectomy is undergoing a continuous technical development. We consider the extraperitoneal approach the logical evolution of laparoscopic radical

prostatectomy because it combines the advantages of laparoscopic surgery and retropubic access and reduces operative time. We also believe that the extraperitoneal technique may shorten the learning curve of laparoscopic radical prostatectomy. Although well standardized, further evaluation of long-term results of this technique is necessary.

SUMMARY

- The creation of a preperitoneal space is standardized and represents a minimally invasive approach to prostate.
- Prostate dissection is performed in a traditional anterograde fashion and allows preservation of the neurovascular bundles.
- The extraperitoneal approach reduces risk of intraperitoneal injuries during laparoscopic access. It may also decrease incidence of postoperative ileus and pain.
- Previous inguinal herniorraphy with mesh increases the complexity of prevesical space development. Pelvic lymphadenectomy is often impossible in these cases.
- Attempts to decrease operative time and perioperative morbidity should not outrival the oncologic principles.
- Further evaluation of long-term results of this technique is necessary.

COMMENTARY

Renaud Bollens and Claude Schulman
Department of Urology, University Clinics of Brussels, Erasme Hospital, Brussels, Belgium

Laparoscopic radical prostatectomy is now an accepted management option for localized carcinoma of the prostate. Laparoscopic access to the prostate gland can be obtained by two distinct techniques. Historically, the transperitoneal approach was based on early identification and dissection of the vas deferens and then the seminal vesicles. This approach was widely adopted and led to the initial resurgence of interest in laparoscopic radical prostatectomy. Some surgeons had even claimed to replicate the open technique of Walsh by using the transperitoneal approach. However, the transperitoneal approach does not adhere to the basic laparoscopic principle of repeating the open procedure and so, respecting this, the extraperitoneal procedure has been developed. The first series to demonstrate this originated from our institution (1).

A number of different blind techniques have been reported to create the extraperitoneal space. We, however, prefer to develop the space of Retzius under laparoscopic vision; this minimizes the risk of peritoneal or vascular injury. To develop the working environment under visual control one needs to be familiar with the anatomy of the abdominal wall and, in particular, the areas where the peritoneum is least adherent to it. We have developed a number of maneuvers to aid in the safe development of the extraperitoneal working space under continuous vision.

Laparoscopic radical prostatectomy in still evolving, and this evolution, we hope, is leading to an improvement in outcome for the patient. The improvement of vision obtained through the use of a laparoscope should be directly translated into enhanced dissection and reconstruction, and so lead to better results. To this end, a number of groups have developed different reproducible techniques. In a manner analogous to Walsh's, we advocate the avoidance of energy sources whilst dissecting the neurovascular bundles, whether this is monopolar diathermy, bipolar diathermy, heat, or ultrasound. In addition to this, we believe it is also important to avoid traction on the neurovascular bundles and, in our experience, this leads to an improvement in the early return of potency.

Continence is mainly related to the technique of apical dissection. The preservation of a long urethral stump improves the immediate and early continence rate. To aid in this, we dissect the apex in two distinct stages: we first dissect the superficial periurethral tissue; this frees and aids in identification of the prostatic apex, and we then divide the urethra.

A number of methods have been described for the vesicourethral anastomosis; these include separate or running sutures, mucosal eversion or no mucosal eversion, preservation of the bladder neck, or reconstruction of the bladder neck. Each technique has its respective advantages and disadvantages, but no one technique has led to an improvement in the outcome.

Finally, we return to the initial question: which is the optimal technique for laparoscopic radical prostatectomy?

By limiting the surgical field to the extraperitoneum, one decreases the risk of bowel injury and prevents intraperitoneal hemorrhage without tamponade, and urine leakage, which may in turn lead to ileus, intraperitoneal adhesions, and even small bowel obstruction. As long as one creates the extraperitoneal space correctly, the volume of the working space is similar for both techniques. The published series do not prove the oncological or functional superiority of

either approach. Anecdotally, reduced Tredelenburg in the extraperitoneal approach may be an advantage for the anesthesiologist (decrease pressure of ventilation) but there is no literature to support this. The only outstanding concern is, does exposure of the peritoneal contents to a malignant prostate gland equate to peritoneal spillage? What will be the outcome of such patients if they relapse and develop hormone refractory disease in the future? By opening up a new body compartment we may potentially see a novel complication, e.g., peritoneal prostatic carcinomatosis. At present, the follow-up is too short to be certain that opening the peritoneum is safe.

Whatever the approach—open or laparoscopic, extraperitoneal or intraperitoneal—all of the technical refinements are striving for a common goal: to optimize the oncological and the functional outcomes of radical prostatectomy and so improve cancer-free survival, as well as aid in the early recovery of continence and potency.

INTRODUCTION AND BACKGROUND

In October 2000, the Vattikuti Urology Institute committed to apply minimal invasive surgical approaches toward radical prostatectomy. Initially, we performed laparoscopic prostatectomies based on the anatomic radical prostatectomy described by Walsh (1) and the Montsouris laparoscopic radical prostatectomy technique (2). Subsequently, we modified the operative approach to incorporate robotic technology using the da Vinci® surgical system[a] starting in March 2001 (3) (Table 1). Robotic technology provides the surgeon with an unparalleled surgical tool, which offers three-dimensional, magnified visualization, wristed instrumentation and scaling of movement. As of July 2004, we have performed over 1200 robotic prostatectomies. Currently, many urology programs have established robotic programs and are routinely performing robotic prostatectomies (4–7). The initial technique has undergone numerous modifications (8,9).

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

> Any patient with clinically organ-confined prostate cancer, who is a candidate for definitive therapy, should be considered for a robotic radical prostatectomy.

Any patient with clinically organ confined prostate cancer, who is a candidate for definitive therapy, should be considered for a robotic radical prostatectomy.

The only contraindications are; if the patient has certain medical problems that would preclude an elective laparoscopic procedure such as a bleeding disorder or severe chronic obstructive pulmonary disease. Furthermore, a history of stroke or cerebral aneurysm is a contraindication because of the prolonged, steep Trendelenburg position. Previous intra-abdominal surgery, including hernia repair with mesh, is not

a contraindication, but rather may be a good reason to consider the robotic approach. At our institution, approximately 30% of patients have had major intra-abdominal surgery, including a Whipple procedure and hemicolectomy, and none have required conversion to an open procedure. Also, a Vattikuti Institute of Prostatectomy has been performed on patients with previous abdominal radiation, as well as, salvage prostatectomies after external beam radiation therapy or radioactive seed implantation. Often patients require lysis of adhesions to varying degrees, either during or after port placement. An alternative surgical approach, such as an open or perineal prostatectomy, may be more appropriate for patients with multiple or extensive abdominal or pelvic surgeries.

While patient habitus is a consideration, morbid obesity is not a contraindication, but can make the dissection more challenging. We have performed the operation in patients with body mass indexes up to 39, but prefer patients with body mass indexes below 30. Furthermore, excessively large prostates are not prohibitive. Ideal prostate size ranges from 30 to 80 g; however, the Vattikuti Institute of Prostatectomy procedure has been successfully performed on glands greater than 200 g. A prominent median lobe or significantly enlarged lateral lobes will impact the bladder neck dissection but is not a contraindication. More importantly, if pelvic dimensions are small relative to the size of the prostate, then the dissection may be more difficult. It is exactly in these circumstances the robot provides excellent visualization in a narrow space and facilitates a more precise dissection.

PREOPERATIVE PREPARATION

Standard preoperative instructions are followed. Discontinuation of aspirin or other anticoagulants prior to surgery is mandatory. Patients are on a clear liquid diet for two days prior to surgery and perform a gentle bowel preparation with magnesium citrate the night before surgery. Preoperative medications include antibiotic prophylaxis (first generation cephalosporin) and deep venous thrombosis prophylaxis (subcutaneous heparin 5000 U). Sequential compression devices are placed on the lower extremities. An orogastric tube that is placed is removed prior to extubation. Also, anesthesia is instructed to avoid certain inhalants as with any laparoscopic procedure and to limit fluids to less than 600 cc until the anastomosis is performed to minimize urine in the field.

DETAILED ROBOTIC PROSTATECTOMY TECHNIQUE

Room Setup

In our operating purpose-designed room, there are two 5-by-6 foot screens, which project a three-dimensional image for the right-sided surgeon and left-sided assistant. The large screens also facilitate instruction for residents and visitors. The console surgeon may also easily view the screens during the operation.

In our experience, when the entire team has the benefit of viewing the same three-dimensional image, the precision of the assistants' movements is greatly increased, which ultimately improves the efficiency of the entire operation.

> In our experience, when the entire team has the benefit of viewing the same three-dimensional image, the precision of the assistants' movements is greatly increased, which ultimately improves the efficiency of the entire operation.

Surgical Team

The team consists of a primary surgeon who operates at the console and two additional personnel who are sterile at the patient's side. The right-sided surgeon should be a physician who is skilled in laparoscopy and facile in port placement and docking of the robot. The left-sided assistant may be a physician, nurse, or surgical assistant. Each assistant is responsible for exchanging the robotic instruments on his/her respective side. The operation can be performed with a single assistant who has moderate advanced laparoscopic skills and with a strong understanding of the operation (10). It has been our experience that observation and second assistance is crucial to a surgeon's understanding of the operation and greatly reduces the time needed to master the roles of first assistant and console surgeon. This training philosophy works especially well in the setting of a residency program and the development of a robotic program. Furthermore, as the level of experience of the entire team increases, so does the ease and efficiency of the operation.

The *da Vinci* Surgical System is a master–slave robot system, which provides a magnified, three-dimensional image with wristed instrumentation.

Equipment

The *da Vinci*®[b] Surgical System is a master–slave robot system, which provides a magnified, three-dimensional image with wristed instrumentation.

The current system has four arms, one for the binocular endoscope and the other three for the articulated instruments.

For this procedure the following EndoWrist® robotic instruments are required:

- Long tip forceps
- Permanent cautery hook
- Bipolar cautery
- Round tip scissors
- Two needle drivers

More recently, the operation has been performed with just three robotic instruments:

- Bipolar Maryland tip graspers
- One needle driver
- Cautery scissors

Essentially, the bipolar Maryland tip grasper replaces the long tip forceps, bipolar cautery, and one needle driver, and the cautery scissors replaces the round tip scissors and the cautery hook. This will decrease the cost of disposables, but the anastomosis is slightly more cumbersome. Conventional laparoscopic instruments are used by the two assistants. The left-sided assistant uses an atraumatic grasper and manipulates the Foley when necessary. The right-sided surgeon uses an atraumatic grasper, scissors, a Surgiflex® WAVE XP™[c] suction-irrigation system and a needle driver.

Positioning

The patient is placed in dorsal lithotomy position with his arms tucked to his side (Fig. 1). Care is taken to pad bony prominences. The shoulders are secured with foam pads, wide cloth tape and then Velcro® straps crisscrossed over the upper body. The table is placed in maximum Trendelenburg position and fully lowered. The legs are then lowered until the thighs are parallel to the floor. The patient is prepped from the subcostal margin to the groin, draped, and then an 18 French Foley catheter attached to a drainage bag is placed.

FIGURE 1 ■ Patient positioning. Patient is in a modified dorsal lithotomy position in steep Trendelenburg.

Port Placement

Pneumoperitoneum is established with a 120 mm Endopath®[d] pneumoneedle through a left lateral umbilical incision. The Carbob dioxide$_2$ insufflator is set to a maximal pressure of 15 mmHg. After adequate pneumoperitoneum is established, a 10/12 mm Endopath bladeless trocar is placed and the camera with the 30 degrees upward-looking lens is introduced. To optimize visualization, the lens should be warmed with hot water prior to insertion. Next, the right-sided 8 mm robotic port is typically placed approximately 1 to 2 cm below the umbilicus and equidistant from the anterior superior iliac spine and the midpoint of the inguinal ligament. A second 10/12 mm Endopath bladeless trocar is placed at least two finger breadths above the iliac crest and as far lateral as possible. Next, the left-sided 8 mm robotic port is placed in a symmetric position to the right. The left-sided 5 mm Endopath bladeless trocar is placed at least two finger breadths above the iliac crest and as far lateral as possible. The right-sided 5 mm assistant port is placed midway between the 12 mm camera port and the 8 mm robotic port and slightly inferior to allow the assistant's instruments to reach the pelvis.

A total of six ports are placed—a 10/12 mm camera port, 2 to 8 mm robotic ports, a 10/12 mm assistant port and 2 to 5 mm assistant ports (Fig. 2).

After port placement, the robot is docked.

Port placement can vary depending upon patient habitus and pelvic anatomy. The camera port may be placed infraumbilical or supraumbilical if the patient is greater than or less than 68 inches tall, respectively. If the patient has a narrow pelvis, the robotic ports can be placed more medially to minimize interference with the bony pelvis. Also,

A total of six ports are placed—a 10/12 mm camera port, 2 to 8 mm robotic ports, a 10/12 mm assistant port and 2 to 5 mm assistant ports.

if adhesions are present, the order of port placement may be varied to allow for laparoscopic release of adhesions.

Development of Extraperitoneal Space

Initially, the 30° upward-looking lens is used along with the cautery hook on the right and the long tip forceps on the left. First, the peritoneal cavity is inspected and any necessary lysis of adhesions is performed. Next, the dissection is started just lateral to the medial umbilical ligament over the vas deferens (Fig. 3). The vas deferens is isolated and divided, care is taken to cauterize the deferential vessel, which courses along the vas. The dissection is continued anteriorly; lateral to the medial umbilical ligament and just above the bladder dome, and inferiorly until the pubic arch and external iliac vein are visualized. The majority of this dissection can be performed bluntly in an avascular plane. Care should be taken to identify the iliac vessels that are just lateral to the plane of dissection. This step is repeated on the contralateral side. Next, the medial umbilical ligaments are divided with electrocautery and the dissection is continued medially from either side until the urachus is divided. The bladder is then reflected posteriorly. Overlying fat is dissected off the pubic arch, endopelvic fascia, puboprostatic ligaments, and the prostatic apex. Care is taken to cauterize the soft tissue in the midline between the puboprostatic ligaments that invariably contain the superficial dorsal vein.

Apical Dissection and Control of Dorsal Venous Complex

The lens is changed to 0°. The endopelvic fascia is scored and the space between the prostate and the levator ani is developed with blunt dissection. Cauterization should be minimized to avoid inadvertent injury to the neurovascular structures. The dissection is carried proximally until fat is seen at the junction of the prostate and bladder (Fig. 4). Distally, the dissection is carried just lateral to the puboprostatic ligaments that are left intact and just beyond the prostatic apex. Often the puboperinealis muscle is visible as a sling of muscle around the urethra just distal to the prostatic apex and care is taken to preserve this muscle (11). Next, the robotic instruments are changed to two needle drivers. A 6 to 9 0-Vicryl (polyglactin 910) suture on a CT-1 needle is used for a vertical mattress dorsal venous suture. The remainder of the suture is used for a prostatic traction suture placed just distal to the bladder neck.

Bladder Neck Transection

The lens is changed to 30° down and the cautery hook is on the right and long tip forceps on the left.

Determining the junction between the prostate and the bladder requires experience and is probably one of the most challenging aspects of this technique.

An assistant provides traction on the prostatic suture. Laterally, an area of fat is often seen at the junction between the prostate and the bladder. The dissection can be started laterally on either side and continued medially. The direction of the

> Determining the junction between the prostate and the bladder requires experience and is probably one of the most challenging aspects of this technique.

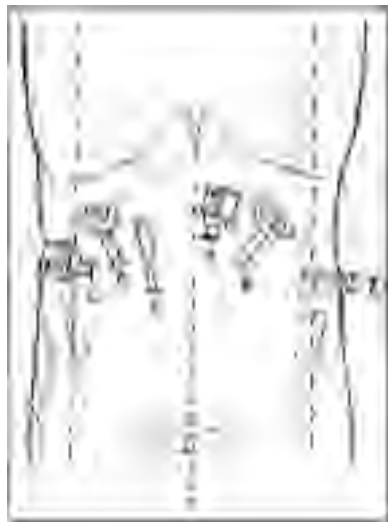
FIGURE 2 ■ Port placement. Six ports are placed; 2 to 10/12 mm ports (A), the periumbilical port is for the camera, 2 to 8 mm robotic ports (B), and 2 to 5 mm assistant ports (C).


FIGURE 3 ■ Transperitoneal view. The bladder is reflected by incising the peritoneum just lateral to the medial umbilical ligament, dividing the vas deferens (*arrowhead*) and continuing the dissection across the midline and dividing the urachus (*incision marked by dotted line*). Care is taken not to injure the spermatic (*arrow*) or external iliac vessels.
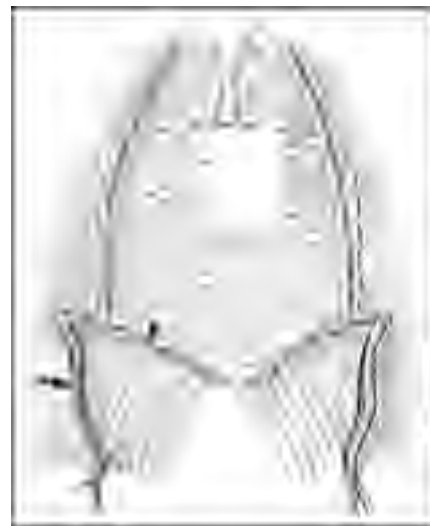

dissection is angled slightly inferiorly and joined at the midline. If the surgeon is in the proper plane, the bleeding should be minimal. Once the anterior bladder is entered, the catheter balloon is deflated, and the second assistant uses the catheter to provide anterior traction. After the bladder is entered, the surgeon should visualize the ureteral orifices and assess for prominent prostatic lobes. If a prominent prostatic lobe is present, the mucosa over the adenoma is incised and dissected off the underlying adenoma.

The posterior bladder neck is divided, and the plane between the prostate and bladder is developed inferiorly and laterally. After the bladder neck dissection is performed, the bladder neck should be examined. If the bladder neck is excessively large, then bladder neck reconstruction may be performed. We have employed two techniques for bladder neck reconstruction. A figure of eight suture, usually a 2-0 Vicryl (polyglactin), RB-1 needle, may be placed at the lateral aspect of the bladder neck on either side prior to the anastomosis. Alternatively, if after the anastomosis is performed there is a gap anteriorly, a tennis racquet handle may be created.

Dissection of Vasa Deferentia and Seminal Vesicles

A plane is identified between the layers of Denonvillier's fascia, and the dissection is continued inferiorly in the midline. Often the vasa is easily visualized in the midline, but may be widely separated, especially with a significantly enlarged prostate (Fig. 5). The second assistant removes the catheter and grasps the posterior prostate and the edge of Denonvillier's fascia for traction facilitating dissection of the vasa. Each vas is dissected free from surrounding tissue then divided. The second assistant grasps the prostatic end and the first-assistant grasps the proximal end. Adequate exposure allows the ipsilateral seminal vesicle to be dissected free from the surrounding tissue. After the vasa and seminal vesicles are isolated, the second assistant grasps both vasa and seminal vesicles and provides anterior and superior traction on the prostate. The dissection is then continued posteriorly in the midline between the layers of Denonvilliers' fascia as far distal as possible, usually to the level of the prostatic apex (Fig. 6). This step greatly facilitates the subsequent dissection of the neurovascular bundles and the apex.

Control of Lateral Pedicles and Preservation of the Neurovascular Bundles

This portion of the operation is typically performed with the bipolar cautery on the left and the scissors on the right, but the cautery hook and forceps can be used. An assistant provides contralateral traction by grasping either the ipsilateral seminal vesicle or the edge of the prostate (Fig. 7). The proximal pedicles are sharply dissected free from

FIGURE 4 ■ Endopelvic fascia dissection. After the endopelvic fascia is incised (*arrow indicating edge of fascia*), a space is developed lateral to the prostate until the prostatovesical junction and corresponding fat pad is identified (*double arrow*). Distally, the puboprostatic ligaments and superficial dorsal vein (*arrowhead*) are seen. After the dorsal vein suture is placed, a traction suture is placed on the prostate (*double arrowhead*).

FIGURE 5 ■ Division of bladder neck. After dividing the bladder neck (*arrow*), the dissection is carried inferiorly, posterior to the prostate, until the vasa and seminal vesicles are identified.

FIGURE 6 ■ Development of the plane posterior to the prostate toward the apex. The left-side assistant provides upward traction on the divided vasa and seminal vesicles (*arrow*).

FIGURE 7 ■ Lateral pedicle dissection. Contralateral traction is provided by an assistant. The pedicle may be divided with clips and scissors as shown. The plane of dissection varies depending on whether a standard nerve-sparing procedure or "veil" is performed.

surrounding tissue. Hem-O-Lok® MLK clips[e] may be used for hemostasis. The majority of the dissection is performed sharply and bipolar is used for discrete bleeding.

For a standard nerve-sparing dissection, a plane is developed posterior and parallel to the prostate. At our institution, an additional accessory nerve preservation procedure is performed in which the main neurovascular bundle as well as perforating micropedicles are preserved. Patients who have excellent preoperative sexual function and minimal volume of Gleason less than seven disease are offered this procedure. A plane of dissection is developed posterolaterally between the layers of periprostatic fascia and is continued distally toward the puboprostatic ligament. A veil of tissue remains, the "veil of Aphrodite," and encompasses the main neurovascular bundles and the perforating branches within the periprostatic fascia and is continuous with the puboprostatic ligament distally (Fig. 8) (12). Furthermore, in a given patient, a standard nerve sparing may be performed on one side and a veil performed on the other.

Apical Dissection and Urethral Transection

> A meticulous apical dissection is crucial to excellent cancer control and maintenance of continence.

A meticulous apical dissection is crucial to excellent cancer control and maintenance of continence.

We have previously reported exclusively on this portion of the operation to highlight the advantages of robotic technology (13). The 0° lens is used for the apical dissection and the remainder of the operation. The bipolar cautery and scissors are used for the apical dissection. The Foley catheter is introduced. An assistant provides gentle traction by pulling the prostatic stay suture superiorly. The periurethral tissue is sharply separated from the urethra and the prostatic apex is defined. The urethra is divided sharply with scissors. Any remaining prostatic attachments are freed and the prostate is placed in an Endopouch™ Retriever[f] to be removed later.

In our experience, and as reported by others, the most common location for a positive margin is the apex (14,15). Therefore, we routinely excise periapical soft tissue for frozen section analysis. If indicated, biopsies from other areas may be obtained at this time. If a biopsy contains carcinoma, then additional tissue is resected until a negative margin is obtained. Analysis of our results has shown that this procedure did not alter the already low (2–4%) positive apical margin rate in patients with organ confined prostate cancer, but did lower the positive margin rate in patients with pT3 disease from 30% to 11%. This may seem like "cheating" to the open surgeon or the traditional laparoscopist, but robotic surgeons realize that three-dimensional visualization and wristed instruments do allow them to remove a generous soft tissue margin around the urethra without sacrificing sphincteric length or compromising continence.

Pelvic Lymph Node Dissection

> The technique of pelvic lymph node dissection is similar to laparoscopic pelvic lymph node dissection; however, the robotic instrumentation allows for a very precise anatomic dissection.

Pelvic lymph node dissection is usually performed at this time, if indicated. The instruments are unchanged from the previous step; 0° lens, bipolar cautery on the left and scissors on the right.

---

[e]Weck Closure Systems, Research Triangle Park, NC.
[f]Ethicon, Cincinnati, OH.

FIGURE 8 ■ Appearance of the prostate after the apex has been divided. Bilateral "veils of Aphrodite" (*arrows*) are preserved and are continuous with the puboprostatic ligaments.

FIGURE 9 ■ Anastomosis. A running anastomosis is performed with the initial pass outside in on the bladder neck and then inside out on the urethra (**A**). The posterior portion of the anastomosis is completed in a clockwise direction (**B**) then the anastomosis is completed by running the other end of the suture in a counterclockwise direction and tying an intracorporeal knot (**C**).

The technique of pelvic lymph node dissection is similar to laparoscopic pelvic lymph node dissection; however, the robotic instrumentation allows for a very precise anatomic dissection.

If necessary, an extended pelvic lymph node dissection is performed in the area of the obturator fossa, the internal and external iliac vessels, as well as, removal of the node of Cloquet. When a lymph node dissection is performed, the prostate and lymph nodes are placed in the same Endopouch Retriever.

Anastomosis

To begin the anastomosis, a needle driver is on the right and the long tip forceps on the left or two needle drivers may be used. In the beginning of our experience, the anastomosis was performed with eight or more interrupted sutures. A running anastomotic suture had been described for laparoscopic prostatectomy and was integrated into the Vattikuti Institute of Prostatectomy technique early in the evolution of the procedure (Fig. 9) (8,16,17). A running suture was found to be more efficient with excellent functional results. Presently, the anastomotic suture is made from two 7–8 cm 3-0 Monocryl (poliglecaprone 25) sutures on an RB-1 needle, dyed and undyed, tied together extracorporeally with the knot in the middle and a needle on either end. The running anastomosis is started with the dyed end, inside out on the bladder at the 4 o'clock position and continues in a clockwise direction. After two to three passes, the suture is cinched down with gentle downward traction on the bladder. After the bladder is brought down to the urethra, a needle driver is used on the left for the remainder of the anastomosis. The suture may be periodically locked to maintain tension or the right-sided surgeon may hold the suture on mild tension. At approximately the 9 o'clock position, the suture is reversed; inside to out on the bladder, outside to in on the urethra for two to three passes, then the second assistant holds the dyed needle on mild tension. Next, the undyed monocryl is passed outside in on the urethra at the 4 o'clock position and continued in a counterclockwise direction until the anastomosis is completed. The needles are removed and a single intracorporeal knot completes the anastomosis. A 20 French Foley catheter is placed, the bladder is distended to assess for anastomotic leaks, and 20 cc of saline is placed in the balloon.

Closing

The robotic instruments and camera are removed from the ports and the robot is dedocked. The first assistant places the camera through the lateral 12 mm port and grasps the endocatch string through the 12 mm umbilical port. Once the string is secured with a clamp, a 15 French Jackson-Pratt drain[i] is placed through the left-sided 5 mm port under visualization. Next, the ports are removed under direct vision to assess for bleeding and the umbilical port site is enlarged to allow removal of the specimen. The fascia is closed with 1-0 Ethibond™ on a CTX needle. The skin is closed with 4-0 Vicryl subcuticular sutures.

Postoperative Course

Patients are admitted for overnight observation and discharged within less than 23 or 24 hours after surgery.

Pain management includes ketorolac and acetaminophen with codeine. The pelvic drain is typically removed before discharge. A cystogram is usually performed on postoperative day 4–6, and if no leak is present, then the catheter is removed. Out-of-state

Patients are admitted for overnight observation and discharged within less than 23 or 24 hours after surgery.

patients may fly home within 48 hours and have their local urologist remove the catheter 10 to 14 days postoperatively.

EXTRAPERITONEAL APPROACH FOR ROBOTIC RADICAL PROSTATECTOMY

An extraperitoneal approach has been described for both laparoscopic and robotic prostatectomy (18–20). We have successfully performed 15 Vattikuti Institute of Prostatectomy's with an extraperitoneal approach. The extraperitoneal space is developed with a balloon dilator in the standard fashion. The ports are placed closer to the pelvic bones than with the transperitoneal approach, otherwise, the remainder of the procedure is identical to the previously described transperitoneal approach. An advantage of this approach is that some of the complications, which are seen with a transperitoneal approach, such as ileus from an anastomotic leak or postoperative bowel obstruction do not occur. The drawbacks are increased operating time (averaging 40 minutes additional per case) because of difficulty in creating the extraperitoneal working space and an increased incidence of lymphocele formation and deep venous thrombosis. For this reason, our preferred approach is transperitoneal for the vast majority of our patients.

SPECIFIC MEASURES TAKEN TO AVOID COMPLICATIONS

General laparoscopic principles should be adhered to regarding port placement and closure. This topic is covered elsewhere in this text. Excessive bleeding is a bothersome complication, not because of the amount of blood lost with regard to hemodynamic stability, but because even a small amount of bleeding obscures vision. Bleeding may be encountered at different steps of this procedure. Occasionally, when the endopelvic fascia is opened there is bleeding which can make the apical dissection more difficult. In such cases, a "cottonoid" Codman surgical strip may be placed on either side of the prostate. After the prostate has been removed, if there is bleeding in the area of the neurovascular bundles or prostatic fossa, a hemostatic sealant, such as, FloSeal® Matrix may be used prior to the anastomosis. Furthermore, additional dorsal venous complex sutures [2-0 Vicryl (polyglactin), RB-1 needle] may be placed after urethral transection, if necessary.

If there is concern regarding the integrity of the anastomosis, additional interrupted sutures [2-0 Monocryl (poliglecaprone) on an SH needle] may be placed to minimize anastomotic leaks. Furthermore, the bladder can be tacked to the pelvic sidewall to prevent tension on the anastomosis in the event of significant ileus or pelvic hematoma. Also, the peritoneum over the bladder can be sutured to the pubic arch in a running fashion to essentially extraperitonealize the retropubic space. We have tried all of these maneuvers and have concluded that they are not necessary in the vast majority of patients.

Postoperatively, if a patient has a significant ileus or abdominal pain, consider computerized tomography scan of the abdomen early in the evaluation. The vast majority of patients have minimal abdominal pain and a rapid recovery. If there is a deviation from the usual postoperative course, then an aggressive evaluation should be performed to exclude a hernia, urinary ascites, significant ileus, or pelvic hematoma.

RESULTS

Our robotic prostatectomy results and our laparoscopic prostatectomy results with experienced surgeons were comparable. However, estimated blood loss was significantly less in the robotic group.

Our institution has published prospective data regarding patient characteristics, preoperative parameters, and oncological and functional outcomes at various points during the development of our program (Table 2) (3,12,15,21–23). Our initial experience with robotic prostatectomy was reviewed after the first 40 cases were performed (3). The mean patient age was 60.7 and mean body mass index was 27.7. The mean operating time (incision to closure) was 4.6 hours, mean estimated blood loss 256 cc, and 80% of patients discharged within 24 hours after surgery.

Our robotic prostatectomy results and our laparoscopic prostatectomy results with experienced surgeons were comparable. However, estimated blood loss was significantly less in the robotic group.

Furthermore, Ahlering et al. has demonstrated that a laparoscopically naive, experienced open surgeon can successfully and efficiently perform a robotic prostatectomy after only 8 to 12 cases (24).

An interim evaluation of our technique prospectively compared our experience with 200 Vattikuti Institute of Prostatectomies to 100 radical retropubic prostatectomies (23).

TABLE 2 ■ Development of the Vattikuti Institute Prostatectomy: a Review of Experience Commensurate with the Evolution of the Technique

Number of patients	40[a] (Ref. 3)	100 (Ref. 15)	First 200 (Ref. 21)	Last 200
Age (yrs)	61	60	60	57
BMI	28	28	28	28
Operating time (min)	274	195	160	150
Estimated blood loss (cc)	256	149	153	<100
Intraoperative transfusions (%)	0	0	0	0
Conversion (%)	0	0	0	0
Discharged in 23 hrs (%)	80	92	93	92
Complications (%)	5	6	5	3
Positive margin rate (%) (T2a–T3a)	18	12	6	9
Continence (% at 6 mos)	N/A	92	90	99 (at 4 wks)
Potency (% at 6 mos)	N/A	59	50	N/A[b]

[a]The Montsouris approach was performed on 33/40 patients.
[b]Potency results are not available, as the follow-up is only 3 mos.
Abbreviation: BMI, body mass index.

There was no difference between the two groups with regards to preoperative parameters. Our average Vattikuti Institute of Prostatectomy patient age was 60 years, mean body mass indexe was 27.7, mean preoperative prostate specific antigen level was 6.4 ng/mL, the two most common clinical stages were T1c and T2b (49% and 39%, respectively), and the most common Gleason scores were 6 and 7 (67% and 28%, respectively). The average operative time was 2.7 hours, similar to radical retropubic prostatectomies, and the mean estimated blood loss was 153 cc, which was significantly less than 910 cc with radical retropubic prostatectomies. Furthermore, there were no intraoperative transfusions with the Vattikuti Institute of Prostatectomy group and the mean postoperative pain score was significantly less (3/10 for Vattikuti Institute of prostatectomies and 7/10 for radical retropubic prostatectomies). Postoperatively, the average hospital stay was 1.2 days compared to 3.5 days with a radical retropubic prostatectomies. Ninety-three percent of Vattikuti Institute of Prostatectomy patients were discharged within 23 hours after surgery.

In a review of 565 patients undergoing a Vattikuti Institute of Prostatectomy, there was no intraoperative mortality, no intraoperative blood transfusion and no conversion to open (12).

Postoperative anemia requiring transfusion occurred in four patients, two for port site hematoma and two for pelvic hematoma. There were 21 unanticipated postoperative office visits after catheter removal for transient urinary retention (15), dysuria (4) or hematuria (2). At 12 months follow-up, nine bladder neck contractures and one meatal stenosis were identified. Prolonged ileus is a bothersome complication of the transperitoneal approach; five patients had an ileus lasting for greater than 24 hours. Deep vein thrombosis was noted in one patient and two patients incurred a bowel injury during lysis of adhesions.

The Vattikuti Institute of Prostatectomy technique allows for early catheter removal with excellent results. A cystogram is routinely performed on postoperative day 4–7, and if the study is negative for urinary extravasation, then the catheter is removed. Our review demonstrated that average duration of catheterization is seven days (23). Total continence was achieved in 96% of patients at six months follow-up with a mean time to continence of 42 days (12).

Postoperative sexual function has been assessed with third-party–validated questionnaires in 565 Vattikuti Institute of Prostatectomy patients (12). A total of 82% of preoperatively potent patients younger than 60 years old had return of some sexual activity and 64% had successful intercourse at six months follow-up. Of patients over the age of 60, 75% had some sexual activity and 38% had intercourse at six months follow-up. Preservation of the lateral prostatic fascia along with the posterolateral neurovascular bundle might preserve additional accessory nerves and better preserve the vascular supply to the nerves. This maneuver (the veil of Aphrodite) is difficult to perform with open or conventional laparoscopic surgery, but is relatively straightforward with robotic surgery. A follow-up was conducted by an independent third-party of 33 patients one year after surgery with a preoperative sexual function (sexual health inventory for men) score of 20 or higher. Twenty-two patients had undergone standard

In a review of 565 patients undergoing a Vattikuti Institute of Prostatectomy, there was no intraoperative mortality, no intraoperative blood transfusion and no conversion to open.

nerve preservation and 11 patients had preservation of the lateral periprostatic fascia (veil of Aphrodite). Seven (32%) patients who underwent standard bilateral nerve sparing and nine (82%) in whom the veil of Aphrodite was preserved bilaterally reported one year sexual health inventory for men scores of 20 or greater ($p < 0.05$). While the sample size is notably small, we are encouraged that the return of potency and the quality of erections were superior in the cohort of patients undergoing the veil of Aphrodite modification of the Vattikuti Institute of Prostatectomy. We continue to perform a veil on appropriate patients and will continue to monitor and report our results.

With regard to oncological outcomes in an interim review of 200 patients, the margin positivity in organ-confined cancers (T2a–T3a) was 6% of whom 5% had focal positive margins and 1% had nonfocal extension (23). A total of 92% of patients had an undetectable prostate specific antigen with an average follow-up of 556 days. As there is variation in pathologists' assessment of positive margins, an independent pathologist, Jonathan Epstein, reviewed the pathologic specimens of 102 patients undergoing Vattikuti Institute of Prostatectomy by a single surgeon (MM). In this series, 60% of the patients had Gleason greater than six tumors and 40% had T3 disease. The positive margin rate was 5% in patients with T2 disease and 11% in patients with T3 disease. Two patients had a detectable prostate specific antigen of less than 0.2 at 12 months, one of whom had a preoperative prostate specific antigen of 25 and probable undetected metastasis preoperatively.

Over 1200 Vattikuti Institute prostatectomies have been performed to date and the procedure continues to be in evolution as minor modifications are introduced in an attempt to improve results and reduce complications. With experience, the average operating time is currently 2.3 hours, demonstrating a marked reduction from our initial experience. We continue to meticulously collect and analyze data to understand the impact of such modifications and to share our experience with fellow urologists.

SUMMARY

- Robotic technology provides the urologist with an unparalleled surgical tool, which can be applied to urologic oncology.
- The three-dimensional visualization and wristed instrumentation facilitates a more precise anatomic dissection of the prostate from surrounding tissues.
- Robotic-assisted radical prostatectomy, as described herein, is an efficient and reproducible technique with minimal morbidity and excellent results.

COMMENTARY

Guy Vallancien
Institut Montsouris, Université Pierre et Marie Curie, Paris, France

The positive experience in robotic laparoscopy, presented by the Detroit group, demonstrates the evolution of surgical telemanipulation systems to benefit the surgeon. For instance, during laparoscopic radical prostatectomy, the reanastomosis of the bladder neck to the urethra occurs at the end of the surgery. At this point, the surgeon is often tired, and it becomes more challenging to execute intracorporal sutures. The execution of these sutures, however, is facilitated by the telemanipulation arms of the robot. The robotic arms provide six degrees of freedom, which allows an enormous flexibility in the "wristed arms." This flexibility allows the surgeon to place his needle in virtually any position, without the usual attention required in needle placement in the needle driver. Laparoscopic surgery, furthermore, can be physically exhausting when the surgeon stands next to the operating table for long periods of time. With the robot sitting at the control console, comfort is increased. One can extend this thought by stating that a more comfortable surgeon may execute a better operation. Nevertheless, robot-assisted laparoscopic prostatectomy does not provide any additional benefit to the patient. When comparing traditional laparoscopic prostatectomy to robot-assisted laparoscopic prostatectomy, a tour center, the only significant difference is a greater blood loss with robotic assistance.

What is the future of telemanipulation? I do not believe that teletransmission will be viable in a center where there is not a large volume of cases. Clearly, to acquire such equipment, the center must already be an important referral center with resources available to acquire current technology. Nevertheless, there is a growing interest in robot-assisted surgery, and this interest is attributable to two main reasons:

1. To train young surgeons in surgery and to expose them to difficult cases. As an analogy, the cockpit simulator of an Airbus A320 is extremely realistic. The most dangerous situations are programmed into the computer; and young pilots are trained through simulated events. Similarly, young surgeons will soon be able to learn operations and practise them multiple times, without operating on living patients.
2. The concept of the industrial revolution in medicine. In the future, laparoscopic prostatectomies can be performed in a large operating room of 250 m^2, equipped with four robots. At the Institut Mutualiste Montsouris, we have a

laparoscopic prostatectomy training program for scrub nurses. Currently, we do laparoscopic prostatectomies with only a scrub nurse at the operating table. This nurse prepares the patient, handles the robotic instruments, and assists the surgeon with the suction and forceps. At Montsouris, our resident controls the robot and the staff surgeon observes the operation. Our vision is to have four trained laparoscopic nurses and four residents, in this specialized setting, performing laparoscopic prostatectomies simultaneously. One staff surgeon would visit each console or, even with a fifth console, help the residents when required, for instance, in the dissection of the neurovascular bundles or the prostatic apex or in completing a difficult anastomosis. Such an evolution may also minimize long-term costs, because only one anesthetist and circulating nurse would be required for all four operations. Thus, technology has shifted the era of the surgeon as artist to the era of industrial surgery.

LAPAROSCOPIC RADICAL PROSTATECTOMY: CURRENT STATUS

Karim A. Touijer, Edouard Trabulsi, and Bertrand Guillonneau

Department of Urology, Sidney Kimmel Center for Prostate and Urologic Cancers, Memorial Sloan-Kettering Cancer Center, New York, New York, U.S.A.

INTRODUCTION

History

Since its first description 12 years ago (1), laparoscopic radical prostatectomy has gained increasing importance in the laparoscopic urologic oncology field and became an established treatment for organ-confined prostate cancer.

With their pioneering efforts, the French teams from Paris refined the technique of laparoscopic radical prostatectomy and reduced it to an efficient and reproducible treatment (2–4). More recently, large series of laparoscopic radical prostatectomy from Germany, Belgium, Japan, United Kingdom, United States, and Italy have been published (5–12). The cumulative worldwide-published experience exceeds 2000 procedures and includes some surgical technique variations.

Theoretical Advantages

The major impetus driving the development of minimally invasive techniques for prostate cancer has been patient satisfaction and quality of life: shorter convalescence with quicker return to normal activity and shorter use of a Foley catheter are attractive goals to be achieved by laparoscopic radical prostatectomy.

Additional potential benefits of laparoscopic radical prostatectomy include a relatively decreased intraoperative blood loss and risk of transfusion, allowed by the tamponade effect of the pneumoperitoneum and the versatile visualization. The 12 to 15 times magnification afforded by laparoscopy allows a precise visualization of intraoperative anatomic details, which could be valuable in all the steps of the surgery. However, the lack of tactile sensation advocated as a useful aid in the assessment of induration, palpable nodules, and delineation of the proximity or involvement of the neurovascular bundles by cancer is an area of concern with laparoscopic radical prostatectomy.

> Since its first description 12 years ago, laparoscopic radical prostatectomy has gained increasing importance in the laparoscopic urologic oncology field and became an established treatment for organ-confined prostate cancer.

TECHNIQUE

Evolution of Techniques

The initial report of laparoscopic radical prostatectomy by Schuessler et al. (1) was of nine cases performed through an intraperitoneal approach in an antegrade fashion. Shortly, thereafter, a single case of a laparoscopic radical prostatectomy through an extraperitoneal approach was reported (13). The largest initial series, however, originated in France, led first by Guillonneau and Vallancien at the Montsouris Institute in Paris, and then by Abbou in Créteil (2–4,14–18). More recently, the use of robotic devices to assist with the laparoscopic radical prostatectomy has been described (19,20).

Intraperitoneal Approach

Schuessler's initial report described an intraperitoneal approach, with the surgeon first dissecting the vasa deferentia and seminal vesicles through the pouch of Douglas, and proceeding in an antegrade fashion (1). After Schuessler's description, the Montsouris technique, also using an intraperitoneal approach, was initially described in 1998 (14). The vesicular complex is dissected first, and then the bladder is dissected off the anterior abdominal wall allowing access to the Retzius space. The endopelvic fascia is opened and the dorsal venous complex is ligated. The bladder neck is then incised at the prostatovesical junction and the previously dissected seminal vesicles are exposed. After control of the lateral pedicle of the prostate, the neurovascular bundle preservation is performed from the base towards the apex. Finally, the urethra is transected and an interrupted urethrovesical anastomosis using 8–12 sutures is performed.

Extraperitoneal Approach

Concerns of potential intraperitoneal complications (bowel injury, uroperitonitis, and ileus) led investigators to develop extraperitoneal approaches to laparoscopic radical prostatectomy (7). The initial report, by Raboy et al. (13), described a single extraperitoneal laparoscopic radical prostatectomy that duplicated the open retropubic radical prostatectomy as described by Walsh and Donker (21). Subsequent reports from Belgium and Germany have demonstrated the feasibility of the antegrade extraperitoneal approach (7,22–24). First the bladder neck is incised, the vasa deferentia and seminal vesicles are dissected through the bladder, and dissection is taken distally toward the apex of the prostate.

The theoretical advantages are the absence of peritoneotomy and therefore lesser risk of bowel injury, peritoneal irritation, and a quicker development of the Retzius' space. However, the drawbacks are a reduced and less ergonomic working space and a potential for increased tension at the urethrovesical anastomosis due to the limited bladder mobilization. Additionally, the extraperitoneal approach does not provide an accurate dissection of the seminal vesicles, which given the proximity of the neurovascular bundles and inferior hypogastric plexus may be relevant if a nerve sparing approach is planned.

Comparison of Approaches

Transperitoneal and extraperitoneal laparoscopic radical prostatectomy were compared by Hoznek et al. (25). In this retrospective study, the last 20 patients receiving transperitoneal laparoscopic radical prostatectomy were compared with the first 20 patients undergoing extraperitoneal laparoscopic radical prostatectomy. The operative time for extraperitoneal laparoscopic radical prostatectomy was significantly shorter (2.9 vs. 3.8 hours, $P < 0.001$), and resumption of a regular diet was significantly quicker (mean 1.6 vs. 2.6 days, $P = 0.002$). The duration of catheterization (4.2 vs. 5.3 days) and positive margin rates (25% vs. 15%) were similar between the two groups. Because of the preliminary nature of this paper, long-term cancer control rates and quality of life measures (potency, urinary continence) were not available. The authors concluded that the shorter operative time and the equivalent or superior morbidity and convalescence results indicated a significant advantage of the extraperitoneal technique over the transperitoneal technique.

A recent, retrospective study analyzing 100 consecutive extraperitoneal laparoscopic radical prostatectomy and 100 consecutive transperitoneal laparoscopic radical prostatectomy at the Montsouris Institute showed no significant differences in operative time (2.8 vs. 2.9 hours), transfusion rate (3% vs. 4%), or positive surgical margin rate (21% vs. 15%) between the two groups and the authors highlighted in their conclusion the importance of the individual surgeon's training and experience in determining the optimal technique to use (26).

A recent, retrospective study analyzing 100 consecutive extraperitoneal laparoscopic radical prostatectomy and 100 consecutive transperitoneal laparoscopic radical prostatectomy at the Montsouris Institute showed no significant differences in operative time (2.8 vs. 2.9 hours), transfusion rate (3% vs. 4%), or positive surgical margin rate (21% vs. 15%) between the two groups. The authors highlighted the importance of the individual surgeon's training and experience in determining the optimal technique to use.

Robotic Assistance

Use of robotics in laparoscopy has been spurred by the commercial availability of master–slave robotic devices such as the *da Vinci*®a surgical robot. These devices have articulating instruments, which afford extra planes of motion that is particularly attractive for urologists with limited laparoscopic surgical skills (20,27–30). Additional reported benefits include improved ergonomics for the operating surgeon, who sits at a computer console separate from the operative field (31). It has been postulated that robotic assistance reduces the technical difficulty and potentially allows novice laparoscopists to complete these procedures (32). Use of the *da Vinci* robotic system has been reported with both transperitoneal and extraperitoneal approaches, with similar results (31,33).

One of the major limitations to the use of robotic devices in prostate surgery is the cost (34). The *da Vinci* surgical robot requires a tremendous capital investment, and the laparoscopic instruments used by the master–slave robot have preprogrammed senescence so that they can be used for only a finite number of procedures before they must be replaced. Additionally, the annual maintenance and per-case disposable instruments costs limit the widespread implementation of such device.

Other criticisms include the inadequacy of the available surgical instruments used in robotic-assisted laparoscopic radical prostatectomy, the loss of the sense of touch or tissue resistance feedback available with conventional laparoscopy, and finally the time-consuming set-up process.

> One of the major limitations to the use of robotic devices in prostate surgery is the cost. The *da Vinci*® surgical robot requires a tremendous capital investment, and the laparoscopic instruments used by the master–slave robot have preprogrammed senescence so that they can be used for only a finite number of procedures before they must be replaced. Additionally, the annual maintenance and per-case disposable instruments costs limit the widespread implementation of such device.

Learning Curve

Laparoscopic radical prostatectomy is generally thought of as a technically demanding laparoscopic procedure, with an extended learning curve. Laparoscopic radical prostatectomy can be learned during residency or fellowship training, and other formats have been explored for the practicing urologist. Training laboratories, with laparoscopic skills trainers and ex vivo models of the urethrovesical anastomosis, have enabled urologists to improve their skills in a short time period (35). On-site mentoring by experienced laparoscopists has created successful laparoscopic radical prostatectomy programs in the United States (31,36). Proficiency and/or "learning curve" cannot be assessed by parameters such as number of cases or operating time. One does not become a skilled laparoscopic surgeon by completing case number 49 nor by performing a laparoscopic radical prostatectomy under 120 minutes, but a dedicated teaching program including laboratory training time, intraoperative video review, and operative participation, is essential to develop laparoscopic skills (depth perception, visual three-dimensional reconstruction of a two-dimensional image, etc.) and most importantly to master laparoscopic anatomy and apply the oncological principles of surgery.

PERIOPERATIVE PARAMETERS

Operative Time

As shown in Table 1, the average operative time has declined substantially with increased experience.

The average operative time from Montsouris, the center with the largest reported experience of laparoscopic radical prostatectomy, declined from more than four hours for the first 100 cases to 2.9 hours for the last 350 cases (17). Similarly, Hoznek et al. (18) reported that the operative time averaged over eight hours for their first 20 cases and declined to four hours for the next 114 cases. Other reports worldwide describe similar declines in operating times after the initial experience. Pelvic lymphadenectomy, which at most centers is performed only in selected, high-risk patients, appears to add 30–60 minutes to the operative times in most series. In our contemporary series from Memorial Sloan-Kettering Cancer Center, the average operative time is 3.3 hours with bilateral pelvic lymph node dissection in performed in 45% of the patients.

> As shown in Table 1, the average operative time has declined substantially with increased experience.

Estimated Blood Loss

The average estimated blood loss for the reported series of laparoscopic radical prostatectomy varies widely, as shown in Table 1. The average estimated blood loss in the series from Montsouris was 380 mL for all 550 patients, declining to 290 mL for the last 350 patients (17). The overall transfusion rate was 5.3% in this series, declining to 2.6%

Heilbronn (39)	438	2003	TP	First 219:288; second 219:218	First 219:1100; second 219:800	First 219:30.1%; second 219:9.6%	First 219:3.7%; second 219:0.5%	First 219:12; second 219:11	7	First 219:1.4%; second 219:0%	10%
Milan (12)	80	2003	TP	218	376	53% autologous; 6% heterologous	0%	4.5	11	None reported	23%
MSKCC	250	2004	TP	200	300	5%	0%	1.9	7	0.4%	15%

Abbreviations: TP, transperitoneal; EP, extraperitoneal; OR, operating room; EBL, estimated blood loss; MSKCC; Memorial Sloan-Kettering Cancer Center.

for the last 350 cases (17). As shown in Table 1, average estimated blood loss at other centers worldwide is similar to that reported from Montsouris; at Memorial Sloan-Kettering Cancer Center the average estimated blood loss is 300 mL and the transfusion rate is 2.5%. The estimated blood loss data from Heilbronn were noticeably higher, with an average estimated blood loss of 1100 mL and a transfusion rate of 30% for their initial 219 patients, and 800 mL with a 9.6% transfusion rate for the last 219 patients (39). The reason for this discrepancy is unclear but could be technical since the Heilbron approach is mainly retrograde. Because lower estimated blood loss represents an advantage of laparoscopic radical prostatectomy over open RP, this parameter requires careful examination.

Hospital Stay and Duration of Catheterization

The hospital stay after laparoscopic radical prostatectomy is dependent on cultural and societal factors unique to each center. In Europe, patients are much more reluctant to leave the hospital with a catheter than in the United States, making this parameter meaningless as an indicator of convalescence; it more correctly represents a measure of the duration of urethral catheterization.

As shown in Table 1, the average duration of catheterization has declined in all series, averaging approximately 4–6 days, which is shorter than historical controls of open retropubic radical prostatectomy.

Early removal of the urinary catheter was examined with cystography by Nadu et al. (40) in 113 patients, and no increase in incontinence rates, anastomotic stricture, or urinary extravasation was noted.

> The average duration of catheterization has declined in all series, averaging approximately 4–6 days, which is shorter than historical controls of open retropubic radical prostatectomy.

Convalescence

Most series reported thus far lack detailed data on convalescence and return to normal activities. In addition, few reports have described the degree and duration of postoperative pain and use of analgesics using validated questionnaires. In a small series from Johns Hopkins, postoperative analgesic requirements and time to complete convalescence after laparoscopic radical prostatectomy were significantly improved compared to open retropubic radical prostatectomy (41). In a prospective study comparing open retropubic radical prostatectomy and laparoscopic radical prostatectomy from Kobe, Japan, quality of life questionnaires were used to measure quality of life differences before and after surgery (8,37). Using the EORTC prostate cancer quality of life questionnaire for general health-related quality of life, the investigators found no significant differences between open retropubic radical prostatectomy and laparoscopic radical prostatectomy (8). Patients receiving laparoscopic radical prostatectomy did, however, express a more favorable attitude towards surgery compared to those receiving open retropubic radical prostatectomy, and significantly more patients undergoing laparoscopic radical prostatectomy would have chosen that therapy again compared to those having open retropubic radical prostatectomy.

Complications

Complication rates after laparoscopic radical prostatectomy have varied significantly, as shown in Table 1, ranging from 3.6% to 34%. Unclear and nonstandardized reporting makes interpretation of the reported complication rates difficult.

Not surprisingly, the difficult learning curve of laparoscopic radical prostatectomy skews the results strongly. In the series from Créteil and Heillbronn, the complication rate dropped significantly as experience increased, falling from 23% to 3.2% and from 13.7% to 6.4%, respectively (18,39).

> Not surprisingly, the difficult learning curve of laparoscopic radical prostatectomy skews the results strongly. In the series from Créteil and Heillbronn, the complication rate dropped significantly as experience increased, falling from 23% to 3.2% and from 13.7% to 6.4%, respectively.

In a large series from Paris, Guillonneau et al. (42) reported on the perioperative complications of laparoscopic radical prostatectomy in 567 patients. In this series, there were 21 major complications (3.7%) and 83 minor complications (14.6%) for an overall complication rate of 17.1%. Perioperative complications requiring reoperation occurred in 21 patients (3.7%), including 13 for a major complication (2.3%), and eight for a minor complication (1.4%). Major complications requiring reoperation included bowel or rectal injury (five patients), hemorrhage (five patients), and ureteral injuries (two patients). There were eight rectal injuries (1.4%), seven of which were noticed immediately and closed laparoscopically in two layers. Two patients with rectal injury required reoperation and temporary colostomy: one patient whose rectal injury was not immediately recognized and one whose injury was repaired but who developed an abscess. Minor complications requiring intervention included epigastric artery injury (0.5%), wound dehiscence (0.7%), and persistent lymphatic drainage (0.2%). Other minor complications included deep vein thrombosis (0.3%), paralytic ileus (1%), vesicourethral anastomotic leakage (0.2%), upper extremity neuropathy (0.4%), and obturator nerve neuropraxia (0.2%). Conversion from laparoscopic radical prostatectomy to open retropubic radical prostatectomy occurred in seven patients (1.2%), all of whom were among the first 70 patients; there were no conversions among the last 500 patients.

In a subsequent report from Montsouris with 1000 patients, rectal injury occurred in 13 patients (1.3%) (43). In 11 patients, the injury was noted intraoperatively and closed primarily in two layers without colostomy or conversion to open retropubic radical prostatectomy. Two patients had delayed rectal injury noted due to development of peritonitis on postoperative day 2 and 4, respectively. These two patients, as well as two patients with immediately recognized and repaired rectal injury who developed peritonitis, required reoperation, and three required temporary colostomy (0.3%). One patient (0.1%) developed a rectourethral fistula despite rectal injury closure in two layers and diverting colostomy, requiring repair through a perineal approach. Of the 13 rectal injuries, 12 occurred during non-nerve sparing procedures, and one occurred during a unilateral nerve sparing procedure. Among the 11 injuries recognized intraoperatively, the injury occurred in 10 patients during dissection of the prostate posteriorly at the apex, and in one patient during wide excision of a neurovascular bundle.

Although rectal injury is a major complication when not recognized, the rate of rectal injuries was similar to that of open radial prostatectomy, and the vast majority was recognized immediately, allowing primary closure and no adverse sequelae (43,44).

> Although rectal injury is a major complication when not recognized, the rate of rectal injuries was similar to that of open radial prostatectomy, and the vast majority was recognized immediately, allowing primary closure and no adverse sequelae.

TABLE 2 ■ Oncologic and Functional Data After Laparoscopic Radial Prostatectomy in Series Worldwide

	No. of patients	Positive surgical margin rate	PSA nonrecurrence	Urinary continence (length of follow-up)	Potency (in previously potent patients undergoing nerve sparing surgery)
Créteil (18)	134	25%	89.6% (11 months)	86.2% (1 year)	BNS: 46%[a]
Créteil (50)	235	N/A	N/A	90% no pad (1 year)	BNS: 58.8%[b]
Berlin (5)	125	26.4%	100% (6 months)	92% 1 pad or less (9 months)	UNS or BNS: 59% (with or without sildenafil)
Brussels (7)	50	22%	94% (3 months)	85% (6 months)	BNS: 83% (with sildenafil)
Heidelberg (39)	438	Table 3	Table 3	90.3% (12 months) 95.8% (18 months)	Not reported
Montsouris (17)	550	16.7%	pT2a: 92.3% (36 months); pT2b: 86.3% (31 months)	82.3% no pad (12 months)	BNS: 85% spontaneous erections, 66% intercourse

Kobe (38)	26	Not reported	100% (1 month)	100% no pad (6 months)	BNS: 71% spontaneous erections, 14% intercourse
Leipzig (23)	70	21%	Not reported	90% no pad (6 months)	BNS: 33% intercourse with sildenafil

[a]Defined as intercourse without sildenafil.
[b]Spontaneous erections.
Abbreviations: UNS, unilateral nerve sparing; BNS, bilateral nerve sparing.

CANCER CONTROL

> The major underlying goal of laparoscopic radical prostatectomy is achieving the best cancer control with the least morbidity.

The major underlying goal of laparoscopic radical prostatectomy is achieving the best cancer control with the least morbidity.

Since the introduction of the modern anatomic open retropubic radical prostatectomy by Walsh and Donker in 1982 (21), the reported five- and 10-year prostate specific antigen nonprogression rates have been 77–80% at five years after open retropubic radical prostatectomy and 54–75% at 10 years (45–49). Because laparoscopic radical prostatectomy has been performed only within the past six years, long-term data on prostate specific antigen nonprogression after laparoscopic radical prostatectomy are unavailable. The short-term oncologic data after laparoscopic radical prostatectomy, however, are encouraging, as shown in Table 2.

The Montsouris experience of about 1000 cases of laparoscopic radical prostatectomy with a median follow-up of 12 months has been published (51). The final pathologic stage was pT2N0/Nx in 775 patients (77.5%), pT2a in 203 patients (20.3%) and pT2b in 573 patients (57.3%), pT3aN0/Nx in 142 patients (14.2%), pT3bN0/Nx in 77 patients (7.7%), and pT1-3N1 in six patients (0.6%). The positive surgical margin rates for each clinical and pathologic stage and each Gleason score are shown in Table 2. The positive surgical margin rate was 19.2% overall, and it varied with pathologic stage from 6.9% for pT2a patients up to 32% for pT3b patients.

In a recent series of laparoscopic radical prostatectomy at Memorial Sloan-Kettering Cancer Center, 77% of the patients had pT2 disease, 19% had pT3, and 4% had pT4 cancers. The positive surgical margin rate by pathological stage was after laparoscopic radical prostatectomy was 3.8% for pT2, 26% for pT3, and 100% for pT4 tumors; the total tumor volume in this series was 2.02 (+2.6) cm^3.

In a retrospective study from Germany, Rassweiler et al. (39) compared three consecutive patient cohorts as Rassweiler's institution made a transition from open retropubic radical prostatectomy to laparoscopic radical prostatectomy. The cohorts consisted of 219 patients receiving open retropubic radical prostatectomy before routine laparoscopic radical prostatectomy was performed, the initial 219 patients who received laparoscopic radical prostatectomy during the "learning curve" (early), and the next 219 patients undergoing laparoscopic radical prostatectomy (late). To maintain the accuracy of comparison, the cohorts included only patients who had concurrent pelvic lymphadenectomy, and 83 patients who had laparoscopic radical prostatectomy without lymphadenectomy were excluded. These patient cohorts were consecutive rather than concurrent, with the open retropubic radical prostatectomy patients having surgery between 1994 and 1999 and the laparoscopic radical prostatectomy patients having surgery from 1999 to 2002. Understandably, the median follow-up was different

for each group: 67 months for the open retropubic radical prostatectomy group versus 30 months for the early laparoscopic radical prostatectomy group and eight months for the late laparoscopic radical prostatectomy group. Probably because of stage migration, the percentage of patients with organ-confined (pT1/T2) tumors was lowest in the retropubic radical prostatectomy group (45.7% vs. 55.3% vs. 65.3% in open retropubic radical prostatectomy, early laparoscopic radical prostatectomy, and late laparoscopic radical prostatectomy, respectively), but not significantly different. The positive surgical margin rate also did not differ significantly in these three groups, as shown in Table 2. With the relatively short median follow-up of 30 months, the PSA nonprogression rate in the early laparoscopic radical prostatectomy cohort was 86.8%.

In a similar, earlier study from Montsouris, Fromont et al. (52) compared a matched cohort of 139 open retropubic radical prostatectomy and 139 laparoscopic radical prostatectomy patients with procedures done by two senior surgeons. The laparoscopic radical prostatectomy patients were matched by preoperative serum PSA level with patients who received open retropubic radical prostatectomy performed by the same two surgeons during an earlier period (1994–1997). There was no significant difference between the open retropubic radical prostatectomy and laparoscopic radical prostatectomy groups in PSA (10.6 vs. 10.4), age (64.3 vs. 63.5 years), biopsy Gleason score (5.7 vs. 5.8), or number of positive biopsy cores (2.3 vs. 2.3). The proportion of T1 tumors was higher in the laparoscopic radical prostatectomy group (46% vs. 69%, $P < 0.01$), likely representing stage migration. In the final pathologic analysis, there were no significant differences between open retropubic radical prostatectomy and laparoscopic radical prostatectomy in the rate of positive lymph nodes (1.4% vs. 1.7%), prostate weight (53.4 vs. 55.5 g), or pathologic stage (pT2a: 20% vs. 18%, pT2b: 80% vs. 82%, pT3: 25% vs. 28%). Additionally, there was no significant difference in the final Gleason score, although there was a trend towards a higher percentage of high-grade cancers (Gleason 8–9) in the open retropubic radical prostatectomy group (8.6% vs. 4.3%). The overall rate of positive surgical margins was significantly lower in the laparoscopic radical prostatectomy group compared to the matched open retropubic radical prostatectomy group (13.7% vs. 25.9%, $P < 0.02$). When examining organ-confined cancers, the positive surgical margin rate for pT2 patients was also significantly lower for laparoscopic radical prostatectomy (10% vs. 20.9%, $P < 0.05$). Apical positive surgical margins appeared to account for the differences. Positive apical surgical margins occurred in laparoscopic radical prostatectomy and open retropubic radical prostatectomy in 7.2% versus 15.5% of patients overall, and in 7% versus 18% of patients with pT2 tumors ($P < 0.05$), with no significant difference in positive surgical margins occurring at other sites (posterolateral, base, bladder neck, or multiple sites). From this study, the authors concluded that laparoscopic radical prostatectomy does not lead to higher positive surgical margin rates compared to open retropubic radical prostatectomy.

Other studies have attempted to delineate anatomic differences between open and laparoscopic approaches, to better understand how positive surgical margins occur. A study by Salomon et al. (53) examined 371 patients with organ-confined prostate cancer (pT2) treated by retropubic prostatectomy (116 patients), radical perineal prostatectomy (PRP, 86 patients), or laparoscopic radical prostatectomy (169 patients). There was no significant difference between each group for age, Gleason grade, or clinical stage, but the serum prostate specific antigen level was significantly lower for laparoscopic radical prostatectomy versus retropubic radical prostatectomy and PRP patients (8.9 ng/mL vs. 11.1 and 11.1, respectively). The overall rate of positive surgical margins did not differ significantly for the three groups. The location of positive surgical margins, however, appeared different among the groups. The apical positive margin rate was lower in PRP compared to retropubic radical prostatectomy or laparoscopic radical prostatectomy; the bladder neck positive margin rate was lower for laparoscopic radical prostatectomy than for retropubic radical prostatectomy or PRP; and the posterolateral positive margin rate was higher for laparoscopic radical prostatectomy than retropubic radical prostatectomy or PRP (8.8%, 4.3%, and 3.4%, respectively). These differences, however, did not reach statistical significance. In a follow-up study from the same institution, changes in laparoscopic radical prostatectomy technique reduced the positive surgical margin rate (54). After switching from a bladder neck sparing approach to wide resection of the bladder neck, the rate of positive margins at the bladder neck decreased. Similarly, after changing technique to avoid preservation of the puboprostatic ligaments by incising them each time, the rate of positive margins at the apex decreased. Attempts at neurovascular bundle preservation in selected patients did not result in more positive surgical margins. These studies demonstrate that differences in technique

directly relate to the chance of having a positive surgical margin, but neurovascular bundle preservation does not appear to affect the rate of positive surgical margins significantly. In another retrospective case-control study by Brown et al. (57), 60 laparoscopic radical prostatectomy patients were analyzed for pathologic efficacy and compared with 60 concurrent open retropubic radical prostatectomy patients, and with 60 patients undergoing open retropubic radical prostatectomy matched with the laparoscopic radical prostatectomy patients by clinical stage and biopsy Gleason grade. In this study, the positive surgical margin rate in laparoscopic radical prostatectomy was not significantly different from that in either of the open retropubic radical prostatectomy groups, and the incidence of isolated apical positive margins and multiple-site positive margins was lower in the laparoscopic radical prostatectomy group.

Because of concerns of positive surgical margins in laparoscopic radical prostatectomy during nerve sparing procedures, surgeons at the Montsouris Institute prospectively sent all laparoscopic radical prostatectomy specimens for frozen section analysis in 100 patients undergoing bilateral nerve sparing laparoscopic radical prostatectomy (58). On each side of the prostate specimen, a wedge of tissue from the posterolateral margin in the vicinity of the neurovascular bundle was excised and immediately analyzed. In patients whose frozen section analysis demonstrated a positive surgical margin, the ipsilateral neurovascular bundle was excised. The frozen section analysis revealed positive surgical margins in 24%, and the complementary resection of the ipsilateral neurovascular bundle revealed residual tumor in one-third of these. Intraoperative frozen section analysis decreased the overall positive surgical margin rate from 33% to 12% and from 26% to 8% in organ-confined (pT2) tumors.

FUNCTIONAL RESULTS

The lack of uniformity in defining, assessing, and reporting functional results after radical prostatectomy leads to a disparity of results between different series. The definition used the methodology by which data are gathered and analyzed, and the time of assessment need to be taken into consideration while interpreting the results of potency and continence.

Continence

Guillonneau et al. reported an 82.3% continence rate at 12 months including only pad-free patients as continent and using a validated questionnaire as a measurement tool. Using the same definition, Rassweiller et al. and Eden et al. reported a 91% and 90% continence rate at 12 months, respectively. In the Creteil's experience, the reported rates of urinary continence defined as no pad required at one year, improved from 78% to 90% in subsequent reports (50,59).

In an evaluation of short-term functional results at Memorial Sloan-Kettering Cancer Center, at three months after laparoscopic radical prostatectomy 49% of the patients had regained urinary continence and did not require the use of any pads, while 22% had mild SUI (leaked only with heavy physical activity) and wore one pad a day as a precaution.

Potency

Most series of laparoscopic radical prostatectomy include potency data only on a small subset of patients, usually treated after the technique of laparoscopic radical prostatectomy and neurovascular bundle preservation was mastered.

The measurement of potency after surgery appears somewhat convoluted, with some centers reporting only the rate of spontaneous erections and others including use of sildenafil as satisfactory for potency. The length of follow-up is another important facet in analysis of sexual function after prostate surgery, since potency can return months or years after surgery.

Potency depends significantly on preoperative sexual function, patient age, and the degree of neurovascular bundle preservation achieved during surgery: bilateral nerve sparing, unilateral nerve sparing, or no nerve sparing. Of their initial 550 patients, Guillonneau et al. reported in a subset of 47 consecutive patients less than 70 years of age. Of those patients who were preoperatively potent, and underwent bilateral nerve sparing, 31 patients (66%) were able to have intercourse with or without sildenafil.

In a contemporary cohort of 110 patients treated at Memorial Sloan-Kettering Cancer Center, 58% of the preoperatively fully potent patients were able to have intercourse (with or without sildenafil) when bilateral neurovascular bundle preservation

The lack of uniformity in defining, assessing, and reporting functional results after radical prostatectomy leads to a disparity of results between different series. The definition used the methodology by which data are gathered and analyzed, and the time of assessment need to be taken into consideration while interpreting the results of potency and continence.

The length of follow-up is another important facet in analysis of sexual function after prostate surgery, since potency can return months or years after surgery.

was performed versus 25% after unilateral preservation ($P = 0.013$; odds ratio, 4.1; 95% CI, 1.3–12.6) at three months after laparoscopic radical prostatectomy. Among patients with bilateral nerve sparing, the outcome was different depending on the quality of preservation. Seventy-one percent of patients with complete bilateral preservation were able to have intercourse versus 57% of the patients who had one nerve completely preserved and possible damage on the other ($P = 0.003$; odds ratio, 12.2; 95% CI, 2.3–65.3) and 16% in patients who had bilateral possible damage ($P = 0.03$; odds ratio, 6.8; 95% CI, 1.2–40.3). On multivariate analysis, the quality of neurovascular bundle preservation was predictive of potency at three months after laparoscopic radical prostatectomy.

NEW INNOVATIONS IN LAPAROSCOPIC PROSTATE SURGERY

As the technique of laparoscopic radical prostatectomy has become standardized and widespread, several centers have begun to use these techniques for salvage laparoscopic radical prostatectomy, and to perform sural nerve grafting during laparoscopic radical prostatectomy.

> As the technique of laparoscopic radical prostatectomy has become standardized and widespread, several centers have begun to use these techniques for salvage laparoscopic radical prostatectomy, and to perform sural nerve grafting during laparoscopic radical prostatectomy.

In an early experience from France, Vallancien et al. (58) reported on laparoscopic radical prostatectomy performed as salvage therapy for seven patients. All had previously undergone radiotherapy (external beam radiation in five and brachytherapy in two) and had a rising PSA level with no evidence of clinical metastasis. The operative parameters were similar to those of standard laparoscopic radical prostatectomy; the urethral catheter was left longer (an average of 13 days) because of concerns with healing in a previously radiated field. There were no intraoperative complications or conversions to open surgery. Five of seven patients are continent (71%), and the postoperative PSA at mean follow-up of 11 months was <0.1 ng/mL in five patients.

Building on the experience of sural nerve grafts during open RP reported by Scardino et al. (59,60), Tuerk et al. (61) demonstrated the technical feasibility of performing nerve grafting during laparoscopic radical prostatectomy. The use of the daVinci robotic system for nerve grafting has also been reported by Kaouk et al. (62). All procedures were performed successfully, demonstrating the feasibility of this procedure. Long-term follow-up with greater numbers is necessary to determine efficacy.

PERSONAL EXPERIENCE OF THE SENIOR AUTHOR (B. G.): THE LESSONS LEARNED

In the last 6.5 years, I have performed laparoscopic radical prostatectomy in approximately 1000 patients. Although the concept of this procedure did not change, the operative strategy has evolved dramatically with experience.

The Laparoscopic Approach in General

Much of the debate at the present time is about the value of the intraperitoneal versus the extraperitoneal approach, and also about the timing of the dissection of the seminal vesicles. It is clear that the extraperitoneal approach is quicker. The Retzius space is developed with either a balloon or finger dissection, thus eliminating the anterior dissection of the intraperitoneal approach. Furthermore, the surgeon senses that the operation starts directly on the prostate.

It is my personal belief that for preoperatively potent patients for whom preservation of potency is intended, the dissection of the seminal vesicles first is paramount in laparoscopy.

> It is my personal belief that for preoperatively potent patients for whom preservation of potency is intended, the dissection of the seminal vesicles first is paramount in laparoscopy.

The reason is anatomical: the seminal vesicles are superficially located behind the peritoneal fold of the pouch of Douglas; their dissection is definitely easier and controlled through this approach. The importance of this step vis-à-vis the functional outcome resides in the close anatomical relationship between the lateral aspects and the tips of the seminal vesicles and the inferior hypogastric plexus (pelvic plexus) and the cavernous nerves. It is essential to avoid any injury to these structures by an accurate dissection of the seminal vesicles in a bloodless surgical field and with a precise control of all the vessels feeding the seminal vesicles. To achieve this goal, it is obvious that dissection is better accomplished through the posterior transperitoneal approach. In the extraperitoneal approach, the seminal vesicles are approached anteriorly through the bladder neck, which most often requires a larger incision laterally towards the pedicles to compensate for an indirect axis of vision, more traction on the seminal vesicles, and

a dissection in an often bloody area. Hence, there is a severe risk of damage to the neurovascular bundles.

However, in patients with preoperative erectile dysfunction, or in case of planned neurovascular bundle resection, or even difficult posterior access secondary to either obesity and/or deep pouch of Douglas, the seminal vesicles are approached anteriorly rather than posteriorly, but the above scenarios are sources of technical difficulties leading to a less accurate seminal vesicle dissection.

The argument that the extraperitoneal approach avoids the potential complications of the peritoneotomy is a false one.

Besides the points listed above, there are no complications solely related to the peritoneotomy. On the other hand, the transperitoneal approach provides a larger working space, with clearly better instrument manipulation and an easier use of the suction without prompt loss of the pneumoperitoneum. But more important is the quality of the anastomosis achieved with the intraperitoneal dissection.

Intraperitoneal dissection provides increased mobility of the bladder allowing a real tension-free anastomosis as compared to the extraperitoneal approach where the anastomosis is often performed under tension. This tension-free anastomosis is, to my knowledge, a better explanation for the very low bladder stricture rate, less than 0.5% in this experience.

Steps in Neurovascular Bundle Preservation

This step impacts greatly on the functional outcome and is the main reason why the operative time has not shortened with experience; any time saved on other steps of the dissection is allocated to the preservation of the nerves.

These nerves are very fragile and any trauma of any nature can definitively damage them and compromise erectile function. The goal is to dissect the nerves in as delicate a way as possible and with the least manipulation. Developing the appropriate plane of dissection close to the prostate is ideal; however, oncological safety must not be compromised.

Only an extended preoperative work-up and a complete comprehension of the anatomy will help in achieving this task. The use of hemostatic tools (clips, bipolar coagulation, and suture) for ligation of the pedicles is of no consequence—as long as this is performed close to the prostate, and is not performed "en bloc." The dissection of the neurovascular bundle itself should be done without any hemostatic means, as long as an intrafascial plane is developed. Bleeding during this step most likely means that the dissection is taken in the neurovascular bundle itself (i.e., interfascial plane): the intracapsular vessels arising from the neurovascular bundle and entering the prostate, usually found at the base and apex, are the source of easily controlled bleeding.

Accessory Pudendal Arteries

Accessory pudendal arteries are frequent; their role and importance however are debatable. An accessory pudendal artery coming in laterally from the inferior vesical arteries is easily recognized laparoscopically. It is certain that in some patients they represent the only arterial supply to the corpora cavernosa and therefore every effort at sparing them should be taken.

But other accessory pudendal arteries encountered at the apex may be branches of the obturator arteries.

The impact of these apical arteries on potency and continence is unclear and for that reason they should all be preserved though a delicate dissection.

The impact of these apical arteries on potency and continence is unclear and for that reason they should all be preserved though a delicate dissection.

Control of the Dorsal Vascular Complex

At the apex, the incision of the dorsal vascular complex should be tangential in order to avoid a positive surgical margin anteriorly. In cases with high suspicion of anterior tumor, the dorsal vascular complex is directly transected as distal as possible, leaving a sufficient amount of vascular structures on the anterior aspect of the prostatic apex and without placing a hemostatic suture prior to incision.

It is always possible to control the bleeding from the dorsal vascular complex, and raising the pressure of the pneumoperitoneum up to 20 mmHg during the stitching is definitively helpful.

It is always possible to control the bleeding from the dorsal vascular complex, and raising the pressure of the pneumoperitoneum up to 20 mmHg during the stitching is definitively helpful.

Dissection of the Apex

The apex is the principal location of positive margins in pT2 tumors, indicating that particular attention should be paid during this step.

At the present time, the urethra is kept intact during all of the apical dissection and used as a landmark: laterally, it helps to identify the junction between the prostate, the urethra, and the neurovascular bundle, and the contours of the prostate are then followed until the neurovascular bundle is totally freed. The urethra is therefore the last structure transected. This modification has certainly contributed to a reduction of the positive margin rate to about 3% in pT2 tumors.

At the present time, the urethra is kept intact during all of the apical dissection and used as a landmark: laterally, it helps to identify the junction between the prostate, the urethra, and the neurovascular bundle, and the contours of the prostate are then followed until the neurovascular bundle is totally freed. The urethra is therefore the last structure transected. This modification has certainly contributed to a reduction of the positive margin rate to about 3% in pT2 tumors.

Analyzing the Specimen

Once the prostate is freed, the specimen is extracted immediately for macroscopic examination. The purpose of this step is to adjust for the lack of intraoperative tactile feeling of laparoscopy and to ascertain oncological safety by giving the surgeon a chance to resect additional tissue based on the gross examination and/or frozen section results.

SUMMARY

- Laparoscopic radical prostatectomy is a relatively new approach to the surgical treatment of localized prostate cancer.
- Since its inception, the technique, however challenging, is undergoing continuous refinements, which made it today a feasible, reproducible, and teachable operation practiced by urologists worldwide.
- The advantages of the laparoscopic approach are a magnified view of the anatomic structures, and a decreased venous bleeding in the surgical field allowing an accurate dissection of the prostate and neurovascular bundles. Theses advantages translate to a low positive surgical margin rate, low morbidity profile, and favorable postoperative quality of life outcomes.
- Performed only in the last six years, long-term cancer control and functional results data following laparoscopic radical prostatectomy are not available.
- For a successful laparoscopic prostatectomy program, advanced laparoscopic skills, knowledge of the prostatic anatomy, and expertise in surgical oncology are required.

COMMENTARY

Robert P. Myers
Department of Urology, Mayo Clinic, Mayo Clinic College of Medicine,
Rochester, Minnesota, U.S.A.

Minimally invasive therapy has as its basic premise the reduction of iatrogenic trauma. This approach must imply that the therapeutic procedure succeeds in a manner no less effective than is currently achievable by established methods of treatment.—*J.E.A. Wickham, 1993 (1).*

The surge of interest in laparoscopic radical prostatectomy (LRP) is certainly an offshoot of the concept of minimally invasive surgery, for which due credit must be extended to John Wickham, who has had so much influence (1). Open radical perineal prostatectomy has been accomplished for more than 100 years (2) and open radical retropubic prostatectomy for more than 50 years (3). Much is known about the long-term results of these open operations in terms of cancer control and functional outcome. The laparoscopic approach is so new, relatively speaking, that long-term outcomes are not at all clear at this time.

There are three distinct arguments for laparoscopic radical prostatectomy over the open retropubic operation. The first argument is reduced blood loss with, on average, likely a higher hemoglobin level at dismissal. This is associated with increased strength, quicker recovery, and more rapid return to work. This argument does not hold for the perineal operation, in which blood loss is minimal and same-day dismissal conceivable. The perineal route is the most direct access to the prostate, and the non–nerve-sparing operation can be completed skin to skin in 40 minutes, as the late Ormond Culp did when I first assisted him as a resident-in-training.

The second argument is the tremendously magnified (×10 to ×15) and detailed view of the relevant anatomy with laparoscopic radical prostatectomy. However, this advantage can be attained in open surgery by wearing magnifying optical loupes of ×2 to ×4.5. I use ×2.5 and have excellent three-dimensional depth of field. In laparoscopic radical prostatectomy, the two-dimensional field must be learned, and the Da Vinci robotic device with three-dimensional imaging makes the two-dimensional learning curve unnecessary.

The third argument for laparoscopic radical prostatectomy is the improved cosmetic result from using multiple tiny ports rather than a midline incision. But this can be achieved for the insistent patient by using either the transverse Langer line Pfannenstiel (in thin patients) or Cherney incisions, the latter providing wide pelvic access even in the deepest pelvis (4). The Cherney incision with its disarticulation of the rectus abdominis tendons

FIGURE 1 ■ Postoperative scar of transverse Cherney incision extended from previous left lower quadrant scar of incision used for placement of kidney transplant.

does necessitate careful reconstruction and convalescence to avoid subsequent hernia and is particularly useful for patients who have had a kidney transplantation to an abdominal lower quadrant (Fig. 1).

Laparoscopic radical prostatectomy provides no obvious advantage in terms of duration of hospitalization. The introduction of preemptive analgesia has made the open retropubic operation virtually pain free and patients are up and about, eating, and able to be dismissed in 24 to 48 hours. (Patients undergoing the perineal operation have very little pain). With careful hemostasis during the open retropubic operation, a hemoglobin value at dismissal of 10 to 12 g/dL, without having a transfusion, is possible; patients, thus, have a sense of strength and well-being at dismissal. If blood bank guidelines allowed transfusion for patients whose hemoglobin value was less than the ideal dismissal range of 10 to 12 g/dL, laparoscopic radical prostatectomy would not have an advantage in this regard.

Cost is not an insignificant issue. If patients who have the open techniques can be dismissed the same day as, or within 24 to 48 hours of, operation, these approaches will be more cost effective not only in operating room time for most surgeons but also certainly in the cost of material and "disposables." In the United States, Medicare reimbursement for radical prostatectomy is so fine-tuned that it is an extraordinary challenge to come in under reimbursement. The *da Vinci*® robotic system, which has an initial cost of $1.2 million, yearly maintenance cost of about $100,000, and a cost for "disposables" of more than $2000 per case, is economically impractical for most institutions. Furthermore, the number of candidates for radical prostatectomy exceeds the number of qualified practitioners of laparoscopic radical prostatectomy, both traditional and robotic.

The ability to succeed in the goals of cancer control, urinary control, and maintenance of erectile function depends on the skill of the surgeon to extract the prostate, seminal vesicles, and portions of the vasa deferentia with the least disturbance possible to the structures that need preservation. Structures that need preservation include the striated urethral sphincter and the "distal sphincter mechanism," to credit Richard Turner Warwick's terminology (5), and the "neurovascular bundles," to credit Patrick Walsh's terminology (6). For successful outcome, it may help to preserve the bladder neck longitudinal smooth muscle, the so-called Bundle of Heiss (7), which can be usefully incorporated for initial passive continence in the bladder neck plication during open surgery (8). Currently, it is not at all clear that laparoscopic radical prostatectomy can achieve minimal disturbance of these structures critical to functional outcome in the same way afforded by open surgery, particularly the open retropubic approach. "Below the abdominal wall level, laparoscopic radical prostatectomy is clearly no less invasive than an open approach." To date, video demonstrations of laparoscopic radical prostatectomy that I have witnessed exhibit remarkable traction on the nerve bundles, and the extensive cautery used must generate considerable heat in the region of the pedicles and nerve bundles. In laparoscopic radical prostatectomy, discrimination and separation of the vascular pedicles from the nerve bundle appear challenging, as does accurate antegrade apical dissection of the prostate. As recently suggested, real-time transrectal ultrasonography can assist in the apical dissection during laparoscopic radical prostatectomy (9). Also, this latter difficulty of apical dissection has been overcome to some degree by takedown of the puboprostatic (pubovesical) ligaments close to their pubic insertion points. This then allows better direct access to the anterior prostatourethral junction for the purpose of optimal urethral transection. If the takedown of the puboprostatic ligaments is not done carefully, the immediately and laterally adjacent tendinous insertions of the puborectalis (puboanalis) sling could be disrupted and postoperative fecal control compromised. With the hands-on control and tactile feedback of open surgery, all of the above issues can be avoided.

Critical appraisal of laparoscopic radical prostatectomy and the open operations will be forthcoming only with prospective studies using internationally recognized, validated questionnaires under third-party control to probe general quality of life, functional outcomes and bother, and cancer control in suitable numbers of patients. Time to functional recovery of pad-free urinary

control and erectile function suitable for satisfactory intercourse is another matter. How quickly do patients recover those functions? For laparoscopic radical prostatectomy to be fully acceptable, the best results of laparoscopic radical prostatectomy must be shown to match, unequivocally, the best results of an open operation.

Finally, how do we improve training opportunities? How many patients are hurt in anybody's learning curve for any type of approach, and how can needless injury be avoided, for example, the 12-hour procedure with ultimate urinary and fecal diversion? This is not a criticism directed at laparoscopic radical prostatectomy. The open retropubic and perineal operations can become instant disasters in the hands of the unknowing when patients become victims of reckless behavior. Importantly, the bottom line is always going to be proper training and judgment in whatever approach is used.

PORT SITE METASTASIS IN UROLOGIC LAPAROSCOPY

Steven M. Baughman and Jay T. Bishoff

Urology Flight, Wilford Hall Medical Center, Lackland AFB, Texas, U.S.A.

INTRODUCTION

The use of laparoscopy in the treatment of malignant disease has generated a great deal of controversy, in part, due to the fear of inadequate cancer control. The early laparoscopic experience cited in the surgical and gynecological literature initially elevated concerns regarding the risk of port site recurrence. Indeterminate surgical margins and loss of precise pathological staging information due to morcellation historically increased these concerns. In urologic surgery, minimally invasive procedures for malignant disease have shown equivalent cancer control when compared to traditional open approaches.

HISTORY: GYNECOLOGIC AND GENERAL SURGERY LITERATURE

Recurrence of malignancy at trocar or port sites following laparoscopy has been described in the general surgical, gynecologic, and urologic literature.

Port site recurrence can be defined as subcutaneous tissue or abdominal wall malignant tumor reappearance following laparoscopy for malignancy, not associated with carcinomatosis at the time of the initial procedure.

To date, however, the majority of port site recurrences have been reported in the general and gynecologic surgical literature. From the early experience with laparoscopic cholecystectomy came reports of unrecognized gall bladder and gastrointestinal tumors recurring at the port sites following laparoscopy (1–6), which caused concern and criticisms of laparoscopy applied to oncologic surgery. As a result, some surgeons expressed the need for more formal prospective randomized studies to further understand this dilemma (7).

In an effort to retrospectively refute these criticisms, an initial broad survey of over 1050 European general surgery programs demonstrated port site recurrence in 17% of laparoscopic cholecystectomies where there was an incidental finding of gallbladder carcinoma and 4.6% of laparoscopic cases for colorectal cancer (8). The authors implicate laparoscopy as an independent factor leading to port site recurrence, without taking into account the incidental discovery of gastrointestinal cancer or unprotected organ removal from the abdomen, violating established cancer surgical principles. A six-year review of 533 procedures (mean follow-up of 13.2 months) from the University of Texas M.D. Anderson Cancer Center identified only four port site recurrences for nongynecologic laparoscopic cancer surgery. Three of the four patients had demonstrable intra-abdominal disease at the time of laparoscopy, with the final patient having the port site as the only site of recurrence. This group concluded that port site recurrence is not only rare, but also indeed more rare in those patients with no evidence of advanced intra-abdominal disease (9). The rarity of port site recurrence is further demonstrated in other contemporary series of laparoscopic oncologic procedures compared to open surgical experiences, with no statistically significant comparative wound recurrence rates (10–12).

Port site recurrence can be defined as subcutaneous tissue or abdominal wall malignant tumor reappearance following laparoscopy for malignancy, not associated with carcinomatosis at the time of the initial procedure.

Vertical midline laparotomy is argued as the gold standard for ovarian malignancy, because large prospective randomized clinical trials comparing laparoscopy are absent from the contemporary gynecologic literature (13). Despite this argument, the ubiquity and benefits of laparoscopy has driven minimally invasive management for many gynecologic malignancies (14). Using laparoscopy for the treatment of uterine carcinoma with bulky adenopathy appears to have a higher gynecologic risk of port site recurrence when compared to open surgery (15–18). Additional citations also reflect that nearly every gynecologic malignancy has reported port site recurrences (19–21).

In evaluating the cases reported regarding port site seeding, several common elements emerge. Many cases are associated with circumstances where malignancy was unexpected or was being determined with diagnostic laparoscopy or biopsy (10,22). As such, basic principles of cancer surgery may have been violated and in many cases metastatic disease (i.e., carcinomatosis) or malignant ascites was already present (23). In addition, the majority of cases involved removal of tissue either directly through a trocar site or through a small incision without entrapment sac protection.

UROLOGIC EXPERIENCE

A careful search of the urologic literature demonstrates a relatively low incidence of laparoscopic port site seeding from adrenal, renal, urothelial, testicular, or prostate carcinomas (Table 1).

Dunn et al. demonstrated no port site recurrence or peritoneal seeding in their initial nine-year experience of 61 laparoscopic radical nephrectomies removed through both intact delivery and morcellation (38). As in other series (39), it is noteworthy that Clayman's group morcellated all specimens within a specially designed, impermeable sac, with the port site redraped in an effort to prevent wound contamination. Their institution's efforts are also successful in obviating port site recurrence following laparoscopic nephroureterectomy (40).

Rassweiler et al. reported a decade's experience of 1098 laparoscopic procedures for urologic malignancies (36). Local recurrence was observed in eight patients following nephroureterectomy for ureteral transitional cell carcinoma, one radical nephrectomy for renal cell carcinoma, one patient with teratoma following retroperitoneal lymph node dissection, three instances of prostate cancer, and one case following adrenalectomy for metastatic melanoma. port site recurrences, however, were observed following metastatic laparoscopic adrenalectomy for small cell carcinoma of the lung (Fig. 1) and following one postchemotherapy retroperitoneal lymph node dissection. Unfortunately descriptions of tissue manipulation, entrapment techniques, and specimen delivery are not discussed with these reports (36).

The inherent aggressive biologic behavior of metastatic disease to the adrenal gland is a likely mechanism for port site recurrence following laparoscopic adrenalectomy. To date, there are no identified primary adrenal malignancy port site recurrence reports. Conversely, there are two reports of port site recurrence following laparoscopic adrenalectomy for metastatic small cell carcinoma (36,37). Chen et al. describe wide en bloc dissection in an attempt to avoid manipulation of the adrenal gland and entrapment in an impermeable extraction device was noted in their report. However, at five months, the patient presented with a palpable port site mass (Fig. 2) and bowel obstruction. Palliative external beam radiotherapy management was attempted, but the patient expired as a result of metastatic disease 10 months postadrenalectomy (37).

To date, there have been four reports of port site seeding following laparoscopic radical nephrectomy for renal cell carcinoma. In a series of 57 laparoscopic radical nephrectomies, with specimen morcellation, one patient with T3N0M0 (Fuhrman IV/IV) disease suffered a solitary recurrence at one trocar site, 25 months after radical nephrectomy (24). Castilho et al. report multiple-site port site recurrences in a 72-year-old–male with a T1N0M0 renal cell carcinoma after laparoscopic radical nephrectomy. In this patient, ascites, relative immunosuppression from cirrhosis, or morcellation within a "plastic" nonimpermeable sac may have each contributed to this port site recurrence (25). Finally, one hand-assisted laparoscopic radical nephrectomy port site recurrence has also been reported (26). A patient with a 10 cm T2N0M0, Fuhrman grade III, renal cell carcinoma was without initial tumor violation, and negative surgical margins, but had the specimen delivered intact through the hand port without entrapment. Specific delivery through the hand port orifice or wound (without port) was not discriminated in this report. At nine months postnephrectomy, however, a 6×5 cm hand port site mass was seen (Fig. 3). The patient was treated with wide

A careful search of the urologic literature demonstrates a relatively low incidence of laparoscopic port site seeding from adrenal, renal, urothelial, testicular, or prostate carcinomas.

TABLE 1 ■ Reported PSR Following Minimally Invasive Management of Urologic Malignancy

References	Pathology (primary TNM stage, grade)	Primary laparoscopic approach	Recurrence identification	Management
Renal cell carcinoma				
24	Renal cell carcinoma (T3N0M0, Fuhrman IV/IV)	Transperitoneal	Port site discomfort with solid mass. CT confirmation at 25 mo	Surgical excision, every 3-mo clinical and radiographic (chest X ray, CT) follow-up. No evidence of disease at 35 mo postnephrectomy
25	Renal cell carcinoma (morcellated specimen, stage not reported, Fuhrman IV/IV)	Transperitoneal	Abdominal masses identified on CT	Alpha-interferon immunotherapy. Patient died 8 mo postnephrectomy
26	Renal cell carcinoma (T2N0M0, Fuhrman III/IV)	Hand-assisted, transperitoneal	Clinically palpable with CT confirmation at 9 mo	Operative excision, biopsy, and immunotherapy referral
27	Renal cell carcinoma PT3a, II/IV	Retroperitoneal	Left lumbar pain 39 wk postnephrectomy with CT confirmation	External beam radiation with no further follow-up reported
TCC				
28	Ureteral TCC (T1NxMx, "high-grade")	Extraperitoneal	Clinically palpable with CT confirmation at 12 mo	Operative excision with negative pathologic margins and 18-mo follow-up
29	TCC (TNM not reported, "high grade") TCCa invasive into renal parenchyma with one positive hilar lymph node)	Extraperitoneal	Painful mass at trocar site, with CT confirmation at 3 mo	Ultrasound biopsy for confirmation. No other management reported
30	TCC T4bNxM0, grade II	Transperitoneal laparoscopic staging and biopsy	Palpable nodule "shortly after" biopsy	Open exploration with positive biopsy. Tumor involvement of urachus, anterior abdominal wall, and preaortic lymph nodes
31	TCC (stage not reported, "high-grade" TCCa invasion with small vascular focus of invasion)	"Laparoscopic" nephrectomy	Painful umbilical port site 8 mo postnephrectomy	Open positive biopsy with CT follow-up demonstrating residual local recurrence at renal fossa, along psoas muscle, and hepatic metastases. Patient referred for chemotherapy. No follow-up reported
Pelvic lymph node dissection				
32	LPLND for CaP (T3N1M0, grade II)	Transperitoneal	Clinically palpable at 6 mo	Aspiration cytologic confirmation with no other diagnostic or therapeutic maneuvers. Patient died 8 mo postlymphadenectomy
33	LPLND for TCC (T3N1M0, grade II)	Transperitoneal	Clinically palpable subcutaneous masses at multiple port sites, with CT confirmation	Observation secondary to previous post-LPLND failure of M-VAC, chemotherapy and external beam radiotherapy. Hepatic mass identified on CT. Patient died one mo after PSR recognition
34	TCC (T2NxM0, grade II (at time of LPLND) (T3N0M0, grade III) after open cystectomy and ureterosigmoidoscopy	Transperitoneal	Right lower extremity edema 3 mo post cystectomy, with positive CT for right pelvic lymphadenopathy and 3 cm right superior port site mass	Open biopsy positive for TCCa. Patient refused chemotherapy and died three mo later
Miscellaneous				
35	Squamous cell carcinoma of the renal pelvis (T3N0M0)	Retroperitoneoscopic nephroureterectomy	Clinically palpable with CT confirmation at 6 mo	Surgical excision with mesh repair of aponeurotic defect. Disease free at 6-mo follow-up from excision
36	1. Metastatic small cell carcinoma to adrenal (TNM not reported) 2. Nonseminomatous germ cell tumor to the retroperitoneum. (TNM not reported)	Not reported	CT (adrenal lesion). Month not reported	Not reported. Each patient died within 6 mo after identification of PSR
37	Metastatic small cell carcinoma to adrenal (stage IIb small cell carcinoma of lung)	Transperitoneal	Clinically palpable with CT confirmation at 5 mo	Palliative external beam radiotherapy. Patient died 10 mo postadrenalectomy

Abbreviations: PSR, port site recurrence; TCC, transitional cell carcinoma; CT, computed tomography; LPLND, laparoscopic lymph node dissection; CaP, carcinoma of the prostate; TNM, tumor nodal metastatic; M-VAC, methotroxin vinblastin adriomycin cisplatin.

local excision and immunotherapy therapy (26). Finally, at 39 weeks post left retroperitoneoscopic radical nephrectomy, Iwamura et al. report the most recent abdominal wall recurrence in a patient with a primary T3a, Fuhrman grade II clear cell renal cell carcinoma. Importantly, tissue entrapment was not used in this case (27).

The exact incidence of laparoscopic port site recurrence following laparoscopic radical nephrectomy is not known. However, wound metastases following open radical nephrectomy for renal cell carcinoma are reported in approximately 0.4% (2 of 518) of cases (41). In open colon surgery for known cancer there is a 1.5% wound recurrence rate reported in the literature (42). In a retrospective multicenter study, with a mean follow-up of 19.2 months (range, 1–72; 51 with greater than two years follow-up), Cadeddu et al. reported no port site recurrence from laparoscopic nephrectomy for renal cell carcinoma in 157 cases (43).

Long-term open versus laparoscopic nephrectomy comparison by Portis et al. demonstrates no significant differences in local or distant metastatic recurrence rates, with no wound or port site recurrence (44).

> Long-term open versus laparoscopic nephrectomy comparison by Portis et al. demonstrates no significant differences in local or distant metastatic recurrence rates, with no wound or port site recurrence.

Transitional cell carcinoma appears to be more biologically susceptible to soft tissue metastatic implantation (45) and port site recurrence (46). In the laparoscopic staging and treatment of transitional cell carcinoma there have been several reports of port site seeding (28–31,33,47). In three instances, port site recurrence developed after laparoscopic staging with a biopsy or laparoscopic pelvic lymph node dissection of a primary bladder tumor. In one of three cases related to nephrectomy, seeding developed in a patient with a tuberculous atrophic kidney containing unsuspected transitional cell carcinoma (29). Loss of entrapment sac integrity was cited as a possible predisposing confounding factor in this case. Another case of port site recurrence was reported after laparoscopic extraperitoneal nephroureterectomy was performed one week following ureteroscopy and ureteral stent placement (Fig. 4). At the time of laparoscopic nephroureterectomy, the ureteral stent was seen protruding outside of the collecting system, possibly seeding the perirenal tissues (28). The uncommon squamous cell carcinoma from urothelial origin has also demonstrated abdominal wall recurrence following retroperitoneoscopic nephroureterectomy (35).

Bangma et al. reported on the first patient with port site seeding after laparoscopic pelvic lymph node dissection for prostate cancer (32). Since their initial report, several additional cases have been reported, each after nonentrapped, piecemeal extraction of lymphatic tissues (31,33,34,48). In contrast, Cadeddu et al. found no cases of port site seeding after 372 cases of laparoscopic pelvic lymph node dissection. A review of a subset of 40 patients with positive pelvic lymph nodes for prostate cancer (at the time of laparoscopic pelvic lymph node dissection) revealed no port site seeding up to three years after surgery. Furthermore, there was no acceleration in the natural history of the disease after laparoscopic pelvic lymph node procedures (49,50). Although pelvic lymph node extractions for urothelial and prostatic carcinomas demonstrate port site recurrence, no laparoscopic prostatectomy procedures have demonstrated port site recurrence.

BASIC SCIENCE AND PREDISPOSING FACTORS

Port site recurrence appears to be multifactorial, influenced by four possible mechanisms: (i) technical factors; (ii) local wound factors; (iii) immune status; and (iv) biologic tumor behavior.

Technical Factors

The technical aspects of laparoscopy have received the most attention in the understanding of port site recurrence. Investigators have demonstrated that tumor cells may be deposited at the port site during laparoscopy either directly from contaminated instruments or indirectly via aerosolization of tumor cells in the insufflation gas (51–54). However, "gasless" laparoscopic models also demonstrate variable tumor cell dissemination or port site recurrences when compared to insufflated cases (55–58), potentially further implicating the peritoneal dissemination of malignant cells via the development of a pneumoperitoneum (59). Studies using a CO_2-pneumoperitoneum reflect a higher incidence of port site recurrence compared to gasless, or other non–CO_2 gas–induced working spaces (60–62). Thomas et al. demonstrated that expelled filtered port site carbon dioxide gas was free from aerosolized malignant cells, but found that every single laparoscopic instrument and trocar themselves had malignant cell contamination, suggesting that direct instrument contamination and not gas dispersion may be the mechanism for port site recurrence (63).

Indeed, contemporary data reflect that direct contamination and seeding are the likely mechanisms (64), as hematogenous and other models (including one renal cell carcinoma model) fail to reflect port site recurrences from pneumoperitoneum creation (65–68).

Tissue manipulation itself may have a significant impact on the rates of port site recurrence. Increased tissue manipulation from laparoscopic-assisted techniques, such as hand-assisted laparoscopic surgery, may also potentiate tumor seeding. The implications on port site recurrence that hand-assisted laparoscopic may demonstrate have been shown in a murine model, where laparoscopic-assisted subcostal splenectomy had a significantly higher port site recurrence rate versus open splenectomy (69). The authors cite increased tissue manipulation as a potential catalyst for wound recurrence. Although not significantly reported in the current literature, one recent renal cell carcinoma port site recurrence was reported at a hand-assisted laparoscopic site (26). Additionally, increased tissue manipulations in concert with "leaking" port sites have promoted implantation and growth of port site recurrences in another murine model (70).

> Indeed, contemporary data reflect that direct contamination and seeding are the likely mechanisms, as hematogenous and other models (including one renal cell carcinoma model) fail to reflect port site recurrences from pneumoperitoneum creation.

Inherent with tissue manipulation are entrapment and morcellation. All potentially cancerous tissue should be entrapped in an impermeable sack and the field well draped prior to morcellation or extraction (39,71). Morcellation of specimens for extraction has raised concerns about both accurate pathological staging and its contribution toward port site recurrence. Computed tomography has been proven to be an effective tool for planning surgery and reliably predicting pathological findings. The overall accuracy of computed tomography in staging renal cell carcinoma ranges from 72% to 90% (72–75). In a review of 172 renal tumors treated with open radical nephrectomy, Shalhav et al. correlated the preoperative computed tomography-based clinical stage with the final pathological tumor stage. They found one patient (0.6%) to be understaged and seven (4%) overstaged by preoperative computed tomography. They concluded that clinical computed tomography staging of low-stage renal tumors is reliable and tends to over stage rather than under stage renal tumors (76).

> Currently, if a patient with clinically localized renal cell carcinoma is found to have microscopically advanced disease, there is no effective adjunct therapy. As such, morcellation does not alter subsequent follow-up or treatment.

Currently, if a patient with clinically localized renal cell carcinoma is found to have microscopically advanced disease, there is no effective adjunct therapy. As such, morcellation does not alter subsequent follow-up or treatment.

The long-term follow-up in laparoscopic series where kidneys are morcellated compared to open radical nephrectomy shows equivalent cancer free survival (77,78). When pathological staging is required, the specimen may be removed intact through a small, low midline, or Pfannenstiel incision.

Local Wound Factors

Local trocar-induced tissue trauma may itself pose an inherent risk to port site recurrence. Formal excision of laparoscopic port sites has demonstrated an actual increase in wound metastases in one model (79). Notwithstanding, the intact peritoneum seems to provide a barrier to tumor cell implantation. Peritoneal trauma has demonstrated tumor ingrowth at damaged surfaces compared to nontraumatized peritoneal sites (80).

When controlling for anesthesia alone, prolonged (30 minutes), low-pressure (6 mmHg) pneumoperitoneal studies demonstrate not only peritoneal damage (81,82), but also adhesion of cancer cells to the peritoneal basal layer (81). Mathew et al. demonstrated a possible synergistic effect of both peritoneal injury (with port site placement) in concert with pneumoperitoneum (83). Rats undergoing isolated laparotomy after purposeful abdominal malignant cellular dissemination had a statistically less histologic wound recurrence when compared to the same model undergoing laparoscopy. These observations may then suggest that obvious peritoneal disruption coupled with creation of a pneumoperitoneum, predispose the potential adhesion and ingrowth of tumor cells.

Immune Response

Various peritoneal immune responses are noted with both open laparotomy and laparoscopic techniques. Authors have suggested that CO_2-pneumoperitoneum diminishes macrophage-secreted tumor necrosis factor (84,85), depressing peritoneal cell-mediated immunity and increasing tumor implantation (84). Despite these findings, Lee et al. demonstrated that a full laparotomy performed in a sealed CO_2 chamber had similar lymphocyte proliferation suppression when compared to room-air–exposed incisions (86). These findings suggest that the incisional size, and not the CO_2 environment, depress peritoneal immunity.

Further work on the importance of peritoneal immunity is demonstrated by Neuhaus et al., where intraperitoneal injection of endotoxin 18 hours prior to laparoscopy decreased tumor growth and port site recurrence. This was challenged against the null effects of systemically injected cyclosporin (87).

> To date, the effects of local wound and peritoneal immunity are poorly understood, but may be a significant variable toward port site recurrence.

To date, the effects of local wound and peritoneal immunity are poorly understood, but may be a significant variable toward port site recurrence.

Tumor Behavior

> The biology of the primary lesion, along with the inoculum size of malignant cells deposited to the trocar site, are also possible sources of port site recurrence.

The biology of the primary lesion, along with the inoculum size of malignant cells deposited to the trocar site, are also possible sources of port site recurrence (88,89).

Cases that support this theory are noted previously in this manuscript. For example, the biologic susceptibility of transitional cell carcinoma to local and ectopic recurrence likely predisposes these tumors to port site recurrence. Squamous cell carcinoma arising from the urothelium is also known to hold aggressive biologic characteristics

TABLE 2 ■ Port Site Recurrence Prevention

Avoid resection and excision of tissue in face of carcinomatosis

Ascitic fluid sent for cytology should be isolated from all wounds

Minimize direct tumor handling to prevent iatrogenic tumor violation

Ensure wide en bloc dissection of tumor and surrounding tissues

All tissues should be placed within an impermeable laparoscopic sac prior to morcellation or tissue extraction

Redrape port sites at the time of tissue removal

All possible contaminated instrumentation should be removed from the newly towel-draped operative field

Change the surgeons' and technicians' gloves prior to formal peritoneal closure

(35). Metastatic disease, regardless of etiology, likely demonstrates biologic activity that is more aggressive. For example, chemoresistant cancers, which have metastasized, may carry a biologic predilection for tissue implantation and growth (36). This argument is also demonstrated with metastatic lesions to the adrenal, where the only port site recurrence cases from this organ are subsequent to metastatic adrenal lesion excision (36,37).

PORT SITE RECURRENCE PREVENTION

Several steps should be taken in order to prevent port site seeding and tumor spillage (Table 2):

■ The historical developments of basic cancer surgery principles must be followed; experience with laparoscopic oncology is paramount—as port site recurrence has been shown to fall with experience (86).
■ Ascitic fluid suspicious for malignancy should be sent for cytology with exhaustive efforts to keep this fluid away from fresh surgical wounds.
■ Direct handling of the tissue must be minimized and attempts made to prevent violation of the tumor.
■ Wide en bloc dissection should be performed to avoid tumor spillage and to obtain appropriate surgical margins.
■ All potentially cancerous tissue should be entrapped in an impermeable sack (examined for perforations prior to abdominal placement) and the field draped prior to laparoscopically monitored morcellation or extraction (24,40,71).
■ During tissue delivery, all possible contaminated instrumentation should be removed from the newly towel-draped operative field, the surgeon's gloves exchanged for new, and formal peritoneal closure performed (90).
■ Potential intraperitoneal immune or adhesion modifiers such as endotoxin (87), heparin (91,92) or helium pneumoperitoneum (93), povidine iodine or taurolidine (92,94–96) may prove beneficial in the prevention of port site recurrence in future.

PERCUTANEOUS ABLATION

Although local recurrence of renal cell carcinoma has been reported following percutaneous radio frequency ablation, no radio frequency-, cryo-, or microwave-probe tract recurrences have been reported in the urologic literature to date.

With the advent of newer minimally invasive techniques such as percutaneous ablative mechanisms, recurrence at needle tract sites may occur.

Although local recurrence of renal cell carcinoma has been reported following percutaneous radio frequency ablation (97), no radio frequency-, cryo-, or microwave-probe tract recurrences have been reported in the urologic literature to date.

In addition, hepatocellular carcinoma seeding has been reported following radio frequency ablation and subcutaneous needle-tract recurrence at a paracentesis site in a patient with ovarian carcinoma (98–100). While the incidence of access site seeding with needle ablative technologies, in the treatment of malignancy, appears to be low these case reports support the theoretical possible for access site contamination and should factor into the surgeons decision to use minimally invasive techniques.

SUMMARY

■ Port site recurrence of malignancy is a recognized entity that carries a poor prognosis.
■ Work on basic science, prevention, and technique refinement has been performed and is ongoing.
■ Implantation of malignant cells into the port site wound are likely secondary to primary tumor characteristics, traumatic tissue handling, slipping or leaking trocars, unrecognized metastases or contaminated ascites, and poor tissue retrieval or extraction techniques.
■ Preventive techniques including radiographic staging, surgical expertise, trocar fixation, careful tissue handling, minimization of abdominal wall or peritoneal trauma, tissue isolation and extraction, and peritoneal closure are paramount.
■ Future peritoneal or trocar-site cytotoxic or immunomodulating irrigants may prove beneficial and are under investigation.

PEDIATRIC LAPAROSCOPY

LAPAROSCOPY IN THE CHILD: SPECIFIC ISSUES

Craig A. Peters

Department of Urology, Children's Hospital, Harvard Medical School, Boston, Massachusetts, U.S.A.

INDICATIONS

The distinction between adult and pediatric urologic laparoscopy begins with divergent indications, reflecting the different patterns of urologic disease between adults and children. The need for laparoscopic procedures in pediatric urologic practice is different from adults, with some elements of overlap.

> The distinction between adult and pediatric urologic laparoscopy begins with divergent indications, reflecting the different patterns of urologic disease between adults and children. The need for laparoscopic procedures in pediatric urologic practice is different from adults, with some elements of overlap.

Most of the procedures being performed are based on an integration of diagnostic and operative laparoscopy for the undescended testis. Procedures involving extirpative surgery are almost always for benign disease of congenital origin. Overlap is emerging, mostly in areas of reconstructive urology. While these differences may discourage sharing of experience, the basic principles are similar and the adult urologist with significant laparoscopic experience can facilitate the development of their pediatric colleagues' laparoscopic expertise. Similarly, the pediatric urologist can bring experience with delicate reconstruction to the adult arena.

As the potential for reconstructive pediatric laparoscopy has emerged, it has been evident that the dispersion of laparoscopic skills into complex reconstruction by pediatric urologists has been limited.

> As the potential for reconstructive pediatric laparoscopy has emerged, it has been evident that the dispersion of laparoscopic skills into complex reconstruction by pediatric urologists has been limited.

The reasons for this are multiple but may largely stem from different practice patterns among adult and pediatric urologists that have limited the number of surgeons willing and able to climb the learning curve for reconstructive work.

The pediatric urologist's practice patterns pose a challenge to the development of laparoscopic skills and experience in that even with a busy practice the fraction of cases that may ever be performed laparoscopically will remain limited. In academic departments, there might be surgeons performing only one or two operations in adult practice, while in pediatric groups nearly all will routinely perform up to 20 different types of procedures from hypospadias to pyeloplasty.

The ability to gain sufficient case numbers to become expert at complex laparoscopy in a reasonable period of time will be difficult and the collaboration of adult and pediatric surgeons will be important to permit development of these skills in the pediatric realm.

> The ability to gain sufficient case numbers to become expert at complex laparoscopy in a reasonable period of time will be difficult and the collaboration of adult and pediatric surgeons will be important to permit development of these skills in the pediatric realm.

ONCOLOGY

Very little laparoscopic work has been performed in any pediatric oncologic applications, yet there should be the potential for such application in the future. For the common neoplasms, however, there will likely be substantial limitations due to the frequent large size of pediatric tumors, particularly Wilms' and neuroblastoma. Adrenal tumors have

been resected laparoscopically with good results in children, usually neuroblastoma (1–3). Genital tumors such as gonadoblastoma have been resected laparoscopically, although often when occult in dysgenetic gonads (4). There is likely a role for laparoscopy as more screening programs directed toward at-risk populations for neuroblastoma or Wilms' tumor in which small volume tumors may be more often detected. Diagnostic or staging applications may also see some development as well. This might be particularly suitable for contralateral exploration of the kidney in Wilms' tumor or in prechemotherapy biopsy to permit more accurate diagnosis and staging.

The evolution of pediatric urologic laparoscopy will continue at perhaps a slower pace than that in adult urology, but it should continue to do so. Much of the current work is being carried out by pediatric surgeons who also perform a variety of intra-abdominal laparoscopic procedures and thereby can develop their skills and experience more rapidly. This may limit the role the pediatric urologists play in the overall development of this field and active participation should be encouraged.

PATIENT PREPARATION

There is little specific preparation needed for children to undergo laparoscopy, although recognition of the smaller operative spaces and the occasional physiological limitations of some children are important.

Children to undergo any possible pelvic surgery laparoscopically, including orchiopexy, antireflux surgery or vesical procedures, should have a limited bowel preparation aimed at debulking the rectosigmoid. This can be efficiently performed using a liquid diet the day before and a bisacodyl suppository or oral tablet the night before the procedure.

While laparoscopy is well tolerated by most children and infants, there is the potential for respiratory compromise due to the elevated intra-abdominal pressures.

Children with limited respiratory reserve such as former premature infants with a history of bronchopulmonary dysplasia, those with restrictive thoracic conditions, and very young infants may show sensitivity to the pneumoperitoneum. They have a very limited ability to maintain adequate oxygenation when intra-abdominal pressure is increased and may show desaturation with increased pressures. These risks may be anticipated and often are adequately controlled by limiting pneumoperitoneum pressures, but if there is concern, preoperative evaluation should be obtained to assess the degree of limitation. Similarly, in children with congenital cardiac anomalies, preoperative evaluation is useful, although we have rarely seen any clinically apparent compromise.

PORT POSITIONING AND SETUP

Port placement is critical for efficient performance of all procedures and in children this is perhaps even more critical as there is less room for maneuvering. Port positions depend upon the procedure and the anatomy of the patient. Location should be in proportion to the size of the patient rather than determined by any arbitrary set distances between ports.

While each type of surgery requires a distinctive port setup, the general principle of a symmetrical array of working ports around the camera-operative site line should be adhered to as much as possible. For example, port placement for transperitoneal pyeloplasty would involve an umbilical port for the camera and working ports in the midline between xyphoid and umbilicus and in the ipsilateral lower quadrant in the mid-clavicular line (Fig. 1). This offers a symmetric alignment toward the ureteropelvic junction to permit the most efficient working arrangement. In the smaller spaces in children, the effect of one port that is asymmetric may be significant and very troublesome in the performance of the procedure. When the operative field is wide, as it might be for a total ureterectomy, some compromise is needed. In those cases, one would give preference to the orientation for the most difficult aspect of the procedure. In the case of total nephroureterectomy, the exposure and access to the renal hilum is the most important part of the procedure, so the port alignment should favor that area, rather than the distal ureter, which may often be mobilized up to an accessible position. Occasionally a fourth port may be needed to complete the operation.

The arrangement of patient, surgeon, and surgical team follows similar principles as with adult surgery, although the small patient size offers some potential advantages.

Sidebar notes (left margin):

While laparoscopy is well tolerated by most children and infants, there is the potential for respiratory compromise due to the elevated intra-abdominal pressures.

Port placement is critical for efficient performance of all procedures. In children this is perhaps even more critical as there is less room for maneuvering. Port positions depend upon the procedure and the anatomy of the patient. Location should be in proportion to the size of the patient rather than determined by any arbitrary set distances between ports.

The arrangement of patient, surgeon, and surgical team follows similar principles as with adult surgery, although the small patient size offers some potential advantages.

FIGURE 1 ■ Port placement for transperitoneal laparoscopic pyeloplasty. The camera port is in the umbilicus while the working ports are in the midline between the umbilicus and xyphoid and in the mid-clavicular line in the ipsilateral lower quadrant.

For upper abdominal procedures, as with the kidney, it may be preferable in the small child to position the surgeon at the feet of the child, reaching over the legs and pelvis to be in comfortable line with the upper abdomen. This arrangement is shown in Figure 2. In larger children, the lower legs may be flexed to permit a similar arrangement. For still larger patients, the surgeon is best positioned at the opposite side, aiming toward the ipsilateral shoulder (Fig. 3).

When the surgical field is the pelvis, the surgeon may be best positioned at the head of the patient (Fig. 4) to be in line with the endoscope and operative area. There is a significant advantage to be gained when working in a linear arrangement, both for orientation, equal efficiency of both working ports and comfort. Surgeon discomfort will detract from surgical efficiency and its emphasis is not to make life easier for the surgeon, but for the patient (5).

CANNULAE

Cannula size is often short for pediatric cases to make the instruments seem more age appropriate, yet this may be a drawback in some cases. If the instruments are of normal length, the shorter cannulae offer no advantage at all. For all situations in which the cannulae are fairly close together, shorter lengths are detrimental as the heads will bump into each other more often. In smaller children with retroperitoneal exposures, the short cannulae are a particular problem, specifically if they have larger heads. If there is a problem with the port being too short to reach the area of surgery, the port should be fixed so as to permit further entry into the working space, but being limited on withdrawal to prevent accidental removal.

HAND INSTRUMENTS

When using pediatric instruments, one should avoid using instruments of differing lengths, as this creates further asymmetry of the surgeon's arm position, one arm being close, the other distant from the patient.

Similar issues are applicable to the working instruments, in which case, short instruments may put the hands too close together for comfortable work. It may be very challenging to perform suturing. Of course, too long an instrument, with the ports at a larger working angle, will put the handles at a wide spread, also limiting the efficiency of the operator.

When using pediatric instruments, one should avoid using instruments of differing lengths, as this creates further asymmetry of the surgeon's arm position, one arm being close, the other distant from the patient.

ACCESS

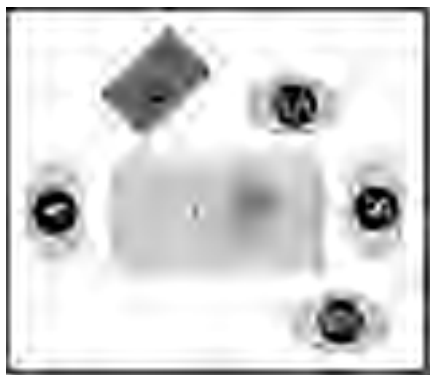
Veress Access
Access using the Veress method is applicable to children as long as the operator recognizes several issues.


FIGURE 2 ■ Diagram of surgical setup with the surgeon at the patient's feet for an upper abdominal procedure in a small child. The surgeon is orientated in a straight line with the operative area. *Abbreviations*: S, surgeon; SN, scrub nurse; SA, surgical assistant; A, anesthesiologist; M, monitor.

FIGURE 4 ■ Diagram showing the surgical setup for a pelvic procedure such as an antireflux operation with the surgeon at the patient's head to permit alignment with the operative filed. *Abbreviations*: S, surgeon; SN, scrub nurse; SA, surgical assistant; A, anesthesiologist; M, monitor.

In the child it is very easy to tent the peritoneum upward at the umbilical attachments and slide the Veress needle along the preperitoneal space.

In the child tissue resistance may not be great and the shield can snap back blunting the needle before the peritoneum is pierced. It is also important to recognize the danger of past-pointing when passing the needle or subsequent trocars in children. It is much closer to the back wall of the body and associated vascular structures.

In general the open access approach is used in our routine pediatric laparoscopic cases. It is likely the lowest risk and most efficient system.

Port fixation is critical in children as it is very easy to dislodge the cannula.

Skin stitches in children may not be as useful as the skin can pull away from the abdominal wall much more easily. Fixation sutures should include some external fascia as well for security.

The author prefers to close all ports of 3 mm and larger.

In the child it is very easy to tent the peritoneum upward at the umbilical attachments and slide the Veress needle along the preperitoneal space.

This space is insufflated, which may make subsequent laparoscopy difficult. There is a tendency of the pediatric peritoneum to pull away from the abdominal wall more readily than in adults, so this problem is more of an issue. Similarly, as the Veress needle advances, the safety shield is pushed back by the resistance of the tissues.

In the child this resistance may not be great and the shield can snap back blunting the needle before the peritoneum is pierced. It is also important to recognize the danger of past-pointing when passing the needle or subsequent trocars in children. It is much closer to the back wall of the body and associated vascular structures.

When using the Veress system it is preferable to utilize a single-pass system that allows positioning of the endoscope through the Veress needle (using a miniature 2 mm endoscope), or to use the sheath placed with the Veress needle to permit placement of the larger cannula, as in the Step® system[a]. This eliminates the need for a second part placement after the insufflation and reduces the risk of inadvertent injury. The Visiport® system has not been of much use in pediatric applications due to its size.

Open Access

In general the open access approach is used in our routine pediatric laparoscopic cases. It is likely the lowest risk and most efficient system.

It is important to be able to create an adequate air-seal after port placement, however. It is not totally free of complications and caution is needed to avoid bowel injury (6). Several simple maneuvers may be performed to facilitate efficient use of the open access system.

There is no formal Hasson cannula in smaller sizes and most are fairly bulky for pediatric use (7). One can modify a conventional cannula by wrapping it with a cuff of rubber tubing and using this to suture to as well as to press into the skin and fascia to improve an air seal. Vaseline gauze may be used if a leak persists.

The most useful tool has been the placement of a purse string suture in the fascia after the peritoneum (or retroperitoneum) has been entered, but before the cannula is placed (8). The purse string is of 3-0 or 2-0 absorbable suture and the loop side is kept loose. The cannula is placed and if there is a gas-leak, the two ends are pulled taut and held in place with a Rummel tourniquet. If the seal is good, the loop is wrapped twice around the gas input stem and pulled snugly at the point where the cannula is in the appropriate amount. This prevents the cannula from being dislodged. The stitch may be used as the fascial closure stitch at the end of the case.

Port fixation is critical in children as it is very easy to dislodge the cannula. Ports cannot be placed too far in to the abdomen or retroperitoneum as they will interfere with the operative field, but with little inside the body, they are more easily prone to inadvertent removal. The abdominal wall is much thinner and there is less to pass through and less resistance. Any method used to secure the cannula must limit the risk of dislodgement. With the Step system, the cannula is unlikely to be dislodged due to the radially expanding design, but this is not guaranteed and fixation is recommended.

When possible, the fascial purse-string stitch is used to keep the cannulae in the body, and makes later port site closure efficient. A simple fixation stitch to the fascia is just as effective.

Skin stitches in children may not be as useful as the skin can pull away from the abdominal wall much more easily. Fixation sutures should include some external fascia as well for security.

Port Site Handling

The author prefers to close all ports of 3 mm and larger. The risk of port site hernia is low in children, but certainly real, and there are anecdotal reports of hernias through the smaller port sites (9,10). The preplaced fascial holding stitches are, therefore, an efficient way to provide closure; alternatively, a simple stitch through the fascia is adequate closure.

MANIPULATION PRINCIPLES

During laparoscopic manipulation in children, the basic principles are the same as in adults with a few extra considerations. The operative area created by the pneumoperitoneum (or retroperitoneum) is smaller, often markedly so. This limits the movement potential,

---

[a] U.S. Surgical Corp., Norwalk, CT.

particularly when handling sutures or retracting. This is not necessarily a direct problem, but requires a different pattern of movements than in adults. The amount of external movement needed to create a particular internal movement can be much less. The pneumoperitoneum is much more sensitive to loss of insufflating gas and small leaks during instrument changes, for example, can produce significant field of view losses. Increased gas flow can compensate for this but may produce excess pressures due to the lag time in pressure sensing. The best approach is to be aware of the problem and limit leakage.

The intraperitoneal space of the child looks different from that of the adult. In many ways it is much clearer to distinguish the anatomy, largely due to lack of fat. This may be disorienting to the experienced adult laparoscopist looking for different visual clues.

It is helpful to take time at the beginning of a case to orient to the anatomy and the proximity of associated structures, all of which are much closer than in the adult. Working in the small spaces of the child requires adjustments of movement and operative planning. While the anatomy may be more plainly visible, the proximity of structures demands a more meticulous and methodical pace to any procedure. Cautery injury is more readily possible and settings should be set lower for children. The amount of force needed to move tissues and organs is less and a degree of delicacy is called for.

The risk of cautery injury from direct contact is higher due to the small spaces, but also from the phenomenon of capacitive coupling (11–13). This is more likely in the smaller instruments due to increased current density at the level of the abdominal wall. There is also less abdominal wall tissue to diffuse the induced current. While this has not been a clinical problem with modern laparoscopic instruments and judicious use of cautery at relatively low power settings, all surgeons should be aware of its causes and potential.

RETROPERITONEAL ACCESS

Retroperitoneal access for renal surgery in the child increases the challenges of smaller spaces for surgical manipulation, even though it is considered advantageous over transperitoneal methods (14–16).

Those advantages are more direct access to the kidney and hilum, less risk of inadvertent injury to adjacent structures, and less chance of postoperative intestinal adhesions. The relative advantage is difficult to define, but the direct access to the renal hilum is a reality that is worth the limitations in space. When space is limited in retroperitoneal access, it is even more important to position ports appropriately and to recognize the limitations in size when working in the smaller space. Maintaining orientation of the camera and the surgical anatomy is essential. A minor rotation in the endoscope may convey a marked apparent difference in the anatomic orientation of some structures including the renal vessels and vena cava. Regular orientation checks are useful, particularly before placing clips on vessels.

During any retroperitoneal procedure it is essential to recognize the location of the peritoneum and its reflections. In children this may be difficult as the peritoneum is very delicate and may be difficult to see. Tearing the peritoneum will allow insufflation, which reduces the working space in the retroperitoneum. Often this is only noted as a gradual diminishment in the working space.

Typical areas of peritoneal violation are the lateral aspect during development of the retroperitoneal space, particularly if performed with the endoscope, and at the superior pole of the kidney where it is immediately adjacent to the peritoneum.

If the peritoneum is violated and insufflation limits the operative field, there are several options for correction. The peritoneal space may be vented using an angiocatheter placed near the lateral margin, the tear may be repaired directly and the peritoneal space evacuated, or a small tear may be opened widely to limit gas trapping in the peritoneum and permit a wider operative field.

In essence the latter turns the case into a retro- and transperitoneal procedure. There is seldom a reason to convert to an open procedure if the peritoneum is violated.

Although the transperitoneal approach is considered more risky and potentially related to small bowel adhesions, this has not yet been reported in children. It has been shown that even after direct laparoscopic intraperitoneal surgery in children, there are very few adhesions produced (17). This was shown in a study of relook procedures for contralateral intra-abdominal orchiopexy in which much of the peritoneal

---

Retroperitoneal access for renal surgery in the child increases the challenges of smaller spaces for surgical manipulation, even though it is considered advantageous over transperitoneal methods.

Tearing the peritoneum will allow insufflation, which reduces the working space in the retroperitoneum. Often this is only noted as a gradual diminishment in the working space.

If the peritoneum is violated and insufflation limits the operative field, there are several options for correction. The peritoneal space may be vented using an angiocatheter placed near the lateral margin, the tear may be repaired directly and the peritoneal space evacuated, or a small tear may be opened widely to limit gas trapping in the peritoneum and permit a wider operative field.

surface surrounding the testis was stripped; yet no substantial adhesions were produced. In most of these cases, as with most transperitoneal renal surgeries, the small and large bowel are manipulated to a minimal degree. It may be that this limited manipulation reduces the degree of adhesive changes. When placed in the context of the facility of renal access, particularly of the ureteropelvic junction, a transperitoneal approach may be preferable.

There is early evidence suggesting that the patterns of tissue healing are different with laparoscopic procedures (18) and these may be distinct between adults and children. The mediators of inflammatory changes seem different in degree and timing of activation after laparoscopic surgery than open surgery (19,20). Whether this plays any role in intestinal adhesions remains to be determined.

PHYSIOLOGY AND ANESTHETIC CONSIDERATIONS

Although there was initial concern regarding the impact of pneumoperitoneum on pediatric cardiorespiratory physiology, the clinical effects appear to be limited. It is rare that any child has significant adverse response to the pneumoperitoneum. Several studies of the anesthetic response of children to laparoscopic procedures have been published demonstrating detectable differences, which do not have major clinical significance (21–25). They do serve to alert the surgeon and anesthesiologist to the potential for problems in the compromised child. Due to the effects of a pneumoperitoneum, it can be anticipated that children with a smaller than normal functional reserve of pulmonary function may have difficulty maintaining oxygenation with increased intra-abdominal pressures. Neonates have relatively less reserve and may have more significant alterations in cardiorespiratory function with a pneumoperitoneum, as well as greater CO_2 absorption (26). We have seen this in a few patients with restrictive pulmonary conditions. In general these alterations may be corrected with reduced intra-abdominal pressures. Cardiac function has not been markedly altered and in some cases this has been examined with transesophageal echocardiography for follow-up of congenital cardiac disease.

> It should be anticipated that certain children would have reduced oxygenation with increased intra-abdominal pressures, including those with restrictive pulmonary conditions, smaller infants or premature infants.

It should be anticipated that certain children would have reduced oxygenation with increased intra-abdominal pressures, including those with restrictive pulmonary conditions, smaller infants or premature infants.

To some degree these children can be managed with increased minute ventilation, but that alone may not be sufficient and reduced intra-abdominal pressures are probably the best initial measure. We have never had to convert a laparoscopic case due to anesthetic conditions.

There was much concern about the effect of laparoscopy on the child's temperature, yet for renal and bladder surgery this has not been a concern (27). Indeed, in infants, we have noted a small but measurable degree of hyperthermia during nephrectomy. The etiology of this is uncertain, but the anticipated hypothermia has not been seen. Anesthesiologists should be informed not to expect significant reductions in body temperature. It is prudent to be prepared to warm the child with the various warming devices available, however, in case the procedure is prolonged or complex and there is loss of body temperature.

> Reduced urine output during pneumoperitoneum is well recognized and occurs in children.

Reduced urine output during pneumoperitoneum is well recognized (28) and occurs in children. The actual physiology remains incompletely defined and while direct pressure effects have been postulated (29), there is evidence of a more complex mechanism as well (30). The effect is rapidly reversible and we have not seen adverse clinical outcomes. The anesthesia team needs to be informed so as to anticipate this occurrence and not respond by overhydrating the child. As more complex patients are undergoing laparoscopic procedures, the question of the effect of pneumoperitoneum-induced oliguria on already reduced renal function was raised. In experimental studies this did not appear to further injure renal function (30) and we have not identified this in clinical practice.

COMPLICATIONS

Ventriculoperitoneal Shunts

Many pediatric patients will have ventriculoperitoneal shunts for hydrocephalus, and one report suggested that these children would require exteriorization of the shunt during laparoscopy to prevent acute rise in intracranial pressure (31). The theory behind this was logical but it has not appeared to be the case clinically and several patients with

ventriculoperitoneal shunts have undergone laparoscopic procedures with no apparent problems (32).

There is no evidence that the presence of a ventriculoperitoneal shunt should pose any risk to laparoscopic procedures. Indeed we have used laparoscopy for intra-abdominal shunt revision.

SURGICAL COMPLICATIONS

Complications in children are the same as in adults, although their clinical presentation may be less distinct and a higher index of suspicion should be established.

The potential for major complications exists due to the smaller size of the surgical field and less sturdy tissues, although the higher visibility in general should limit this risk. Early in the development of pediatric urologic laparoscopy, a survey reported an incidence of 2% with the need for surgical intervention in 0.4%. In a large review of pediatric laparoscopic complications, with the majority including diagnostic procedures, a complication rate of 2.7% was reported, with no mortality. Conversions were required in one-third of these. The most significant complications were bleeding, while others included bladder perforation during orchiopexy (Esposito, 2003 p. 310). The major risks of acute injury are obvious and rarely missed, including bleeding and injury to adjacent structures.

Occult injury to the bowel is a recognized possibility and as with adults, it seems that the clinical presentation is subtler than in bowel injury with open procedures (33). Reported cases suggest that there is less of a febrile response, more subtle clinical signs of peritonitis and a lower leukocytosis. The reasons for this remain unclear, but some authors have focused on altered immune responses following laparoscopy (34). Use of C-reactive protein as an indicator of bowel injury after laparoscopy has been reported in adults (35). None of these issues have been studied in children,

When dealing with children, following any surgical procedure, it is important to recognize their ability to maintain a well-compensated state for long periods but then to rapidly decline in their ability to remain compensated.

They will deteriorate rapidly after appearing to be stable and healthy. Early, subtle signs of that compensation should be recognized in the appropriate context, including persistent tachycardia, increased respiratory rate, and poor feeding. Of course, these patterns may simply represent postoperative effects that will resolve, but one must be cognizant of the potential for subsequent rapid deterioration. In the situation of a difficult procedure that may not have progressed as well a usual, it may be prudent to delay discharge if the child is not making a rapid recovery, just to be able to identify warning signs of either peritonitis or hemorrhage. While routine blood tests are seldom performed, these might be the situations to consider doing so.

POSTOPERATIVE COURSE

There is little difference in recovery patterns among children of different ages and it is difficult to determine what might predict the rapidity of recovery in particular cases. There does seem to be a tendency among children to be very quiet and sluggish in recovery for 6 to 18 hours following complex laparoscopic procedures, and then very rapidly return to their baseline level of comfort and activity. This is in contrast to the pattern seen after open surgery, which shows a steady, but usually more prolonged recovery phase. The basis for this is unclear. Most children under the age of five are ready to return home, on oral analgesics (often no more than acetaminophen), taking liquids and some solids and moving comfortably within 36 hours of the procedure, some within 24 hours. Older children usually require two or three days to achieve a similar level of comfort. Some infants have been ready for discharge on the same day following partial nephrectomy or pyeloplasty. There seems to be a general sense of malaise in the recovery period for children, although they do not usually seem to localize their pain. Even older children do not complain specifically of focal discomfort.

Rarely do children complain of shoulder pain, as is often noted in adults. A few teenagers have done so, but this is unusual. It may simply reflect the general tendency of children to be unable to localize abdominal pain.

SUMMARY

■ Laparoscopic procedures in children are well tolerated and have an excellent potential for improving surgical outcomes with reduced morbidity in a variety of urological procedures.
■ It is important to recognize the unique characteristics of laparoscopic surgery in children. While many of the principles of laparoscopy in adults are completely applicable to children, the smaller size, distinct tissue textures and strengths, and their lack of physiological reserve offer special challenges to performing these procedures in the young patient.
■ With attention to detail, recognition of a child's unique physiology, and their patterns of healing, more complex laparoscopic procedures are being more commonly performed and should continue to evolve.

INTRODUCTION

Cryptorchidism is the absence of a testicle in the scrotum. In most cryptorchid boys, the testicle is palpable in the groin. In only about 20%, is the testicle nonpalpable (1). A nonpalpable testicle can be absent, can be intraabdominal, or within the inguinal canal. Intraabdominal testicles can be found along the normal path of descent or can be ectopic. Likewise, "inguinal" undescended testicles can either be undescended along the normal path of descent, i.e., canalicular or can descend to an ectopic location (such as the perineum) (2,3).

Orchidopexy is recommended (i) for easier examination of the testicle, (ii) to correct any associated inguinal hernia, (iii) to prevent testicular torsion, and (iv) to alleviate possible psychologic trauma resulting from the young child or man having an empty hemiscrotum. Additionally, the concepts of improving fertility or diminishing the potential for malignant transformation have been offered as indications (4). With regards to fertility, it has been shown that fertility is impaired in approximately 50% to 70% of boys born with one undescended testicle and as many as 75% with bilateral undescended testicles, even after orchidopexy (5). Histologic deterioration is believed to be worse for higher testicles; fertility was thus felt to vary in association with location. Likewise, histologic abnormality has been proposed as an indicator of the possibility for malignant transformation (6).

- ■ Laparoscopy has been useful as a diagnostic modality as well as a therapeutic modality.
- ■ There are many who feel that laparoscopy is the gold standard for localization of the undescended gonad.
- ■ Increasing evidence has developed that laparoscopic orchidopexy may be the best of the surgical modalities.

Prior to 1976, the nonpalpable testicle was located by inguinal exploration. If the gonad, an atrophic nubbin, or blind-ending vessels were not found in the groin, then the inguinal exploration could be and was extended allowing exploration of the retroperitoneum. It was rare for the surgeon to be unable to locate the gonad, or residua thereof.

In 1976, Cortesi et al. first described laparoscopy as a modality that could reveal the location of the nonpalpable testicle (7). It was not long after that, that laparoscopy was used therapeutically. Bloom in 1991 described a procedure for staged pelvioscopic orchidopexy. At the first stage, the vessels were ligated with a Hulka clip (8). The second stage was, as described by Bloom, then accomplished via an open technique.

Jordan et al. described the first laparoscopic orchidopexy (9). In that procedure, the testicle was located laparoscopically and was brought down to the scrotum using pure laparoscopic techniques. In 1993, Bogaert et al. also described a series of laparoscopic

In 1976, Cortesi et al. first described laparoscopy as a modality that could reveal the location of the nonpalpable testicle.

orchidopexy. Initially, the utility of laparoscopy for diagnostic purposes and especially laparoscopic orchidopexy caused a great deal of debate among pediatric urologists (10–13). As mentioned, however, diagnostic laparoscopy and therapeutic laparoscopy for the undescended testicle now have found good acceptance and have been incorporated into the practice of many pediatric urologists.

CONSIDERATIONS FOR ORCHIDOPEXY

It has been shown that undescended testicles at birth and throughout the first year of life have normal histology, and that includes a normal population of germ cells.

Huff et al. showed that beyond age of 18 months, both light microscopy and electron microscopy showed the development of abnormal histologic changes (15).

This was one factor that dictated timing of orchidopexy. Anesthesia risks also dictated timing of orchidopexy; however, infants aged four to six months have been shown now, with modern pediatric anesthesia techniques, to have risks similar to the healthy adult.

Recent studies would suggest that orchidopexy at six months is optimal as it capitalizes on the anatomic advantages conferred by the child's small size, while exhausting the real chances for spontaneous descent (16).

The role for orchidopexy in the older child, adolescent, and young adult is less well defined. Clearly, the undescended testicle will almost certainly have poor fertility potential; however, its usefulness for androgen production must be considered. There is then also the risk of malignant change, and as mentioned, relocation to the scrotum may not alter that risk at all. A recent analysis comparing anesthetic risks of orchiectomy versus the lifetime-adjusted risk of germ cell cancer was performed by Kibel and coworkers (17).

Kibel and coworkers recommend that healthy males with undescended testicles undergo orchiectomy until the age of 50 years. For patients with comorbid conditions [American Society of Anesthesiologists (> 2)] the risks of surgery might contraindicate orchiectomy even before the age of 50 years (17).

The preoperative diagnostic modalities used in the evaluation of the patient with a nonpalpable testicle include radiological tests and hormonal challenge. Medical management will not be discussed in this manuscript. However, radiologic evaluation will be discussed as many feel that a real alternative to laparoscopic localization. Virtually, all imaging modalities have been used. These would include ultrasound, venography, magnetic resonance imaging, and computed tomography. None of these modalities have been found to be sufficiently sensitive to answer the questions: (i) is there a testicle present, and (ii) where is that testicle (18–22)?

Radiographic imaging can be useful in some instances. One such instance is in the overweight boy with a nonpalpable testicle, which can be proven to be inguinal. Likewise, there is utility in adolescents for follow-up who are not surgical candidates because of comorbid conditions. One should not forget the examination under anesthesia at the time of orchidopexy or laparoscopic localization, because that oftentimes will reveal the location of the testicle (3).

Laparoscopic Evaluation

As mentioned, laparoscopy has proven itself to be an excellent localization and diagnostic tool (23–26). It is useful in patients with bilateral undescended testicles as well as in cases of unilateral undescended testicles. It also has been helpful in allowing the surgeon to plan subsequent therapy (i.e., to decide whether orchidopexy or testicular removal is indicated). Motility of the testis and its vas deferens as well as the vascular supply can be assessed on laparoscopic diagnosis.

Diagnostic laparoscopy requires general anesthesia and the patient should be secured to the operating table to allow the bed to be manipulated to all extremes. Patient preparation and draping must be suitable for an open exploration should it be required. A Foley catheter and an oral gastric tube are placed. A supra- or infra-umbilical skin incision is made and the peritoneum is accessed via an open technique. In children, the use of Veress needle insufflation has been abandoned at most centers. Likewise, true Hasson access is cumbersome.

In the young child, the peritoneum can be controlled and a trocar easily dilated into place under direct vision. Holding sutures placed in the fascia are helpful in elevating the fascia and peritoneum prior to peritoneotomy.

Side notes (margin):

Huff et al. showed that beyond age of 18 months, both light microscopy and electron microscopy showed the development of abnormal histologic changes.

Recent studies suggest that orchidopexy at six months is optimal as it capitalizes on the anatomic advantages conferred by the child's small size, while exhausting the real chances for spontaneous descent.

Kibel and coworkers recommend that healthy males with undescended testicles undergo orchiectomy until the age of 50 years. For patients with comorbid conditions the risks of surgery might contraindicate orchiectomy even before the age of 50 years.

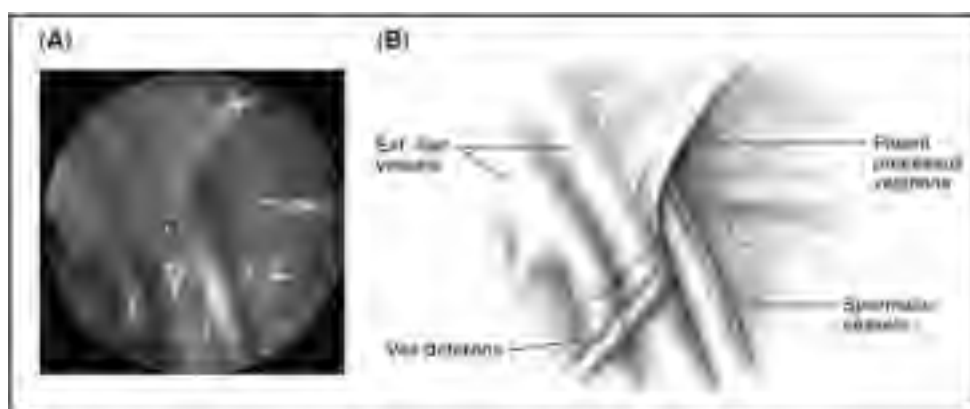
FIGURE 2 ■ (**A**) Laparoscopic photograph. (**B**) Diagram of the right internal ring with a patent processus vaginalis.


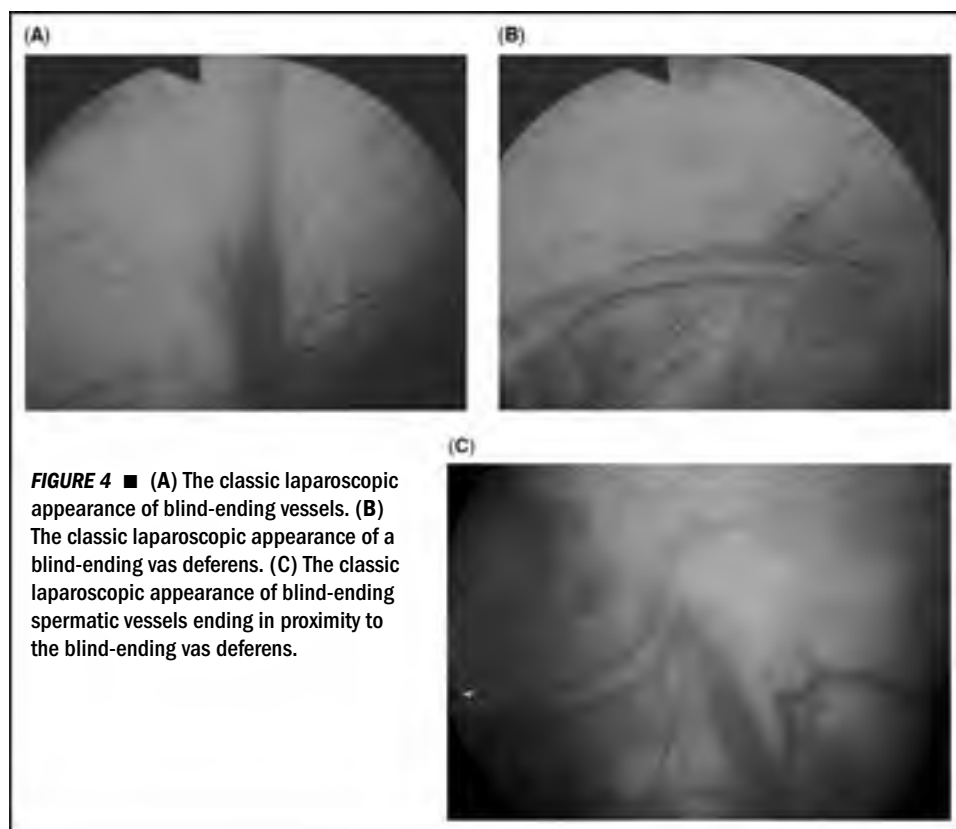
The InnerDyne® Radial Dilating Step[a] introducer system is helpful but not mandatory (27,28). In most cases, 5 mm access is more than adequate. Alternatively, 2 or 3 mm needlescopic ports and access can be used (27,29,30). The abdomen is insufflated to 14–15 millimeters of mercury pressure, the peritoneum is inspected to ensure proper positioning at which point the working cannulas can be placed as needed. The patient should already be in Trendelenburg position; however, if further exposure is needed in the pelvis further Trendelenburg positioning is helpful along with some lateral tilt. This will expose each internal ring, which can then be inspected. If the rings are difficult to visualize, and there is a descended testicle, traction on that descended testicle will very easily make the spermatic vessels more prominent at which point the opposite groin can be examined in a similar location. A number of findings are possible (see box).

■ The vas and testicular vessels appear normal and exit a closed internal ring (Fig. 1). The groin can be explored for a descended remnant. Alternatively, an open inguinal approach can be used. These nubbins do need to be removed as approximately 10% contain viable germ cells and ostensibly could be at risk for undergoing malignant change (31–33).

■ The vas and testicular vessels appear normal and exit an open internal ring (Fig. 2). Oftentimes, gentle pressure over the groin pushes a canalicular (peeping) testicle or nubbin into the abdomen (Fig. 3). If the gonad is not pushed back into the abdomen, the groin must be explored and again this can be done by either open or laparoscopic techniques (34).

■ The blind-ending vessels are clearly identified and have a "horsetail" appearance. A blind-ending vessel is often in direct proximity to a blind-ending vas. These findings are pathognomonic for the vanished testicle and the procedure can be terminated. Most would agree that only in the case of a prominent nubbin being noticed would intervening tissue have to be removed (Fig. 4).

[a]Tyco International, Inc., Princeton, NJ.

FIGURE 3 ■ **(A)** Laparoscopic photograph of the right internal ring in a patient with a peeping testicle. **(B)** With external pressure on the inguinal canal, the peeping testicle can be visualized.


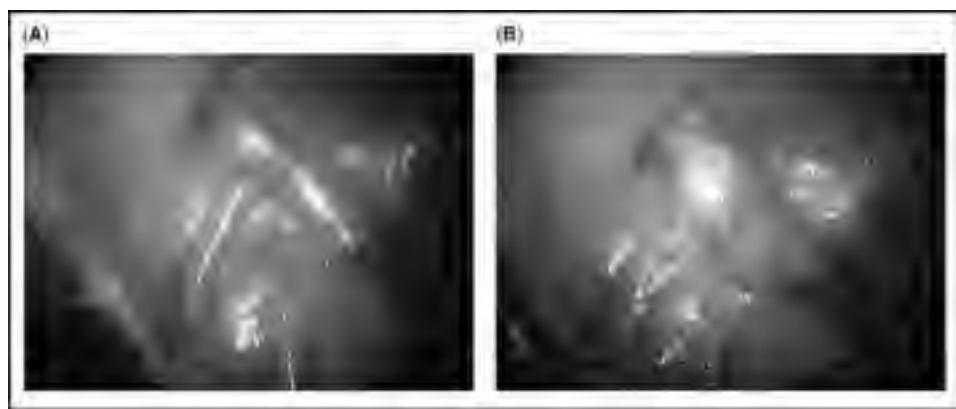


FIGURE 4 ■ **(A)** The classic laparoscopic appearance of blind-ending vessels. **(B)** The classic laparoscopic appearance of a blind-ending vas deferens. **(C)** The classic laparoscopic appearance of blind-ending spermatic vessels ending in proximity to the blind-ending vas deferens.

- The blind-ending vas is seen without blind-ending vessels in vicinity. The testicular nubbin is always in proximity to the blind-ending vessels; and hence, the laparoscopic exploration must be carried rostrally seeking those findings.
- An intra-abdominal testicle is located (Fig. 5).

Analyzing the existing data, 50% to 60% of all cases of nonpalpable testicles are identified as an intra-abdominal testicle or peeping testicle, 30% as an atrophic nubbin, and 20% as an absent or vanished testicle. A testicle located within 2 cm of the internal ring or is proven to be peeping in about 38% of cases and those testicles are usually normal in size with a normal vessel leash, vas, and epididymis. Testicles located higher in the abdomen are either along the normal path of descent, 44.8%, or are in an ectopic site in 7.1% (35).

When the testicle is not clearly identified just with placement of the camera alone, either small probes or working instruments are ideal to improve exposure. Because therapeutic maneuvers will be required in about 90% of cases, moving on to cannula

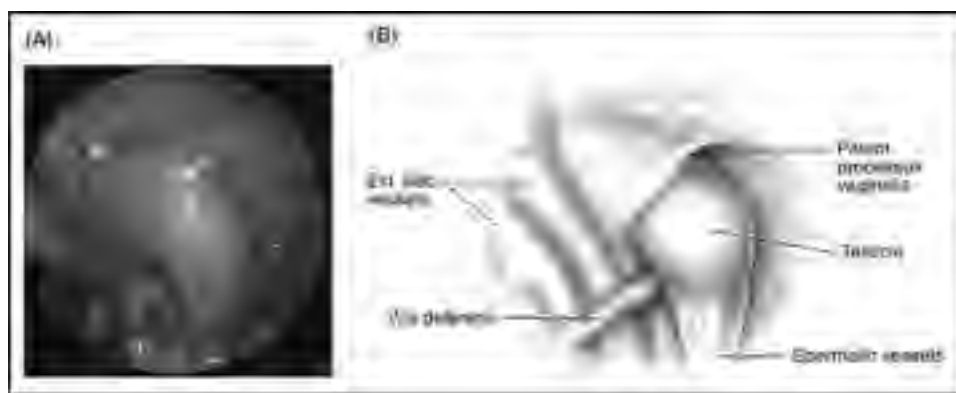
FIGURE 5 ■ (A) Laparoscopic photograph of the right groin in a child with a low abdominal undescended testicle. (B) Diagram of the right groin in a child with low abdominal undescended testicle.


FIGURE 6 ■ Diagram of the cannula placement for a right laparoscopic orchidopexy.

For primary laparoscopic orchidopexy, maximal exposure of the inguinal and groin area is obtained by placing the table in steep Trendelenburg with the bed tilted contralateral to the undescended testicle.

Cautery is used for this maneuver, as there can be rather prominent vasculature in the gubernaculum. Care must be taken to identify a long looping vas, which unusually can be encountered.

If the testicle can be placed across the abdomen to the opposite groin, then usually there is sufficient ability for the testicle to be placed in the ipsilateral hemiscrotum.

placement and placement of working instruments is probably most expedient. Correct placement of the working cannula is shown in Figure 6. During working cannula placement, insufflation is increased to 20 mmHg pressure, which can then be decreased to 10–15 mmHg.

THERAPEUTIC LAPAROSCOPY

Laparoscopic Surgery for Unilateral Nonpalpable Testicles

The goal of therapeutic laparoscopy for a unilateral undescended testicle is either permanent fixation of the testicle in the scrotum or removal of a grossly abnormal testicle. The choice of surgical procedure is determined and our usual approach is summarized in the algorithm shown in Figure 7.

For primary laparoscopic orchidopexy, maximal exposure of the inguinal and groin area is obtained by placing the table in steep Trendelenburg with the bed tilted contralateral to the undescended testicle.

The open inguinal ring or the testicle is located and a peritoneotomy is made to either completely surround the open inguinal ring or to expose the gubernacular structures (Fig. 8). The authors prefer to leave the peritoneum between the vas and the vessels undissected and hence the peritoneotomy is extended along the spermatic vessel leash allowing for dissection rostral on the vascular cord structures. A peritoneotomy is likewise made over the vas deferens. To achieve sufficient mobility on the vas and vessels, eventually those two peritoneotomies need to be connected leaving a triangle of peritoneum in the area between the juncture of vas with vessels (Fig. 9). Ostensibly, this leaves the collateral circulation in that area undisturbed; and if one needed to proceed to single-stage Fowler–Stephens orchidopexy, then the results would be optimized by not having disturbed this area.

The testicular vessels, testicle, and vas are elevated on the "peritoneal pedicle." The testicle is then rostrally retracted inverting the processus vaginalis and the gubernaculums, and the gubernaculum is thinned and then cut across.

Cautery is used for this maneuver, as there can be rather prominent vasculature in the gubernaculum (Fig. 10). Care must be taken to identify a long looping vas, which unusually can be encountered (Fig. 11).

Current hemostatic modalities include Ligasure™[b] or Harmonic Scalpel™[c]. However, because cautery is minimally employed throughout the entire orchidopexy procedure, the expense of these additional instruments, we feel, is not justified.

The testicle is further freed, maximizing the length of vessels and vas.

If the testicle can be placed across the abdomen to the opposite groin, then usually there is sufficient ability for the testicle to be placed in the ipsilateral hemiscrotum (Fig. 12).

Elder has shown that vigorous dissection of the vas may be more related to testicular atrophy than vigorous mobilization of the spermatic cord. If length is inadequate

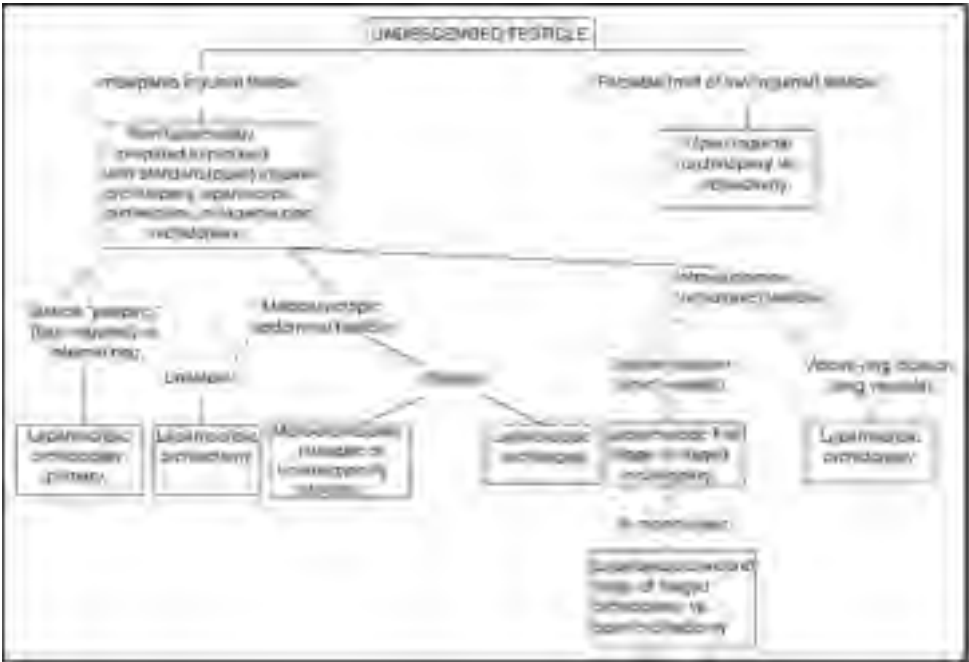

FIGURE 8 ■ Laparoscopic photograph of a child with a peeping testicle; the appearance of the right groin as the peritoneum is opened around the patent processes vaginalis.
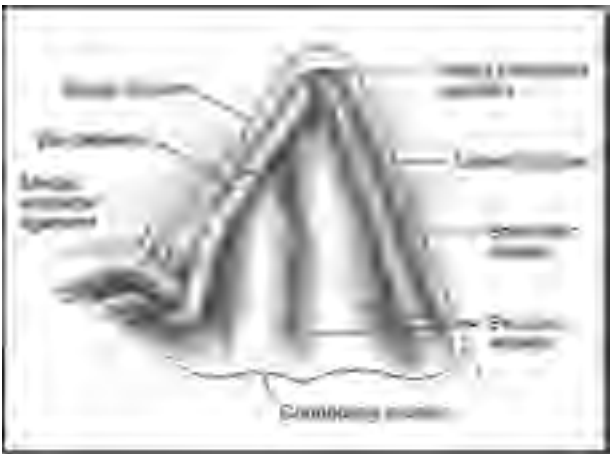

FIGURE 9 ■ Diagram of the peritoneal incisions.

after connecting the peritoneotomies and maximally dissecting vas and vessels, then the spermatic vessels can be divided. It is the authors' opinion that this scenario is best avoided; and hence, we make every effort to be sure that length will be adequate prior to proceeding this far with the dissection.

A number of techniques have been described for passing the testicle into the ipsilateral hemiscrotum, including the retrograde passage of a hemostat. A laparoscopic port can be primarily placed from below using a dilating trocar system or the path can be developed from within by passing a grasper into the hemiscrotum and then a dilating trocar system or step cannula used for the transfer. Lucent cannulas can be very helpful and prototype reusable lucent cannulas are in development.

The path that the testicle will take is medial to the inferior epigastric vessels and medial to the ipsilateral medial umbilical ligament but lateral to the bladder. The vessels are placed just over the top of the pubic ramus and down the inguinal canal.

A scrotal skin incision is made in the ipsilateral hemiscrotum and we prefer a subdartos pouch for fixation. In passing the testicle, a laparoscopic grasper is passed through the cannula into the abdomen grasping either the testicle or the gubernaculum

The path that the testicle will take is medial to the inferior epigastric vessels and medial to the ipsilateral medial umbilical ligament but lateral to the bladder. The vessels are placed just over the top of the pubic ramus and down the inguinal canal.

FIGURE 10 ■ Laparoscopic photograph of the testicle freed; the gubernaculum is exposed and is divided with cautery (same child as in Fig. 8).

FIGURE 11 ■ Laparoscopic photograph of the appearance of a long looping vas deferens; the testicle is being retracted into the abdomen and the vas is noted coursing along the path of the gubernaculum.

(Fig. 13). There are graspers which atraumatically grasp the testicle. The testis is then delivered through the port (Fig. 14). Should the vessels come under tension, then with the additional retraction, further dissection of vas and vessels can be accomplished above. Once the testicle is adequately mobilized to the level of the hemiscrotum, the pneumoperitoneum is immediately reduced and the internal surgical field is assessed for bleeding. The peritoneum in the area of dissection of the groin is not closed. In children, all port sites, 5 mm or greater, must be closed. The skin wounds can be injected with a long acting local anesthetic, adjuvant caudal anesthesia may also be beneficial.

The children are recovered from anesthesia and are discharged. In most cases, activity is somewhat diminished in the first 12 to 24 hours following surgery, but parents report that children very rapidly get back to normal activities.

No limit to activities is necessary other than asking parents to prohibit the child from straddle activities for at least six weeks.

In most cases, diet can be rapidly advanced.

Complications of Laparoscopic Orchidopexy

- Complications of laparoscopic orchidopexy can include the following:
- Bleeding
- Infection
- Anesthesia risks
- Injury to intra-abdominal or retroperitoneal organs necessitating emergent laparotomy
- Acute atrophy of the testicle
- Mechanical injury to the vas, epididymis, testis, or testicular vessels
- Poor testicular position
- Unrecognized need for a staged operation

As mentioned, if vessel length after significant dissection is found to continue to be inadequate, then the testicular vessels are clipped and transected, allowing further mobility and easier placement in the hemiscrotum. However, single-stage transfer in this fashion is clearly associated with higher atrophy rates than with single-stage primary orchidopexy and in most cases should and can be avoided.

Two-Stage Fowler–Stephens Laparoscopic Orchidopexy

A two-stage Fowler–Stephens orchidopexy can be performed when diagnostic laparoscopy reveals a testicle high in the abdomen and the surgeon deems the placement of the testicle in the ipsilateral hemiscrotum not feasible despite significant dissection. In stage I, a 5-mm port is placed and a clip applier is used to control the testicular vessels. The clips should be placed relatively proximal to avoid interference with collaterals between the junction of the vas and the testicular vessels, if present. Although

No limit to activities is necessary other than asking parents to prohibit the child from straddle activities for at least six weeks.

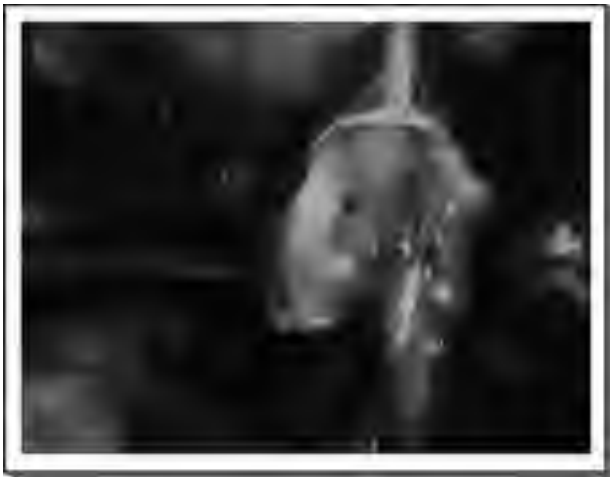
FIGURE 12 ■ Laparoscopic photograph of the appearance of the testicle, with the spermatic vessels and the vas dissected.


FIGURE 13 ■ Laparoscopic photograph showing the testicle drawn into the cannula.

FIGURE 14 ■ Photograph showing the appearance of the testicle as it is brought down into the scrotum within the cannula.

the vessels may be transected, in most cases mere placement of clips is adequate. After a six-month interval, a collateral blood supply via the enhanced paravasal arteries develops (Fig. 15). At stage II, cannula placement is identical for primary orchidopexy. If the vessels were not previously transected, they are transected and the testicle is mobilized on the vas (Fig. 16). Great care is taken with the triangle of peritoneum between the juncture of the vas and the distal spermatic vessels. Placement in the scrotum is identical to that already described (Fig. 17).

TABLE 1 ■ Comparison of Open vs. Laparoscopic Orchiopexy Success Rates from Two Large Published Series[a]

	Primary orchiopexy		Single-stage Fowler–Stephens		Two-stage Fowler–Stephens	
	n	%	*n*	%	*n*	%
Open orchiopexy (43)	80	81.3	321	66.7	56	76.8
Laparoscopic orchiopexy (35)	178	97.2	27	74.1	58	87.9

n, number of testes.
[a]Success was defined as scrotal position and lack of atrophy.

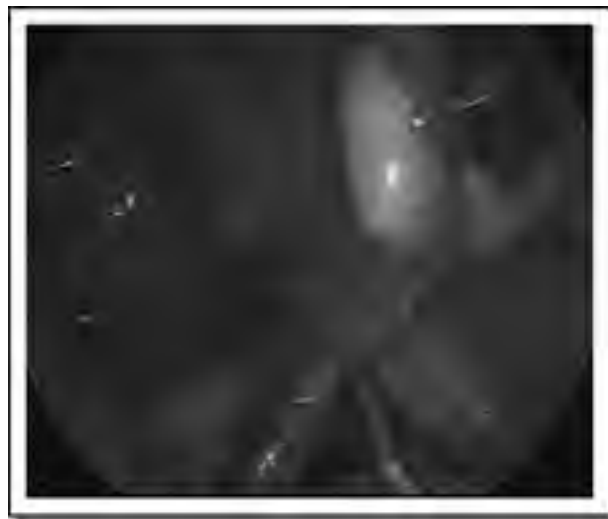
FIGURE 15 ■ Laparoscopic photograph of the appearance of the right groin in a child, who had a clip placed across the spermatic vessels six months earlier, and now is back for second-stage Fowler–Stephens orchidopexy.


FIGURE 16 ■ Laparoscopic photograph—additional clips are placed and the spermatic vessels are divided.
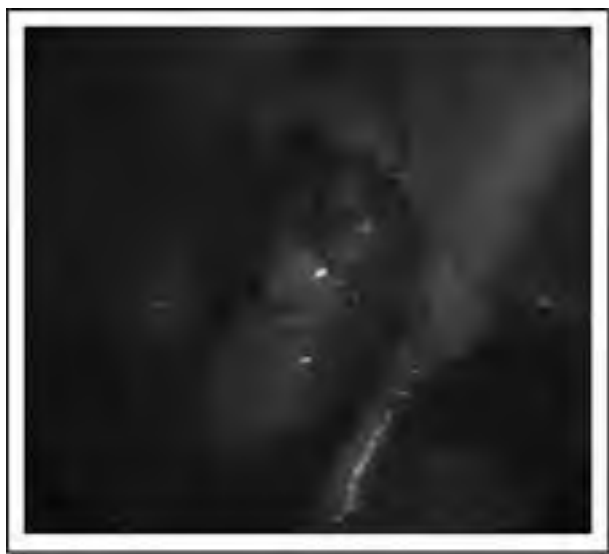

FIGURE 17 ■ Laparoscopic photograph—after dissection to free the testicle on the enhanced vassal vasculature of the vas deferens, the testicle is brought to the ipsilateral hemiscrotum.

FIGURE 18 ■ Laparoscopic photograph of the left groin in a child with an abdominal medial ectopic testicle.

Testicles having a horizontal lie in the abdomen and often appearing to be "ovarian" on laparoscopy can be quite difficult to deal with. Although no studies examining the histology of these testicles have been conducted, orchiectomy is probably indicated if unilateral. Micro-orchidopexy might be considered for bilateral cases.

In the case of normal vessels and vas entering a closed ring, most would agree that some form of inguinal exploration is required and that can be done in most cases from above with a laparoscopic approach. Occasionally, the testicle will migrate intra-abdominally to a medial ectopic position. These abdominal medial ectopic testes are quite difficult to manage because they have short spermatic vessel leashes and also a short vas deferens (Fig. 18). Thus, the advantages of the Prentiss maneuver are obviated.

Testicles having a horizontal lie in the abdomen and often appearing to be "ovarian" on laparoscopy can be quite difficult to deal with. Although no studies examining the histology of these testicles have been conducted, orchiectomy is probably indicated if unilateral. Micro-orchidopexy might be considered for bilateral cases.

"Micro-orchidopexy" is the term applied to the procedure in which an abdominal undescended testicle is autotransplanted to the scrotum by microvascular techniques. Originally described by Silber and Kelly (36), the procedure was modified by Wacksman et al. (37). Wacksman et al., who have accumulated the greatest experience,

recently described the use of laparoscopy to elevate and move the testicle. Then through an open incision, the microcoaptation to the recipient vessels is performed (38). In a small series of what clearly are difficult situations, they report excellent results.

SUMMARY

- Laparoscopies for the nonpalpable testicle have become the standard approach in many U.S. and European centers.
- The advantages of laparoscopic diagnosis, localization, and orchidopexy are felt to outweigh the disadvantages.
- The alternative to laparoscopic localization and diagnosis and laparoscopic orchidopexy is open inguinal exploration and open orchidopexy. However, some investigators have raised serious concerns regarding the reliability of open inguinal exploration to rule out an intra-abdominal testis. In fact, a number of series have reported abdominal testicles identified via laparoscopy after "negative open explorations" (25,35,39–42).
- A critical assessment of the surgical outcomes of open orchidopexy for the intra-abdominal testicle has shown less than optimal success rates with regards to acute atrophy (43,44).
- A multicenter review by Baker et al. suggests that therapeutic laparoscopy offers the highest success rate for orchidopexy for the management of the intra-abdominal testicle (Table 1) (35).
- Laparoscopic orchidopexy like all other surgeries can be associated with complications (35).
- Many of the complications were due to the practice of blind cannula placement and Veress needle insufflation. Most pediatric surgeons have now abandoned such approach in children.
- Reported complications include (i) acute testicular atrophy; (ii) bowel perforation (45); (iii) cecal volvulus; (iv) bladder perforation (13); (v) ileus, vas injury, bowel incarceration at the site of the parietal peritoneal closure of the internal ring, spermatic vessel avulsion necessitating an unplanned single-stage Fowler–Stephens orchidopexy (35).

LAPAROSCOPIC URETERAL REIMPLANTATION

Jonathan H. Ross and Richard Sutherland

Glickman Urological Institute, Cleveland Clinic Foundation,
Cleveland, Ohio, U.S.A.

INTRODUCTION

Vesicoureteral reflux refers to the retrograde flow of urine from the bladder into the ureter(s) with filling or voiding. Reflux in itself is benign, but the reflux of infected urine can lead to pyelonephritis and subsequent renal scarring. High-pressure reflux in patients with neurogenic bladder can also lead to renal injury. Because most cases of reflux resolve spontaneously over several years, the initial management of reflux is usually medical—preventing infections with antibiotic prophylaxis and treating underlying conditions such as constipation and voiding dysfunction that may predispose to urinary tract infections or propagate reflux. Surgical intervention is generally considered for children with breakthrough infections despite prophylaxis, children with high-grade reflux (which is unlikely to resolve spontaneously), or for children who cannot tolerate or comply with medical treatment and periodic testing.

VESICOURETERAL REFLUX: MANAGEMENT

The standard surgical treatment for vesicoureteral reflux is ureteral reimplantation. Historically, this has been accomplished by transvesical approaches with either a cross-trigonal (Cohen) or orthotopic (Glenn–Anderson or Leadbetter–Politano) creation of the new intramural tunnel. Ureteral reimplantation is a well-established technique with a high success rate of greater than 95%. Failures usually have persistent reflux or, less frequently, ureteral obstruction requiring reoperation. To minimize the morbidity of the operation, an extravesical approach has been developed which allows ureteral mobilization and reimplantation without opening the bladder. In theory, this decreases the irritative voiding symptoms and hematuria that accompany a transvesical approach. However, there have been occasional patients with prolonged urinary retention following the extravesical approach. Both intravesical and extravesical open procedures have evolved to the point where many patients may be discharged the following day without a catheter or drain. However, there is still significant postoperative pain, and school-age children usually require recovery at home for one week before returning to school.

In an effort to minimize the morbidity of surgical intervention, minimally invasive techniques have been developed for the management of reflux. Subureteric injection is a minimally invasive technique that has been available for nearly 20 years, but has recently been popularized because of the Food and Drug Administration approval of dextranomer/hyaluronic acid copolymer (Deflux). Subureteric injections are performed with a needle through a cystoscope under a brief general anesthetic. There is virtually no morbidity or significant recovery associated with the procedure. Injection of a bulking agent under the ureteral orifice adds support to the intramural tunnel of the ureter, discouraging reflux. In Europe, Teflon® has been used successfully for this approach. Teflon injection was abandoned years ago in the United States because of reports of migration of the Teflon particles throughout the body—including to the brain. When injectable collagen became available, it was employed with reasonable

success—approximately 75%. However, concerns regarding the use of an agent obtained from cows—the possibility of transmitting infectious agents and allergic reactions—along with the tendency of collagen to be absorbed over time have limited its use. Deflux is a synthetic material which is easy to inject and appears in initial reports to be durable. Success rates of 72% and 86% following a single injection have been reported (1–3). Success is related to the grade of reflux ranging from 90% for grade 1 reflux to 65% for grade 4 reflux. Most failures can be salvaged with a second injection. Ureteral obstruction occurs in only about 1 in 1000 injections. The introduction of this less invasive procedure to treat reflux has lowered the threshold for surgical intervention. Many parents will prefer an outpatient procedure to years of antibiotic prophylaxis and repeated radiographic studies. Indeed at some centers nearly all patients are treated initially with an injection, while other centers still use injection therapy only in those patients that fulfill the traditional criteria for surgical intervention.

Laparoscopic/percutaneous approaches to ureteral reimplantation have been developed in an attempt to achieve the high success of open reimplantation with the decreased morbidity associated a minimally invasive approach (4–7).

> As with other laparoscopic operations, the strategy for obtaining a high degree of success is to reproduce the open operation and simply change the approach from an incision to the percutaneous placement of instruments. Both percutaneous cross-trigonal and laparoscopic extravesical reimplantations have been described.

As with other laparoscopic operations, the strategy for obtaining a high degree of success is to reproduce the open operation and simply change the approach from an incision to the percutaneous placement of instruments. Both percutaneous cross-trigonal and laparoscopic extravesical reimplantations have been described.

TRANSVESICAL CROSS-TRIGONAL APPROACH

Under general anesthesia, cystoscopy is performed with the patient in the modified lithotomy position. A double-pigtail ureteral catheter is placed in the ureter. Two 5-mm balloon tip ports are inserted suprapubically into the distended bladder under cystoscopic visualization. These are passed one fingerbreadth superior to the pubic symphysis on either side of the midline. The balloons are inflated and the cuffs cinched down and secured to prevent extravasation of irrigation during the procedure. Both ports are placed to light wall suction to maintain a partially distended bladder throughout the procedure. Suction is adjusted to allow adequate distension for exposure, but to prevent overdistension and resulting extravasation. The cystoscope is exchanged for a resectoscope with Collins knife. Visualization for the entire procedure is maintained through the resectoscope.

Patients are kept in the hospital for 24 to 48 hours postoperatively and require minimal analgesia. Patients have been sent home with a Foley catheter for one week, though a shorter duration may be adequate. No drain is necessary, and the double-J stent may be removed at the end of the procedure or left in place at the surgeon's discretion.

LAPAROSCOPIC EXTRAVESICAL APPROACH

To begin a laparoscopic extravesical reimplantation, trocars are placed at the umbilicus and the right and left midclavicular lines. Trocars at the umbilicus and contralateral midclavicular line are working ports and the ipsilateral port is the camera access with a 30° lens. In the older child with a larger pelvis the contralateral working port may be placed slightly lower than the umbilicus on the midclavicular line to increase the working angle of the instruments. This helps with eventual suturing and knot placement. A final working port is placed midline in the suprapubic region to manipulate the ureter during suturing of the extravesical tunnel.

Postoperative care includes antibiotics and analgesics. A Foley catheter is not left in place unless a hole is made in the mucosa during creation of the tunnel. In that case, overnight drainage should be adequate with the Foley removed the next morning. In an uncomplicated case, the child can be expected to go home the same day as surgery.

SUMMARY

■ A minimally invasive approach may be used both for transvesical and extravesical ureteral reimplantation. In both cases, postoperative pain and duration of recovery seem to be reduced compared to open approaches.

■ The extravesical approach offers a technically easier ureteral dissection and reimplantation and avoids the need for postoperative catheter drainage. However, the risk of temporary urinary retention after bilateral extravesical reimplants is well documented. While retention is uncommon,

> even a short course of intermittent straight catheterization would seem to defeat the goal of minimal morbidity, and so one might limit this extravesical approach to patients with unilateral reflux.
> ■ The transvesical approach avoids the risks of a transperitoneal approach and dissection at the bladder base, but is technically more challenging and currently utilizes postoperative catheter drainage. To date, this approach has also only been employed in unilateral cases.
> ■ The availability of injection therapy for reflux—an even less invasive approach—will limit the utilization of laparoscopic/percutaneous approaches, particularly because they are technically more challenging.
> ■ Laparoscopic/percutaneous approaches do not have the long track record of success seen with standard open techniques, and the morbidity of the open approach is relatively mild because it is an extraperitoneal operation with a relatively quick recovery. Nonetheless, the laparoscopic/percutaneous approaches offer some marginal advantage in postoperative morbidity compared with open techniques while holding out the promise of greater success than injection therapy.

INTRODUCTION

Over the last decade, the use of laparoscopy by urologists has grown exponentially. From its initial use in pelvic lymph node dissections to contemporary use in radical prostatectomies, laparoscopy is quickly becoming a staple in the armament of modern urologic surgery. Because of its technical challenge and steep learning curve, however, laparoscopy tends to be limited to younger, fellowship-trained surgeons. In addition, standard laparoscopic techniques even in the most skilled hands are not routinely used for removal of kidneys with large tumors.

Hand-assisted laparoscopic nephrectomy was introduced in 1996 when Bannenberg et al. (1) performed the first nephrectomy in the pig. They reported that the hand-assisted laparoscopic nephrectomy technique was quick and easy to perform, and compared with conventional laparoscopic nephrectomy, operative times were shorter (30–45 vs. 90–120 minutes). In 1997, Nakada and colleagues (2) reported the first hand-assisted laparoscopic nephrectomy in a human for removal of a chronically infected kidney from stone disease. Since 1997, numerous publications have reported the use of hand-assisted techniques for radical nephrectomies, nephroureterectomies, donor nephrectomies, partial nephrectomies, and dismembered pyeloplasties (3–7). Since 1998, we have performed over 500 hand-assisted laparoscopic renal procedures using hand-assisted techniques.

> Hand-assisted laparoscopic offers a minimally invasive technique, which is easy to learn even for the nonlaparoscopic surgeon. This technique has given hundreds of community-based urologists the ability to offer their patients a minimally invasive alternative to standard extirpative techniques.

Hand-assisted laparoscopic offers a minimally invasive technique, which is easy to learn even for the nonlaparoscopic surgeon. This technique has given hundreds of community-based urologists the ability to offer their patients a minimally invasive alternative to standard extirpative techniques.

Hand-assisted techniques utilize all the principles of standard laparoscopy but offer the surgeons the advantage of using their most versatile instrument available: their hand. The hand aids in dissection, exposure, retraction, and maintaining hemostasis. The hand may also assist in more advanced techniques such as intracorporeal suturing and knot tying. Furthermore, by maintaining tactile sensation, the surgeon is able to palpate vessels and organs that may not be discerned by visualization alone, thereby potentially minimizing the risk of injury to vital structures, particularly during difficult dissections. In essence, hand-assisted laparoscopic combines the advantages of laparoscopic and open surgery (8).

Pure laparoscopic nephrectomy has inherent limitations. When operating on large, bulky tumors, it may be difficult to adhere to principles of oncologic surgery using standard laparoscopic techniques. In addition, removal of an intact specimen

requires an incision usually as large, or larger, than a "hand-access" incision. Hand assistance helps the urologist maintain standard principles of oncologic surgery while employing a minimally invasive approach. In addition, the operative time can usually be shortened as compared to pure laparoscopic surgical techniques. Finally, if an incision is going to be utilized to remove the intact kidney, there is a clear benefit in making this incision early on in the procedure and using the hand to facilitate the entire procedure.

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

Indications for hand-assisted laparoscopic nephrectomy can include almost any scenario in which an open nephrectomy is warranted. The most common indications include nephrectomy for functional renal masses (renal cell carcinoma being the most common pathology), nonfunctioning kidneys, and renovascular hypertension. Hand-assisted techniques can also be applied to nephroureterectomy hand-assisted laparoscopic nephrectomy for live donor renal transplants and upper tract transitional cell carcinoma.

> The most favorable patients, especially during the initial learning phase, include those who are relatively thin, have unviolated abdominal cavities, and have small lower pole tumors located away from the renal hilum.

Care must be taken in evaluating whether a patient is appropriate for hand-assisted laparoscopic nephrectomy. The most favorable patients, especially during the initial learning phase, include those who are relatively thin, have unviolated abdominal cavities, and have small lower pole tumors located away from the renal hilum.

Several conditions make a patient less than ideal for initial attempts at hand-assisted cases. Obese patients can be a significant challenge since excessive adipose tissue can make dissection tedious and difficult. Multiple prior abdominal surgeries predispose to intraperitoneal adhesions, which are time consuming to lyse and increase the risk of visceral injury. Patients with extremely muscular abdominal walls have reduced abdominal wall compliance that reduces the working space, restricting the use of the hand. Relative contraindications to hand-assisted techniques also include extremely large tumors, extensive renal vein or inferior vena cava thrombus, history of severe perirenal and/or intra-abdominal inflammatory conditions, ipsilateral abdominal wall stomas, and pregnancy. As the surgeon's experience grows, patients with relative contraindications become more amenable to the hand-assisted technique. Absolute contraindications include caval thrombus extending above the hepatic veins, large tumors with direct extension into the body wall or adjacent viscera, and uncorrectable bleeding disorders.

PREOPERATIVE PREPARATION

Patients should be appropriately informed of the surgeons experience and the risks and benefits of hand-assisted techniques versus standard laparoscopy and open surgical techniques. Preoperative discussions should always include the caveat that conversion to an open nephrectomy is possible. Consent must include permission for open nephrectomy. A type and screen should be obtained. Patients are instructed to take a clear liquid diet starting the day prior to surgery. Since an empty bowel helps maximize working space and allows for more comfortable dissection, a mechanical bowel prep is suggested. We use an 8 oz bottle of magnesium citrate the afternoon before surgery followed by a Fleets™ enema in the evening. The patient should have nothing to eat or drink by mouth after midnight except for a sip of water with medi-cations the morning of surgery.

Prior to induction of general anesthesia and endotracheal intubation, pneumatic antiembolic stockings are applied. After induction of anesthesia, a nasogastric/orogastric tube and a Foley catheter are used in order to keep the stomach and bladder decompressed. Prophylactic antibiotics are administered. The patient is then positioned in semilateral decubitus position at a 45° angle, using gel pads to support the side of the pathology (Fig. 1). A padded neuro-armrest is used to support the upper arm. An axillary roll is not required using the semilateral position. The lower leg is flexed and the upper leg extended with pillows placed in between. The table is left flat and not flexed. In order to allow the patient to be rolled intraoperatively from a near supine position to the full flank position, three inch cloth tape is wrapped over the patient and passed under the operating room table several times to secure the patient's head, shoulders, chest, hips, and legs. Upper and lower body warming blankets are used to maintain core body temperature throughout the case. The surgical field from nipples to pubis and laterally to the mid axillary line should be shaved. After the patient is positioned, it is

FIGURE 1 ■ Patient positioning.

important to widely prep and drape in order to accommodate placement of the hand-assist device and trocars.

DETAILED LAPAROSCOPIC TECHNIQUE

Equipment and Hand-Assist Devices

The operating room is assembled in a similar manner as for any laparascopic procedure. Equipment used in hand-assisted cases versus pure laparascopic cases is similar as well.

> Two important instruments exclusive to hand-assisted surgery include a ringless laparotomy pad and the hand-assist device.

Two important instruments exclusive to hand-assisted surgery include a ringless laparotomy pad and the hand-assist device.

A clean, rolled up laparotomy pad with the ring removed is placed into the abdomen through the hand incision. The laparotomy pad is used to help retract and dry tissues. Drier tissues are easier to grasp and dissect, and tissue planes are easier to identify. It also saves time not having to stop and insert a suction/irrigating instrument. If the laparotomy pad becomes excessively bloody it can absorb a significant amount of light, which can darken the video image. Replacing a bloody laparotomy pad with a clean one can dramatically brighten the video image.

> The purpose of the hand-access device is to enable the surgeon to comfortably insert the nondominant hand into the abdominal cavity through a small incision without the loss of the pneumoperitoneum. There is no perfect hand-access device.

The purpose of the hand-access device is to enable the surgeon to comfortably insert the nondominant hand into the abdominal cavity through a small incision without the loss of the pneumoperitoneum. There is no perfect hand-access device.

Each device has its advantages and disadvantages. Factors determining the ideal choice of a hand-access device for a specific case include the patient's body habitus and pathology, and the surgeon's experience and preference using each individual device. All devices require similar-size incisions (3–4 in) in the abdominal wall, but vary widely on how these maintain a seal around the surgeon's arm and wrist. Unlike the first-generation devices, none of the new products adhere to the body wall using adhesive seals. These adhesives seals were tedious and difficult to apply and were very prone to leakage.

Devices that are currently on the market include Gelport[a], Lapdisc[b], and Omniport[c]. All of these devices secure to the body wall using two concentric rings that are attached together with vinyl or rubber. One ring is inserted on the undersurface of the abdominal wall and the other ring rests on the outside surface of the body wall. The material holding the two rings together is placed on stretch, maintaining the seal at the body wall and acting as a wound protector. These second-generation devices can be directly inserted into the abdominal cavity without first insufflating, which is a definite time saver.

Advantages of the Gelport (Fig. 2) device include an excellent seal, flexibility, and comfort offered by the gel. The unique gel-like polymer through which the

FIGURE 2 ■ Gelport device. *Source*: Courtesy of applied medical.

FIGURE 3 ■ Lapdisc device. *Source*: Courtesy of Ethicon.

surgeon's hand is inserted is flexible and soft around the wrist. Additionally, this polymer can be temporarily pierced by an instrument or trocar and maintain a seal at the puncture site. Instruments can even be inserted through the gel while the hand is inserted in the device. Other advantages include the fact that removal of the surgeon's hand from the abdominal cavity does not cause loss of pneumoperitoneum and rarely causes the device to become dislodged. The Gelport device has the largest template or footprint, requiring a large area for application. This is not a problem in most cases, but in small-framed patients the device may be too large to use in a right lower quadrant incision that is commonly used for a right-sided nephrectomy. In these cases, the anterior iliac spine may prevent the device from sitting evenly against the body wall, thereby jeopardizing the seal. A smaller version of this device has recently become available to obviate these problems. Gelport is the most expensive hand-access device on the market.

The Lapdisc (Fig. 3) is the least expensive device on the market and is the easiest to use. There are no pieces that need to be assembled, and insertion of the device is quick and easy. This device has the smallest footprint, fitting almost anywhere on most abdominal walls and rarely interferes with adjacent trocars. An oversized device is available for patients with thicker than normal abdominal walls. The iris that tightens around the surgeon's wrist, to develop the seal, can alternatively be tightened around a trocar or completely closed on its self to maintain the pneumoperitoneum. This iris requires meticulous adjustment around the wrist. If it is too tight the hand will quickly tire and become painful, if too loose, the device will leak. When removing the hand from the abdomen the iris must be adequately loosened or the Lapdisc will inadvertently be removed. Pneumoperitoneum is lost when the hand is removed but can easily be re-established by quickly closing the iris.

The Omniport (Fig. 4) is an inflatable device, which maintains an excellent seal and rarely becomes dislodged once it is inserted. As with the Gelport and Lapdisc, the surgeon's hand can rapidly be removed and reinserted, which is a major advantage for resident teaching programs when the teaching surgeon must quickly take over the case to avert or manage a potential complication. The device can be insufflated to maintain pneumoperitoneum without the hand being inserted, but an accessory trocar or instrument cannot be inserted through the device. Unfortunately, the device can be difficult to insert. Additionally, care must be taken to assure that bowel or omentum is not caught under the rigid inner ring, which is unforgiving and can easily damage soft tissue.

As with all forms of minimally invasive surgery, products will continue to change and improve. It is not practical or cost effective for any one operating room to have all products available. Surgeons performing hand-assisted laparoscopic should periodically evaluate the hand-access devices available and select the one or two devices they feel are best suited for their needs.

Trocar and Hand-Port Configuration

FIGURE 4 ■ Omnport device. *Source*: Courtesy of intermed.

We have used the following hand incision and trocar configurations successfully in over 500 cases with little modification. Numerous factors must be considered when determining the optimal positioning of trocars and the hand incision. These factors include

the specific operation being performed, the patient's anatomy, the surgeon's experience and the surgeon's hand and forearm size.

At the start of the case the table is rolled so that the patient is in a near supine position. The midline should always be marked, which aids in trocar placement as well as provides a quick and accurate guide if emergent laparotomy is necessary. Placement of the hand incision is made with the patient in this position as this allows for easier access to the peritoneal cavity and ensures better cosmetic results, especially in obese patients.

The length of the hand incision in centimeters is usually equal to the surgeon's glove size. Once the incision is made and the peritoneal cavity is entered, test the size and length of the incision for comfort. If the incision is too small, parasthesias and cramping of the surgeon's hand can result, which will make the operation more difficult. Too large of an incision may result in the hand device coming dislodged and loss of the pneumoperitoneum.

The renal hilum is approximately 8–12 cm cephalad to the umbilicus, but this distance can vary widely based on patient body habitus and vascular anatomy. Examine the patient's computed tomography scan and calculate this distance by counting the number of tomographic images between the renal hilum and the umbilicus. If the distance is greater than 12 cm, the surgeon has short arms, the patient is obese, or the girth of the abdominal cavity is larger than normal consider moving the hand incision cephalad and/or lateral, which allows improved access to the renal hilum.

The hand incision should be far enough from the operative target to allow insertion of the entire hand and wrist into the peritoneal cavity.

The surgeon's wrist should have free range of motion and the fingertips should comfortably reach the renal hilum (the most important part of the dissection).

If the hand incision is placed too close to the kidney, the hand will not be able to be completely inserted into the abdominal cavity, loosing maneuverability of the wrist and fingers. The hand will act more as a retractor and less optimally as a dissector.

Attempt to place the hand incision as low as possible on the abdominal cavity, as this will result in decreased postoperative discomfort and respiratory compromise. Additionally, always try to avoid cutting muscle fibers, as this will reduce postoperative morbidity and reduce the risk of incisional hernias. We use a low midline or periumbilical hand incision for a left nephrectomy and a muscle splitting right lower quadrant incision for a right nephrectomy.

For a right-sided nephrectomy (Fig. 5), the hand incision is placed in the right lower quadrant lateral to the rectus muscle, just below the level of the umbilicus. The skin is incised in line with the external oblique fascial fibers and the abdominal wall musculature is split. In a small percentage of right-sided cases, the incision is made in line with the internal oblique fibers and shifted more cephalad. This alteration gives the surgeon the option to extend the incision cephalad and medially, creating a low lateral subcostal incision if the case cannot be completed laparoscopically.

If emergent conversion is required, an incision should be made in a location that will allow most efficient and safe management of the situation at hand. Trying to manage a complication or difficult case through an extended hand incision if it will not offer optimal exposure is not recommended.

After insertion of the hand-assist device, the working instrument port is placed just below or above the umbilicus and the camera port is placed in the supraumbilical midline approximately 8 cm cephalad to the working trocar. The camera and working instruments may be switched at any time to facilitate the dissection. A third port is placed in the right mid-clavicular line at the costal margin that allows placement of a liver retractor. Placement of this port more medially will result in the liver retractor leaning against the gallbladder, potentially causing injury.

For a left nephrectomy (Fig. 6), the hand port is placed midline in the infraumbilical or periumbilical region. The camera port is placed in the anterior axillary line at the level of the umbilicus while the working instrument port is placed in the midclavicular line, just below the level of the umbilicus. For very large upper pole tumors, an additional superior midclavicular working port may be used for the most cephalad part of the dissection. Adequate mobilization of the spleen obviates the need for a splenic retraction port.

In morbidly obese patients or patients with very rotund and protuberant abdominal walls, the hand and trocar template is shifted lateral and cephalad. In a left-sided nephrectomy, the hand incision is placed lateral to the rectus muscle belly and the two trocar sites are moved approximately equidistance lateral to their standard locations. In a right-sided nephrectomy, the hand-access incision and trocar sites can

be moved lateral any distance, as the hand-access incision is already lateral to the rectus muscle belly.

In almost all cases, we start out by making the hand incision and inserting the hand-access device and working trocar prior to establishing a pneumoperitoneum. In cases where there is a high index of suspicion for significant adhesions, the hand incision allows direct visualization of the abdominal cavity and open surgical lysis of adhesions. Lysis of extensive intra-abdominal adhesions through the hand incision can save a significant amount of time as compared to using a purely laparoscopic technique.

Another option is to initially establish the pneumoperitoneum using a Hasson trocar or Veress needle and inspect the peritoneal cavity using the laparoscope. This allows the surgeon to identify adhesions and appreciate variations of anatomy that may alter the positioning of the hand-assist device and/or trocars. We stopped using this technique after our first 100 cases, as we found that the placement of our hand incision and trocar placement was rarely, if ever, modified.

Once the pneumoperitoneum is established, it is maintained at a pressure of 12–15 mmHg as per standard laparoscopy.

Stepwise Dissection Technique

Left Radical Nephrectomy

The colon is released from the lateral sidewall by incising the white line of Toldt. Dissection is carried out from the splenic flexure to the iliac vessels. The colon is reflected medially using the back of the hand, while the fingertips help dissect the mesocolon off of the anterior aspect of Gerota's fascia. Dissection is continued in the cephalad direction, freeing the splenic flexure and releasing the splenorenal ligaments. The lateral attachments from the body sidewall to the spleen are now released up to the level of the gastric fundus, which allows the entire spleen and splenic flexure to fall medially.

Lateral attachments of the kidney to the body sidewall should be preserved, as these attachments are used for counter traction, which aids in the medial dissection of the renal hilum.

The plane between the tail of the pancreas and the anterior aspect of Gerota's fascia is then developed, which allows the tail of the pancreas to rotate medially with the spleen. The back of the hand is used as an atraumatic retractor on the spleen and the pancreas while the fingertips aid in dissection. Care is taken to leave the entire anterior aspect of Gerota's fascia intact. The colon and mesocolon are mobilized medially to allow identification of the aorta and renal hilum. Investing tissue overlying the hilar vessels is grasped with the fingertips, retracted anteriorly and a plane between these tissues and renal vein is developed using the harmonic scalpel or scissors. Once the anterior wall of the renal vein is exposed, meticulous dissection allows identification of both the gonadal vein and left adrenal vein entering the renal vein. These veins are dissected free of their surrounding tissues and doubly clipped both proximally and distally.

In some cases, we choose not to clip and divide the gonadal and adrenal vessels at this point in the procedure, as we do not want to have clips potentially interfere with the subsequent firing of the linear stapling device across the renal vein later in

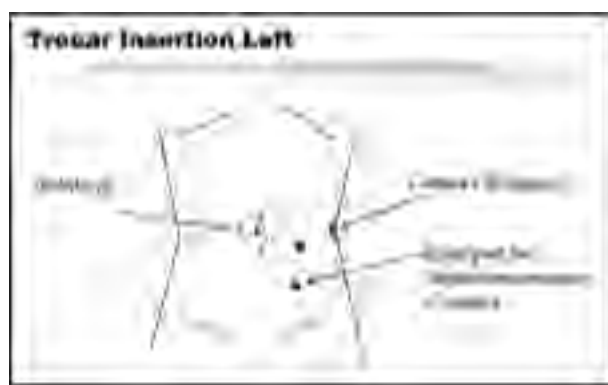
FIGURE 5 ■ Right-sided nephrectomy.


FIGURE 6 ■ Left-sided nephrectomy.

the case. In other cases, the anatomy may be favorable for dividing the renal vein proximal to the adrenal vein, obviating the need for division of the adrenal and gonadal veins as long as the surgeon plans on removal of the adrenal gland with the kidney.

At this point, the surgeon must not be tempted to continue dissection of the renal vasculature from this anterior approach. The key to success of the hand-assisted laparoscopic nephrectomy technique is obtaining the vascular control from a posterior approach, which allows the fingertips to surround the renal hilum, helping with palpation, dissection, and control of the renal artery and vein.

In a very rare case, the main renal artery will be easily accessible anteriorly and should obviously be ligated and divided at this point in the procedure.

Dissection now continues at the most inferior lateral portion of Gerota's fascia, identifying the body sidewall and psoas muscle. The fingertips and the dissecting instrument of choice, either electrocautery scissors or harmonic scalpel, are used to reflect the perinephric fat in a medial and anterior direction off the psoas muscle. The surgeon works from a lateral to medial direction, coming across the gonadal vein, which is doubly clipped proximally and distally with hemoclips and divided. If a radical nephrectomy is performed, the ureter is also identified, clipped, and transected. Obviously, during a nephroureterectomy, the ureter is left intact. If a donor nephrectomy is being performed, the periureteral tissue is left adjacent to the ureter as well as leaving the ureter intact, and dissection of the ureter with all of its surrounding tissue is continued into the true pelvis below the iliac vessels.

The surgeon continues reflecting the inferior pole of the kidney, adjacent perinephric fat and overlying Gerota's fascia anteriorly and medially, releasing the posterior and lateral attachments to the body sidewall and posterior wall. All lateral attachments are now released up to the level of the adrenal gland, as the kidney is reflected anteriorly and medially with the back of the hand. Care must be taken not to enter Gerota's fascia. As the lateral attachments to the inferior aspect of the diaphragm are encountered, the surgeon must be careful not to perforate through the diaphragm. If perforation occurs, rapid loss of pneumoperitoneum will occur resulting in a tension pneumothorax. Perforations can be closed using hand-assisted laparoscopic suturing techniques; conversion to open nephrectomy may be necessary.

After releasing all lateral and posterior attachments, the kidney can be rolled anteriorly and medially, exposing the posterior aspect of the renal pedicle. The kidney should then be rolled back to its normal position and the tips of the second and third finger are placed just above the exposed anterior aspect of the renal vein. Using the thumb and dissecting instrument, the kidney is now rolled anteriorly and medially and the thumb is placed on the posterior aspect of the renal vessels. This maneuver helps identify the renal artery by direct palpation and allows for presentation of the artery to the dissecting instruments. Additionally, if bleeding is encountered the fingers can compress the pedicle achieving rapid hemostasis. Using curved electrocautery shears, a Maryland dissector or a harmonic scalpel to dissect the surrounding lymphatic tissue, the posterior and inferior aspects of the renal artery are exposed. Oftentimes, a lumbar vein is seen coursing across the posterior aspect of the proximal renal artery. This lumbar vein can complicate expos-ure and dissection of the renal hilum, as it may tether the renal vein or obscure the renal artery. In these situations, the lumbar vein must be clipped and divided. Following this, a right angle dissector is passed around the renal artery, completely freeing the vessel from all remaining attachments. The artery can be controlled using either three locking clips, two proximally and one distally, or by using an endoscopic linear stapling device.

After the renal artery is divided, the renal vein is freed of all surrounding lymph-atic and connective tissues, and controlled using an endoscopic linear stapling device or large hemoclips. When the endoscopic stapler is used, great care must be taken not to engage any previously placed clips in between the jaws of the stapler. Both visual inspection and palpation with the hand assures that the stapler has not engaged any extraneous tissue or clips. Engaging clips in the jaws of the stapler will cause the device to misfire, resulting in a disruption of the staple line and significant bleeding.

If the adrenal gland needs to be removed with the left kidney, attention is now directed to the most superior phrenic attachments. With the spleen completely mobilized medially, diaphragmatic attachments are identified and controlled using hemoclips or the harmonic scalpel. There is usually a single artery originating from the diaphragmatic attachment, which must be adequately controlled with the harmonic scalpel or clips. The remaining vessels can usually be divided using the harmonic

scalpel. Care must be taken to identify any accessory phrenic veins that may exist, coursing from the diaphragm along the medial aspect of the adrenal gland toward the renal vein. These structures can be easily mistaken for the adrenal vein when dissecting in the region of the superior aspect of the renal vein. The superolateral attachments from the adrenal gland to the body sidewall are left intact and the medial attachments to the aorta are divided using the harmonic scalpel and clips when necessary. The remaining superolateral attachments and posterior attachments are now divided using the harmonic scalpel or electrocautery scissors and the specimen is completely freed.

If the adrenal gland is to be left intact, use visual inspection and palpation with the fingertips to locate the groove separating the adrenal gland from the kidney. The attachments between the adrenal gland and the superior aspect of the kidney are divided using the harmonic scalpel. If the adrenal vein has not already been divided, it should be doubly clipped proximally and distally, and sharply transected. Usually, a single large arterial branch originating from the renal artery feeds the most inferior lateral aspect of the adrenal gland. Hemoclips can be used on this vessel for adequate hemostasis.

Once dissection is complete, the kidney is removed through the hand incision. Oncologic principles are no different in the hand-assisted technique from that of open surgery. The specimen is delivered intact, without the need for morcellation, preserving the pathologic integrity of the specimen. The hand is placed back into the abdomen and pneumoperitoneum is re-established. Adequate hemostasis should be assessed at lower insufflation pressures (5–8 mmHg) confirming vascular control of all arterial and venous structures. Renal hilar vascular stumps are re-examined and any bleeding staple lines or vascular stumps can be controlled with laparoscopic suture ligation.

Left Donor Nephrectomy

The operative technique is a modification of the above description. After the anterior wall of the renal vein is identified, Gerota's fascia is entered along the medial inferior aspect of the kidney. The entire inferior aspect of the renal capsule is identified. Perinephric fat is released from the capsule using either electrocautery shears or the harmonic scalpel. The entire anterior aspect of the renal capsule is now exposed and the inferior and lateral perinephric fat is also cleared away. The adrenal gland is now released from the medial superior aspect of the renal capsule using the harmonic scalpel. The adrenal vein is identified, doubly clipped proximally and distally and sharply divided. Usually, there is one large arterial branch coming off the renal artery, feeding the lower aspect of the adrenal gland, which requires control with hemoclips. The gonadal vein is now clipped and divided. Ureteral dissection is now accomplished, leaving as much periureteral tissue with the ureter as possible, hopefully preventing subsequent ischemia of the transplant ureter. Ureteral dissection is continued into the true pelvis, distal to the common iliac vessels. The ureter is not divided until later in the procedure, just before division of the renal vasculature, thereby preventing leakage of large amounts of urine into the wound, which will compromise exposure and visualization. The posterior and remaining lateral attachments are now divided and the kidney is rolled anteromedially using a similar maneuver as described in the above left-sided operative technique. Great care must be taken not to place the renal artery on stretch, as this can cause both spasms of the renal artery and potential intimal disruption. Lumbar veins are now identified originating from the renal vein and usually coursing over the proximal aspect of the renal artery. Using Maryland and right angle dissectors, the veins are isolated, controlled using hemoclips, and sharply divided. The renal artery should now be completely freed from surrounding tissue and ready for division. The remaining posterior and inferior attachments to the renal vein are now divided and the renal vein should be completely freed proximally to the level of the vena cava. The renal artery is divided using the linear stapling device with a vascular load or secured with locking Weck clips and divided distal to the clips. The linear stapling device with vascular load is used to divide the renal vein at the level of the vena cava. The kidney is promptly removed and placed in iced preservation solution.

Right Radical Nephrectomy

After insertion of the hand device and trocars as previously described, the liver retractor is inserted and the liver is retracted medially. The right lobe of the liver is released from the body sidewall by incising the triangular ligament and, if necessary, the

anterior and posterior divisions of the coronary ligaments. There may also be significant attachments between the undersurface of the right lobe of the liver to the anterior/superior aspect of Gerota's fascia that must be released using the harmonic scalpel.

With the liver adequately mobilized medially, the attachments of the hepatic flexure to the overlying Gerota's fascia are released using the fingertips to develop pedicles, which are transected using the harmonic scalpel. The duodenum is now identified. If the vena cave is covered by the duodenum at the level of the renal hilum, a standard Kocher maneuver is performed using sharp dissection, mobilizing the duodenum medially off of the underlying renal hilum and vena cava. Investing tissue over the vena cava and renal vein is released and the anterior wall of the renal vein is skeletonized. The tendency would be to continue dissection on the renal hilum and vasculature at this time, but the surgeon should remember that it is imperative to obtain vascular control from the posterior approach.

Posterior exposure of the renal hilum is obtained by releasing all attachments of Gerota's fascia and perinephric fat to the body wall and rotating the kidney anteriorly and medially. We start this part of the dissection by directing our attention to the perinephric fat inferior to the lower pole of the kidney. Using fingertip dissection, the psoas muscle is identified and the fingers are passed lateral to medial raising the most caudal attachments of the perinephric fat off the psoas muscle. This large pedicle of tissue may include the right gonadal vein and ureter. The entire pedicle can be divided using an endoscopic linear stapling device. Alternatively, individual pedicles of fat can be divided using the harmonic scalpel, while the gonadal vein and ureter are individually clipped and sharply divided. In some cases, the gonadal vein can be gently retracted medially and division of the vein is unnecessary. Attachments of Gerota's fascia and perinephric fat to the lateral and posterior body sidewall are released using the harmonic scalpel or electrocautery shears.

With the hand placed posterior to the kidney, the kidney is elevated. Any remaining inferior medial attachments to the vena cava or lower pole accessory veins are identified and secured using clips or the harmonic scalpel. The second and third fingers are now curled behind the renal pedicle, allowing identification of the renal artery. Using gentle traction with the index finger, the artery can be pulled inferiorly and dissected free of surrounding lymphatic tissue using the harmonic scalpel, Maryland dissector, or right angle dissector. The artery can be controlled using locking clips or an endoscopic stapling device with a vascular cartridge. The renal vein is dissected free from surrounding lymph-atic and investing tissues and transected using the endoscopic stapling device.

If the adrenal gland needs to be removed with the kidney, the liver must be aggressively mobilized medially. The most superior phrenic attachments and vessels feeding the adrenal gland should now be controlled and ligated with clips or the harmonic scalpel. The superolateral attachments should be left intact and dissection should continue along the vena cava, releasing medial attachments. The adrenal vein will now be easily identified and should be ligated using large hemoclips and sharply divided. The remaining posterior and lateral attachments can easily be transected using the harmonic scalpel.

If the adrenal gland does not need to be removed, use visual inspection and palpation with the fingertips to locate the groove separating the adrenal gland from the kidney. The attachments are divided using the harmonic scalpel.

PROS AND CONS OF DIFFERENT TECHNIQUES

Since the first laparoscopic nephrectomy was reported in 1991, the urologic community has increasingly accepted laparoscopic approaches for many urologic conditions (9). This acceptance has been fostered by numerous articles demonstrating certain advantages to laparoscopic surgery, particularly decreased postoperative pain and a quicker recovery time to normal activity. In examining whether a new surgical technique is appropriate, one must address the technique's outcomes, morbidities, and costs. Many factors may affect more than one of these criteria, e.g., operative times may affect both morbidity and cost. If outcome, morbidity, and cost results are acceptable, one must then determine whether the new technique is transferable to other surgeons and institutions. While such comparisons of different procedures are often difficult to interpret, certain trends are apparent when one examines open laparoscopy, and hand-assisted laparoscopic renal surgery.

For a purely ablative procedure, results demonstrate that laparoscopic and hand-assisted laparoscopic approaches are as efficacious as open surgery.

For a purely ablative procedure, results demonstrate that laparoscopic and hand-assisted laparoscopic approaches are as efficacious as open surgery.

With five-year follow-up, Portis et al. (10) demonstrated equal oncologic effectiveness for open and laparoscopic radical nephrectomy. This had also been similarly demonstrated by Ono et al. (11) in 2001 for renal masses less than 5 cm. Two-year follow-up data for laparoscopic and hand-assisted laparoscopic nephroureterectomy are also encouraging (4,12).

Laparoscopic partial nephrectomy can be daunting because of the potential for large blood loss and the need for reconstruction, which can be difficult. However, the laparoscopic procedure has been shown to have good pathologic outcomes (13,14).

Numerous studies have demonstrated equivalent graft function for open, laparoscopic, and hand-assisted laparoscopic donor nephrectomy (15,16). A randomized trial of hand-assisted laparoscopic versus open donor nephrectomy clearly demonstrated less analgesic use, shorter hospital stay, and quicker return to normal activity in the hand-assisted laparoscopic group (17). Similarly, shorter hospital stays and quicker returns to normal activity were seen when hand-assisted laparoscopic radical nephrectomy is compared to open radical nephrectomy (18). Postoperative complications were similar across all groups in each of these studies. Numerous other studies have similarly shown quicker recoveries for hand-assisted laparoscopic compared to open surgery. The biggest area of controversy is currently whether laparoscopic nephrectomy, particularly with morcellation, offers improved convalescence compared to hand-assisted laparoscopic. Several studies suggest this is not the case.

Despite larger tumors in the hand-assisted laparoscopic group, a nonrandomized study by Nelson and Wolf (19) demonstrated equal recovery and morbidity in the hand-assisted laparoscopic and morcellated laparoscopic groups.

A comparison of open, laparoscopic, and hand-assisted laparoscopic donor nephrectomy showed equally shorter recovery times with laparoscopic and hand-assisted laparoscopic nephrectomy (16).

A comparison of open, laparoscopic, and hand-assisted laparoscopic donor nephrectomy showed equally shorter recovery times with laparoscopic and hand-assisted laparoscopic nephrectomy.

During laparoscopic nephrectomy, no differences are seen in postoperative pain or hospital stay whether a specimen is morcellated or removed intact (20). Thus, hand-assisted laparoscopic and laparoscopic renal surgery appear to be equivalent when examining postoperative recovery.

Cost analysis, while important, is a very difficult issue to address. Some studies have demonstrated increased costs associated with laparoscopic procedures due to instrument costs, while other studies have shown decreased costs due to decreased hospital stays (21,22). The issue becomes even more confusing once physician time, patient work hours lost/gained, etc. are entered into the equation. Each element in the process (patient, surgeon, institution, etc.) will have a different cost/benefit ratio that should be considered though absolute values will always be lacking.

While hand-assisted laparoscopic and laparoscopic renal surgery show similar benefits, hand-assisted laparoscopic is a more easily mastered technique and can be utilized in situations where laparoscopy alone may not be sufficient. Overcoming the lack of three-dimensional viewing is very difficult for the novice laparoscopist; hand-assisted laparoscopic allows the surgeon's hand to be in the operative field and can compensate for the two-dimensional view. Open surgeons are not accustomed to operating with the long instruments and fulcrum points needed for laparoscopy; surgeons are comfortable dissecting and retracting with their open hand. Hand-assisted laparoscopic can also be helpful for large renal tumors that might not be as easily removed with straight laparoscopy. We have removed tumors up to 22 cm with hand-assisted laparoscopic and feel that nephrectomy under these conditions is more easily performed with hand-assisted laparoscopic than laparoscopy. Together, these factors describe a technique that is more easily learned and can be more widely applied than standard laparoscopy.

TECHNICAL CAVEATS/TIPS

- Trocar and hand incisions noted in the operative technique section are for right-handed surgeons. Use mirror image placement for left-handed surgeons.
- The nondominant hand should be in the operative field and the dominant hand performs fine dissection using laparoscopic instruments.
- Hand incisions are positioned to allow the back of the hand to be used as a retractor while using the fingers to grasp and dissect.

- If you are using your hand just as a retractor, your incision was not properly placed or you are not using your hand correctly.
- If you are using your hand as a retractor and not for dissection, think about locations where you can insert a 5 mm trocar for a laparoscopic retractor, freeing up your hand to be used as an instrument.
- Experienced laparoscopists initially may not use their hand properly. Do not use your hand as a passive instrument and perform standard laparoscopic surgery. You will be surprised how fast you can progress with your hand compared to standard laparoscopy.
- The surgeon with the hand in the operative field should be using the dissecting instruments. The surgeon has the proprioception, depth perception, and control of the tissues and should control the instruments.
- Insert a rolled-up lap pad into the abdominal cavity with your hand. It can help retract and dry tissues. Drier tissues are easier to grasp and dissect, and tissue planes are easier to identify. It also saves time not having to stop and insert a suction/irrigating instrument.
- Uses of your hand include: determining optimum position of trocars and insertion of trocars; locating laparoscopic instruments as they are inserted into the abdominal cavity; palpation; depth perception; proprioception; counter traction; and vascular control.
- Exposure! Do not work in a hole. Obtain wide exposure. Work in layers. If you get into bleeding while working in a hole, it is hard to get control of the bleeding vessel. If you have good exposure you will more likely be able to get control of the bleeder.
- Do not use monopolar cautery near veins, especially large veins such as the renal vein or vena cava. The large volume of fluid in these vessels acts as a great conductor and may be the path of least resistance for the current to get back to the ground plate, resulting in a hole in the vein wall.
- The harmonic scalpel is much safer for dividing small vessels compared to monopolar electrocautery instruments, but takes longer to divide the tissues. If ever uncertain, be safe and patient; use the harmonic scalpel.

SPECIFIC MEASURES TAKEN TO AVOID COMPLICATIONS

Many complications can be prevented with thoughtful, preoperative planning and attention to detail during surgery. As usual, this process begins with a thorough history and physical examination. Comorbidities should be assessed preoperatively with the physiologic changes unique to laparoscopic surgery kept in mind. For instance, an obese patient with obstructive pulmonary disease and CO_2 retention may be difficult to ventilate with resultant hypercapnia during hand-assisted laparoscopic nephrectomy. Radiographic studies should be carefully examined for mass size and location, level of the renal hilum, renal vein, or caval involvement, duplicated renal vessels, retroaortic renal veins, etc. These factors will influence hand/port placement and allow the surgeon to anticipate minor anatomic anomalies. Occasionally, we will also perform preoperative renal artery embolization for tumors in which we feel that the ability to control and transect the renal vein before the artery will be beneficial. While intraoperative bowel complications are rare, we still conservatively have all our patients perform a bowel preparation with clear liquids and magnesium citrate the day before surgery (23).

While most anesthesiologists are comfortable with short laparoscopic procedures such as cholecystectomy, hernia repair, etc., they may be less versed in major, longer laparoscopic cases and inappropriately treat the patient as they would an open nephrectomy. Given the decreased blood loss, decreased insensible loss, and decreased urine output due to insufflation pressures, this can result in fluid overload. Avoid nitrous inhalants, as they can cause bowel distension with decreased exposure. Insufficient ventilation can result in hypercapnia with pulmonary arrest or fatal arrythmias. A multi-institutional review by Gill et al. (24) revealed that 35% of complications were due to the physiologic changes that occur during laparoscopy. Open communication before and during the surgery with the anesthesia team will avoid many of these complications.

When positioning the patient, be sure that all pressure points are well padded and the arms are positioned to avoid neurologic injuries. Initial access and trocar placement during laparoscopic surgery can be the cause of significant morbidity. As previously mentioned, we therefore make the hand incision first and place all subsequent trocars with hand guidance and/or direct visualization. Transilluminate the abdomen to avoid major vessels, particularly the epigastric. Having the patient secured to the table allows the surgeon to rotate the table for optimal exposure; exposure is obviously crucial in avoiding intraoperative injuries.

During right nephrectomy, incision of the triangular ligament with adequate liver mobilization will help avoid hepatic injuries. Similarly, the spleen and pancreas must be

adequately mobilized during left nephrectomy. Care should be taken to avoid diaphragmatic injuries during splenic or hepatic mobilization as well as during the mobilization of large, upper pole tumors. In our experience, the most common indication of a diaphragm laceration is loss of space around the upper pole as the diaphragm is pushed inferiorly by the insufflation pressure. At times, this can be accompanied by hemodynamic or ventilatory changes. As long as there is no lung laceration and the patient is stable, the injury can be repaired and the CO_2 will be rapidly reabsorbed. If the pneumothorax is preventing adequate exposure or the patient is hemodynamically unstable, a small Heimlich valve tube can be placed to evacuate the pneumothorax and complete the procedure.

> Bleeding is not an uncommon complication of hand-assisted laparoscopic nephrectomy. Bleeding can be due to renal or adjacent organ injury as well as vascular injuries. These injuries can occur due to thermal injury, blunt trauma, or stapler/clip misadventure. Depending on the situation, pressure, endoclips or staplers, fibrin sealants, Surgicel, temporarily raising the insufflation pressure, or free suturing techniques can generally salvage the situation. However, one should not hesitate to obtain adequate assistance when necessary or to convert to an open procedure.

Bleeding is not an uncommon complication of hand-assisted laparoscopic nephrectomy. Bleeding can be due to renal or adjacent organ injury as well as vascular injuries. These injuries can occur due to thermal injury, blunt trauma, or stapler/clip misadventure. Depending on the situation, pressure, endoclips or staplers, fibrin sealants, Surgicel, temporarily raising the insufflation pressure, or free suturing techniques can generally salvage the situation. However, one should not hesitate to obtain adequate assistance when necessary or to convert to an open procedure.

Large tumors should be placed in a retrieval bag to prevent tumor breakage, spillage, or port seeding. All trocars should be removed under laparoscopic visualization to assess for bleeding. Significant bleeding can be controlled with fulguration or endoscopic suturing with a Carter Thomason needle. Care should be taken to completely close all indicated port sites as well as the hand incision to prevent postoperative herniations.

At the end of the procedure, the patient should be examined for signs of significant subcutaneous emphysema. The presence of diffuse crepitus is associated with mucosal absorption and resultant laryngeal obstruction in a patient in whom hyperventilation may be required to expel excess CO_2. Therefore, extubation in this setting must be controlled: Lack of cuff leak around endotracheal tube with a deflated balloon, chest X-ray evidence of pneumomediastinum, direct visualization of laryngeal coaptation, or baseline pulmonary insufficiency are all indications for delayed extubation.

In any surgery, diligent preoperative assessment and preparation, thoughtful operative planning and attention to detail during surgery, and open communication with the operative team will avoid most perioperative complications. The majority of complications during hand-assisted laparoscopic nephrectomy can be addressed laparoscopically, particularly with increased surgeon experience and skills. However, one should not hesitate to enlist the aid of a more experienced laparoscopic surgeon or convert to open surgery when the situation warrants.

SUMMARY

- ■ Pure laparoscopy tends to be performed by younger, fellowship-trained surgeons.
- ■ Hand-assisted laparoscopic offers a minimally invasive technique, which is easy to learn even for the nonlaparoscopic surgeon. This technique has given hundreds of community-based urologists the ability to offer their patients a minimally invasive alternative to standard extirpative techniques.
- ■ For a purely ablative procedure, results demonstrate that laparoscopic and hand-assisted laparoscopic approaches are as efficacious as open surgery.
- ■ Numerous studies have demonstrated equivalent graft function for open, laparoscopic, and hand-assisted laparoscopic donor nephrectomy.
- ■ Numerous other studies have similarly shown quicker recoveries for hand-assisted laparoscopic compared to open surgery.
- ■ While hand-assisted laparoscopic and laparoscopic renal surgery show similar benefits, hand-assisted laparoscopic is a more easily mastered technique and can be utilized in situations where pure laparoscopy alone may not be sufficient. hand-assisted laparoscopic can also be helpful for large renal tumors that might not be as easily removed with pure laparoscopy.

INTRODUCTION

As with any surgical tool, hand-assisted laparoscopy is used differently by different practitioners. Some urologists perform only standard laparoscopic surgery, without ever using hand-assited laparoscopy. Others use hand-assisted laparoscopy either selectively or as stepping stone to more difficult standard laparoscopic procedures. Still others use hand-assisted laparoscopy as virtually the only laparoscopic technique that they offer.

Whatever role hand-assisted laparoscopy has in a given urologist's practice, there is no doubt that hand-assisted laparoscopy has played a major role in the integration of laparoscopy into the mainstream of urologic practice.

> Whatever role hand-assisted laparoscopy has in a given urologist's practice, there is no doubt that it has played a major role in the integration of laparoscopy into the mainstream of urologic practice.

HISTORY

It is difficult to attribute the concept of hand-assisted laparoscopy to any single person or report, but rather it may be described as a concept that evolved into a reality due to the rapid insurgence of standard laparoscopy in urology (1). In response to the difficulty of standard laparoscopy, particularly in complex cases, several physicians reported hand-assisted procedures, including nephrectomies, in the mid-1990s (2–4). What was most significant is that these reports revealed shorter operating room times and the removal of larger specimens.

As more urologists began performing hand-assisted laparoscopy, it soon became clear that improvements in the technology were necessary (5). Various approaches were described to troubleshoot hand access devices (6). The essence of an effective hand access device is the ability to maintain the pneumoperitoneum while a hand is inserted in the abdomen. Since the initial report using the PneumoSleeve, several companies and iterations of hand access devices have emerged (4,7,8). What is of clinical interest to most urologists is the evolution of hand access devices, from "sleeveless," to "glueless" and finally to "one-piece, multifunctionality" (Table 1).

EXPERIENCE WITH HAND-ASSISTED LAPAROSCOPY

Simple Nephrectomy

There are logical benefits of performing inflammatory nephrectomies using hand-assisted laparoscopy because the normal anatomic planes are not often present. Simple nephrectomy is often not so simple.

The initial report of hand-assisted laparoscopy nephrectomy included a patient with a severely inflamed kidney and obstructed ureter and a chronic indwelling nephrostomy tube (4). The benefits of hand-assisted dissection are useful when tissues are firm, and cannot be easily dissected without tactile feedback (9). There have been formal reports of hand-assisted laparoscopy simple nephrectomy and the technique, highlighting these concepts (10,11).

Another procedure that can be improved by using hand-assisted laparoscopy is laparoscopic nephrectomy for autosomal dominant polycystic kidney disease.

Initially reported using standard laparoscopy by Elashry et al., this series offered the first alternative to open surgery, which had higher complication rates and prolonged convalescence compared to its laparoscopic counterpart (12). The main concerns with standard laparoscopy for these patients include the management of large specimens and lesion extraction. In addition, access to the abdomen can be complex because the abdomen is filled by cystic disease. Making the hand incision to start the case can be beneficial when performing these cases as closed entry risks injuring cysts and other structures.

Similarly, bilateral nephrectomies are well suited to hand-assisted laparoscopy. Bilateral nephrectomy for autosomal dominant polycystic kidney disease has been reported using a single midline incision (13,14). These rather complex operations could be performed in four to five hours. Typically, repositioning the patient is not necessary.

Radical Nephrectomy

Radical nephrectomy was first reported using hand-assisted laparoscopy in 1996 (4). Including only the most recent updates of series, nine retrospective series have been published to date (Table 2) (15–23).

Hand-assisted laparoscopy radical nephrectomy has proven to be an excellent approach to remove even larger specimens with reasonable operative times and convalescence similar to that of other minimally invasive nephrectomies (17).

In many ways, the strongest benefit of hand-assisted laparoscopy is the ability to manage large renal specimens intraoperatively, because these can be challenging using the standard approach. While many laparoscopists morcellate cancer specimens, those that select intact removal should consider using hand-assisted laparoscopy as an incision is necessary regardless.

The use of early posterior artery control is effective in laparoscopic radical nephrectomy, a maneuver particularly suited to hand-assisted laparoscopy (9). Although a much newer approach than standard laparoscopic nephrectomy, series have accumulated quickly. The latest report by one of the authors (SYN) showed sustained convalescence, as well as cancer control similar to open nephrectomy at up to five years (23).

In addition, the urologist should consider using an entrapment sack for larger tumors, to minimize the risk of local recurrence at the extraction site.

Partial Nephrectomy

Partial nephrectomy is a technically difficult operation, and is probably the most challenging laparoscopic renal procedure. Hand-assisted laparoscopic and standard laparoscopic (both transperitoneal and retroperitoneal) approaches have performed with success, with an even wider variety of maneuvers for collecting system closure and hemostasis. There have been four published series of hand-assisted laparoscopy partial nephrectomy for renal masses suspicious for malignancy (Table 3) (24–27). In none of the series were any final margins positive, although in the experience of Brown and associates additional resection was required in five patients based upon intraoperative frozen sections. All procedures were completed laparoscopically except for one conversion to open surgery in the series of Stifelman and associates. In the series of Wolf and associates, two of procedures were performed with standard laparoscopy and one was converted to hand-assisted laparoscopy from standard laparoscopy.

Nephroureterectomy

Following the first report of hand-assisted laparoscopy for nephroureterectomy, a single case among a series of 22 laparoscopic nephroureterectomies reported by Keeley and Tolley (28), there have been 10 series reported, totaling 196 cases (Table 4) (29–38). Resection of the distal ureter was performed in a variety of manners, including open resection of a bladder cuff, laparoscopic resection of a bladder cuff with either sutured or stapled closure, and transurethral resection of the bladder cuff. The mean operating time, including repositioning and removal of the distal ureter, was 315 minutes, not

including the 2.6% of patients in whom the procedure was converted to open surgery. The overall minor and major complication rates were 12% and 9.5%, respectively. With a mean follow-up of 17.6 months, the nonvesical recurrence rate has been 5.5%.

Donor Nephrectomy

Many of the series of donor nephrectomy reported by surgeons who did not start performing the procedure until the advent of hand-assisted laparoscopy have been performed using hand-assisted laparoscopy (Table 5) (39–51). Among these 13 series reporting 454 patients in total, the mean operative time was 224 minutes and the mean warm ischemia time of the harvested kidney was two minutes and 36 seconds. Aside from conversion to open surgery in 2.0% of patients, the minor and major complication rates were 13.2% and 2.7%, respectively. Of the studies, four detailed donor convalescence, reporting a mean return to nonstrenuous activity levels in 8.7 days.

The results of the graft after hand-assisted laparoscopic donor nephrectomy have been excellent, with 97% functioning at a mean follow-up of 8.6 months.

Ureteral complications occurred in 1.7% of recipients. Among the first 200 hand-assisted laparoscopy donor nephrectomies performed by one of the authors (JSW) at the University of Michigan, the one month, one year, and three year actuarial graft survival rates have been 97%, 96%, and 91%, respectively. The ureteral complication rate has been 6% overall, with a 16% ureteral complication rate prior to modifications in ureteral dissection (first 24 cases) and 4.5% in the 176 cases since then.

Cystectomy

Hand-assisted laparoscopy in urology was initially (4) and has been most frequently applied to renal disease. Concurrent with the more recent interest in laparoscopic prostatectomy and cystectomy, hand-assisted laparoscopy has been applied as well. A pure hand-assisted laparoscopy radical prostatectomy has not been reported, although authors have described open surgical prostatectomy through the lower midline incision used to place the hand-assisted laparoscopy device for concomitant radical nephrectomy (52,53), but hand-assisted laparoscopy cystectomy has been described. In their series of multiple-organ removal using hand-assisted laparoscopy, Troxel and Das reported a case of simple cystectomy for pyocystis performed at the same time as simple nephrectomy for pyonephrosis. The first published description of hand-assisted laparoscopy radical cystectomy for urothelial carcinoma of the bladder was from Peterson et al. in 2002 (54). The ileal conduit urinary diversion was created with open surgical techniques through the incision for the hand-assisted laparoscopy device. The operative time was seven hours, there were no complications, the patient was discharged from the hospital seven days postoperatively, and he was back to work four weeks postoperatively. One of the authors (JSW) performed a similar (unreported) case in 2000, although the patient remained in the hospital for eight days postoperatively and suffered a small bowel obstruction requiring adhesiolysis six weeks postoperatively. The only series of hand-assisted laparoscopy radical cystectomy has been described by McGinnis et al. (55). In all seven patients, the hand-assisted laparoscopy device was placed through an infraumbilical midline incision. The cystoprostatectomies (all patients were men) were performed with hand-assisted laparoscopy and four laparoscopic ports, followed by open surgical ileal conduit urinary diversion through the hand-assisted laparoscopy incision. Of the seven procedures, one was converted to open surgery following cystoprostatectomy for failure to progress with the dissection of lymph node encircling the right external iliac vein. For the six cases completed with hand-assisted laparoscopy, the average operative time was 7.6 hours and the estimated blood loss was 420 mL. After a use of an average of 28.8 mg morphine equivalents, the patients were discharged from the hospital three to six days postoperatively (mean, 4.6 days). Aside from the one conversion to open surgery and two patients requiring transfusion of one and two units of blood, there were no other postoperative complications. All margins were negative except for one right ureteral margin positive for carcinoma-in-situ on final reading. Of the patients, two had positive pelvic lymphadenectomy specimens and received chemotherapy; one had progression of metastatic disease and died. Of the remaining five patients, all with negative pelvic lymphadenectomy specimens, one died of unrelated causes eight months postoperatively, two have no evidence of disease, and two developed local recurrences. The latter two are particularly concerning; a 29% pelvic recurrence rate is higher than expected. Although this may be simply an artifact of a small case series, it deserves further consideration.

COMPLICATIONS OF HAND-ASSISTED LAPAROSCOPY

Specific Complications

Hedican et al. reported a multi-institutional complications report including 196 patients undergoing various hand-assisted laparoscopy renal procedures (56). Procedures included 57 radical nephrectomies, 50 donor nephrectomies, 38 nephrouretectomies, 24 partial nephrectomies, 2 simple nephrectomies, and 2 other renal procedures. The data showed that 28 patients (14%) had minor complications, including urinary retention in 11 and prolonged ileus in four. Of the patients, 9.2% suffered major complications, including small bowel injury (3), hemorrhage requiring conversion (3) and reintubation (3). There were 12 (6.2%) intraoperative complications. Multiple complications occurred in 11 patients, accounting for 46% of all the complications. There were only two delayed complications, including one port site hernia and one small bowel

obstruction (57). It is important to emphasize that these institutions were pioneers of the approach, and many of the procedures were on the learning curve.

Conceptually, hand assistance should reduce complication rates, particularly intraoperative complications. More rapid dissection, better hemostasis, and more rapid identification of structures are all well publicized benefits of hand-assisted laparoscopy. In contrast, potential added risks of hand-assisted laparoscopy include incisional complications, namely wound infection or hernias (see below), and inadvertent bowel or adjacent organ injury due to the presence of the intra-abdominal hand, which sometimes is not always in view laparoscopically. Similarly, concerns of increased abdominal pain, and higher risks of ileus as compared to standard laparoscopy may be part of the postoperative expectations of patients undergoing hand-assisted laparoscopy procedures.

The morbidly obese are a controversial subgroup in laparoscopy. Hedican et al. (58) reported that hand-assisted laparoscopy was not only safe but also in fact beneficial in the obese subgroup.

They also assessed the profoundly obese (body mass index > 40) and found those patients doing similarly well. This finding is in contrast to the report of Mendoza et al. (59), which showed a greater risk of complications in the morbidly obese with standard laparoscopy. However, this study was a multicenter trial published in 1996, and thus may reflect technology and the global status of laparoscopy at that time. More recent data in standard laparoscopy have shown a similar complication rate in the morbidly obese (60).

It is the authors' belief that hand-assisted laparoscopy is particularly useful in the obese population, because the hand incision may be less significant in this patient subgroup. Moreover, these patients have capacious abdomens, which also favor the use of hand-assisted laparoscopy.

Finally, neuromuscular complications are worthy of note. Wolf et al. (61) reported a 2.7% risk of neuromuscular complications during laparoscopy, and although some cases in this series were hand-assisted laparoscopy procedures, the shortened operating room time for hand-assisted laparoscopy should decrease the risk of neuromuscular injury. Additionally, positioning for hand-assisted laparoscopy does not require as aggressive a flank position as standard renal surgery. Conversely, hand-assisted laparoscopy appears to produce more physical pain in some body parts of the surgeon than does standard laparoscopy (62).

Controversial Circumstances

There is some evidence that there is an increased risk of paralytic ileus using hand-assisted laparoscopy (44). However, this has not been borne out by other large series of hand-assisted laparoscopy. Nevertheless, the amount of bowel manipulation during the procedure, more pronounced early in a surgeon's experience, may lead to increased ileus and pain at the incision site postoperatively. Similarly, urologists must be careful closing the hand access incision, as with aggressive manipulation, the fascial incision may become torn. Similarly, the incision should be copiously irrigated once the hand device is removed, as often a midline hand access incision can be close to the edge of the sterile drape.

Conclusion

Many of the complications of standard laparoscopy are understated in the literature. Despite this, hand-assisted laparoscopy complications have been fairly well described. In general, we counsel our patients undergoing hand-assisted laparoscopy in a similar manner to those undergoing standard laparoscopy. Over time, every urologist will reach his or her comfort level with hand-assisted laparoscopy and risk of complications when using hand-assisted laparoscopy. It is likely that the amount of hand dissection plays some role in the convalescence of these patients.

COMPARISON OF HAND-ASSISTED LAPAROSCOPY TO OTHER LAPAROSCOPIC TECHNIQUES

The first comparison of hand-assisted laparoscopy and standard laparoscopy in urology was reported by the two authors in 1998, describing the first 13 hand-assisted and eight standard transperitoneal laparoscopic nephrectomies performed at the University of Michigan and the University of Wisconsin (5). The mean operative time for hand-assisted laparoscopy was 1.5 hour less than that for of standard laparoscopy, and there were fewer major complications in the hand-assisted laparoscopy group. These advantages were incurred without impact on convalescence. In 2003, Kercher et al. (63)

[a]One case in this series was a simple nephrectomy.
[b]One case was converted from retroperitoneoscopic to HALS.
Abbreviations: HALS, hand-assisted laparoscopy; OR, operating room; RP, retroperitoneoscopic; TP, transperitoneal laparoscopic.

In the personal series of 424 hand-assisted laparoscopy nephrectomies by one of the authors (JSW), infections and incisional hernias at the hand-assisted laparoscopy incision site have occurred in 6.8% and 3.5% of patients, respectively, compared to rates of 0.5% and 0.2% at the laparoscopic ports in the same patients. This increased rate of wound complications is an important consideration for hand-assisted laparoscopy.

reported a larger comparison with their analysis of 39 patients undergoing standard laparoscopic nephrectomy and 80 patients undergoing hand-assisted laparoscopy nephrectomy. Importantly, the operations occurred over generally the same time period and there were no differences in preoperative characteristics of the patients and lesions. Differences in these factors have flawed other comparisons of these two techniques (see below). Similar to the findings of the earlier study (5), the hand-assisted approach reduced mean operative time by almost an hour and was associated with a lower complication rate. Hospital charges and length of stay were similar between the two groups. Noteworthily, wound complications tended to be less in the hand-assisted group. Both of these studies suggest that, at least early in a surgeon's experience, hand-assisted laparoscopy "shortens the learning curve" for transperitoneal nephrectomy. With regard to the wound complications, however, the data of Okeke et al. (64), who compared 13 hand-assisted laparoscopy nephrectomies with 16 standard laparoscopic ones, revealed a 23% incidence of major wound complications at the hand-assisted laparoscopy incision site compared to none in the standard group (two severe wound infections requiring readmission, and one incisional hernia).

In the personal series of 424 hand-assisted laparoscopy nephrectomies by one of the authors (JSW), infections and incisional hernias at the hand-assisted laparoscopy incision site have occurred in 6.8% and 3.5% of patients, respectively, compared to rates of 0.5% and 0.2% at the laparoscopic ports in the same patients. This increased rate of wound complications is an important consideration for hand-assisted laparoscopy.

Radical Nephrectomy

There have been four retrospective series comparing hand-assisted laparoscopy and standard laparoscopic radical nephrectomy (Table 6) (15,16,18,22). An additional small series reported by Okeke et al. (64) is described below in the section on nephroureterectomy. Of 38 laparoscopic radical nephrectomies in the study of Nelson and Wolf (16), 16 were performed with standard transperitoneal laparoscopy and 22 with transperitoneal hand-assisted laparoscopy. Cases were performed during the same time period, with those selected for hand-assisted laparoscopy being based primarily upon greater tumor size, specimen weight, and body mass index. Despite this, hand-assisted laparoscopy was 1.5 hours faster than standard laparoscopy during the first half of the series and 30 minutes faster in the second half (overall 65 minutes faster). The intensity and duration of convalescence was similar between the two groups, although there was a trend toward more abdominal pain with hand assistance. The other three series all found that hand-assisted laparoscopy improved operative time only minimally, and that there was a trend (not statistically significant) toward greater estimated blood loss, more analgesic use, and/or longer hospital stay in the hand-assisted laparoscopy group. Unfortunately, all four studies had factors that confound the comparisons. In that of Batler et al. (15), the comparison was with retroperitoneoscopic nephrectomy rather than standard transperitoneal laparoscopic nephrectomy as in the others. The greater tumor size, specimen weight, and body mass index in the hand-assisted laparoscopy group in the study of Nelson and Wolf would tend to make the hand-assisted laparoscopy results less favorable in comparison to standard laparoscopy. The responsible surgeon in the series of Baldwin et al. (18) had more than five years prior experience with standard laparoscopic

nephrectomy. Finally, Hayakawa et al. (22) performed the hand-assisted laparoscopy radical nephrectomies before the standard laparoscopic radical nephrectomies, rather than concurrently. Although these factors preclude an unbiased comparison between standard laparoscopy and hand-assisted laparoscopy for radical nephrectomy, important information can nonetheless be gleaned.

Partial Nephrectomy

With increasing experience with pure laparoscopy, the advantage of hand-assisted laparoscopy in terms of operative time diminishes, and is also less when the comparison is to retroperitoneoscopic radical nephrectomy, which is an inherently faster technique in properly selected patients.

There have been no published series directly comparing hand-assisted laparoscopy and standard laparoscopic partial nephrectomy. Some relative assessment can be made nonetheless. Of the hand-assisted laparoscopy partial nephrectomy series listed in Table 3, none included the use of renal hilar clamping. An advantage of hand-assisted laparoscopy for partial nephrectomy is direct parenchymal compression with the hand for hemostasis. That the estimated blood loss in these hand-assisted laparoscopy series tended to be greater than that reported in series that employed renal hilar clamping (65,66) likely owes to the lack of renal hilar clamping. If renal hilar clamping is used during hand-assisted laparoscopy partial nephrectomy, and hand-assisted laparoscopy does allow the use of large open surgical bulldog clamps that are helpful, then estimated blood loss should be similar. The other important aspect of partial nephrectomy to consider is final hemostasis and closure of the collecting system. Among the hand-assisted laparoscopy partial nephrectomy series listed in Table 3, laparoscopic suturing was used sparingly. Final hemostasis and collecting system closure were obtained primarily with coagulation devices and biologic sealants. A technique of closure that may be the best among the nonsutured techniques, that being a "patch" of fibrin glue and gelatin sponge (24,26), is best applied using hand-assisted laparoscopy.

Hand-assisted laparoscopy may be better suited to a nonsutured technique of hemostasis and collecting system closure, as some aspects of laparoscopic suturing are awkward with hand-assisted laparoscopy.

Hand-assisted laparoscopy may be better suited to a nonsutured technique of hemostasis and collecting system closure, as some aspects of laparoscopic suturing are awkward with hand-assisted laparoscopy.

Although delayed hemorrhage or urinary leak occurred in only two and six patients, respectively, among the combined 66 patients in Table 3, as larger and deeper renal masses are approached in order to expand the pool of patients benefiting from laparoscopy, the nonsutured methods may prove to be unreliable. In the series of one of the authors (JSW), the hemorrhage/urine leak rate was 41% in 17 cases in which the collecting system and/or renal sinus were entered during laparoscopic partial nephrectomy (compared to 3.4% rate without such entry) when closure was performed

with only fibrin-glue–based products. In 18 subsequent cases in which suture of the collecting system and sutured bolsters of the parenchymal defect were used, the postoperative hemorrhage rate fell to 11%, with no urine leaks. Inasmuch as laparoscopic suturing appears to be useful when resecting larger and deeper masses, and some find hand-assisted laparoscopy suturing of the renal defect awkward, the standard laparoscopic approach may be more attractive in some cases.

In select cases, depending on the anatomical relationship of the mass to the rest of the kidney, the direct manual control of the operative site provided by hand-assisted laparoscopy is of great advantage.

Nephroureterectomy

Landman et al. (34) compared 11 standard transperitoneal laparoscopic and 16 hand-assisted laparoscopy nephroureterectomies. The authors already had extensive prior experience with standard transperitoneal laparoscopic nephroureterectomy. Nonetheless, they found that hand-assisted laparoscopy reduced mean operative time by 72 minutes but did not alter significantly any measure of the intensity and duration of convalescence. The length of hospital stay did tend to be longer in the hand-assisted group, but the difference was not statistically significant (3.3 days vs. 4.5 days).

In a report by Okeke and associates, although the operative time for laparoscopic radical nephrectomy was not improved by hand-assisted laparoscopy, the operative time for nephroureterectomy was reduced by 66 minutes compared to standard laparoscopy.

Donor Nephrectomy

Standard transperitoneal laparoscopic and hand-assisted laparoscopy donor nephrectomy have been compared in six nonrandomized, retrospective series (Table 7) (44–47,50,67). The comparison of standard laparoscopy and hand-assisted laparoscopy is cleanest for this procedure, because candidates for donor nephrectomy are fairly a homogenous group. The results of all six studies have been remarkably similar.

Although recovery parameters were not assessed in a similar fashion, in three of the studies (44,47,67) there tended to be more postoperative narcotic use and/or slightly longer duration of convalescence in the hand-assisted laparoscopy group.

Hand-assisted laparoscopy tends to be faster and associated with shorter warm ischemia time. While there is also a small trend to fewer complications, less frequent conversion to open surgery, and shorter hospital stay, the differences are not clinically significant.

Learning Curve

The first few standard transperitoneal laparoscopic nephrectomies can be very challenging for the novice laparoscopist; operative times and complications are greatest in the first 20 cases (68). Ponsky et al. (69) reported use of one of the hand-assisted laparoscopy devices that can accept a laparoscopic port to simplify the adoption of standard laparoscopic nephrectomy for those already facile in hand-assisted laparoscopy nephrectomy. After insertion of a laparoscopic port within the hand-assisted laparoscopy device, the laparoscope is placed there and the usual working ports are inserted. At any time during the procedure, the laparoscope can be moved to another port to allow use of the surgeon's hand through the hand-assisted laparoscopy device. In this way, a surgeon can perform standard laparoscopy in those first few cases confident in the ability to rapidly convert to hand-assisted laparoscopy when necessary. Series have also documented that the "learning curve" of hand-assisted laparoscopy is shorter than the 20 or so cases that is estimated for standard transperitoneal laparoscopic nephrectomy. Gaston et al. (70), in a prospective survey of senior urology residents trained in open surgical nephrectomy but new to laparoscopy, found that by the fourth procedure residents reported a difficulty level less than that of open surgical nephrectomy. Operating time also decreased with each case, falling to half the duration of the first case by the time of the sixth procedure. Similarly, Wolf et al. (39), in their first 10 hand-assisted laparoscopy donor nephrectomies, found that the mean operative time was reduced from 4.2 hours in the first five patients to 2.9 hours in the second five patients. In a subsequent study, Hollenbeck et al. (71) determined that residents in training performing hand-assisted laparoscopy donor nephrectomy had a statistically and clinically signifi-cant reduction in operating time by the sixth case as primary surgeon.

The decline in hand-assisted laparoscopy operative time with experience is more rapid than has been reported in series of standard laparoscopic nephrectomy.

The decline in hand-assisted laparoscopy operative time with experience is more rapid than has been reported in series of standard laparoscopic nephrectomy.

Overall Comparison

Overall, the published data suggest that hand-assisted laparoscopy is generally faster than standard transperitoneal laparoscopy, but that several factors alter the impact of hand-assisted laparoscopy with regard to operative time.

The intensity and duration of postsurgical recovery appears to be slightly increased by hand-assisted laparoscopy, but the magnitude of the difference between hand-assisted laparoscopy and standard laparoscopy is much less than that between hand-assisted laparoscopy and open surgery. For advanced procedures such as donor nephrectomy, hand-assisted laparoscopy appears to reduce the likelihood of conversion to open surgery.

The benefit of hand-assisted laparoscopy is greater in the setting of more complex procedures (such as nephroureterectomy and donor nephrectomy), but is less when there is extensive prior experience or when compared to retroperitoneoscopy.

SELECTION OF PATIENTS FOR HAND-ASSISTED LAPAROSCOPY

Ultimately, it is the surgeon's decision whether patients should undergo open, standard laparoscopic, or hand-assisted laparoscopic approaches. Generally, hand-assist techniques are favored anytime intact removal of the kidney is indicated, such as nephroureterectomy, donor nephrectomy, and certain large radical nephrectomies (72). Some believe that hand assistance is an approach that is more straightforward for more urologists, making hand-assisted laparoscopy an option whenever a minimally invasive nephrectomy or procedure is feasible.

Unique Factors

Patients with prior peritonitis, or abdominal surgery with postoperative complications that would be expected to worsen abdominal scarring, are the only subgroups in which we distinctly avoid a transperitoneal laparoscopic approach. Interestingly, patients with smaller abdomens, or prior abdominoplasty procedures, tend to be more challenging for hand assistance, because there is less room to work once the surgeon's hand is in the abdomen. These patients may benefit more from standard laparoscopy.

When selecting patients for hand-assisted laparoscopy, several factors play a role. While prior abdominal surgery poses an increased risk in standard laparoscopy, we have found making the hand incision first, gaining safe abdominal access, and then inspecting the insufflated abdomen with the laparoscope and placing ports under endoscopic control to be quite efficient.

In contrast, morbidly obese patients do very well with hand-assisted laparoscopy, as their abdomens are usually capacious, and the significance of the hand incision is much less over an over significant surface area. Finally, cosmesis plays a role in the decision-making. While standard laparoscopy avoids any incision, often more trocar sites are utilized. The hand incision in many patients can be Pfannesteil, and thus cosmetically preferable as there are fewer port sites. However, generally we utilize a midline or lower abdominal location, and thus create an abdominal scar.

In general, the overriding benefit of hand-assisted laparoscopy is the surgeon's confidence in the approach. Many times, a surgeon may opt for a hand-assisted laparoscopy procedure over a standard laparoscopic approach, and visa versa based on technical preference.

Hand-assisted laparoscopy allows shortened operating time, reduced need for conversion, enhanced teaching capability, and ease of control of hemorrhage, all if which benefit the busy clinician.

Preferences by Procedure

For extirpative renal surgery, we generally favor hand-assisted laparoscopy for procedures that require intact specimen extraction (nephroureterectomy and donor nephrectomy) as well as for large radical nephrectomies. Approaches to partial nephrectomy are in flux. For procedures with smaller specimens (adrenalectomy, prostatectomy, and lymph node dissection) and most reconstructive procedures, we prefer either the standard or robotic approaches. Other novel procedures, such as cystectomy and diversion, simultaneous bilateral nephrectomies and nephrectomy for polycystic kidneys, also favor hand-assisted laparoscopy. Regardless, guiding principles of selection for hand-assisted laparoscopy focus on approach (morcellation vs. intact removal), prior history (abdominoplasty and prior operations), body habitus, and surgeon's competence.

The benefit of hand-assisted laparoscopy is greater in the setting of more complex procedures (such as nephroureterectomy and donor nephrectomy), but is less when there is extensive prior experience or when compared to retroperitoneoscopy.

Patients with prior peritonitis, or abdominal surgery with postoperative complications that would be expected to worsen abdominal scarring, are the only subgroups in which we distinctly avoid a transperitoneal laparoscopic approach. Interestingly, patients with smaller abdomens, or prior abdominoplasty procedures, tend to be more challenging for hand assistance, because there is less room to work once the surgeon's hand is in the abdomen. These patients may benefit more from standard laparoscopy.

Hand-assisted laparoscopy allows shortened operating time, reduced need for conversion, enhanced teaching capability, and ease of control of hemorrhage, all if which benefit the busy clinician.

SUMMARY

- ■ Hand-assisted laparoscopy has played a major role in the integration of laparoscopy into the mainstream of urologic practice.
- ■ Overall, the published data suggest that hand-assisted laparoscopy is generally faster than standard transperitoneal laparoscopy.
- ■ The benefit of hand-assisted laparoscopy is greater in the setting of more complex procedures (such as nephroureterectomy and donor nephrectomy), but is less when there is extensive prior experience or when compared to retroperitoneoscopy.
- ■ The intensity and duration of postsurgical recovery appears to be slightly increased by hand-assisted laparoscopy, but the magnitude of the difference between hand-assisted laparoscopy and standard laparoscopy is much less than that between hand-assisted laparoscopy and open surgery.

GASLESS LAPAROSCOPY

Kazuo Suzuki
Department of Urology, Shintoshi Clinic, Iwata, Shizuoka, Japan

> Gasless laparoscopic surgery means performance of operative procedures under video monitoring or direct vision in the abdominal cavity by lifting the abdominal wall.

INTRODUCTION

Gasless laparoscopic surgery means performance of operative procedures under video monitoring or direct vision in the abdominal cavity by lifting the abdominal wall.

Gasless laparoscopy is different from minilaparotomy, in which all procedures are performed with ordinary surgical instruments under direct vision by illumination of the operating field with headlights through a small skin incision.

HISTORY

Cholecystectomy and Gastrointestinal Surgery

In 1991, Gazayerli introduced laparoscopic surgery by the peritoneal planar lifting method with a simple T-shaped retractor for herniorrhaphy and cholecystectomy (1). Strictly speaking, it was not pure gasless surgery because the abdominal wall was lifted as an adjunct to carbon dioxide pneumoperitoneum.

> In 1991, Nagai et al. first performed gasless laparoscopic cholecystectomy by the subcutaneous wire lifting method, a technique for lifting the abdominal wall by using both ends of a Kirschner wire that was inserted subcutaneously.

In 1991, Nagai et al. first performed gasless laparoscopic cholecystectomy by the subcutaneous wire lifting method, a technique for lifting the abdominal wall by using both ends of a Kirschner wire that was inserted subcutaneously (2).

Abdominal wall lifting methods that employed various wires were subsequently developed in Japan (3,4). In the United States, laparoscopic surgery by the peritoneal planar lifting method (Laparolift™a) was performed from around 1993 (5–7). In 1999, Sampietro developed a unique method for lifting the whole abdominal wall and used it to perform gasless laparoscopic surgery in Italy (8).

Subsequently, carbon dioxide pneumoperitoneum has become the mainstream mode of laparoscopic surgery because of its technical simplicity and ability to provide a wide operating space. Previously, gasless laparoscopic surgery was routinely used in restricted hospitals and was used for patients with serious cardiopulmonary complications at most medical institutions. However, hand-assisted laparoscopic surgery has recently been used for technically demanding procedures such as distal gastrectomy and colorectal surgery.

> When combined with minilaparotomy, gasless laparoscopic surgery allows surgeons to perform an operation via a small incision under direct vision and still insert a hand easily.

When combined with minilaparotomy, gasless laparoscopic surgery allows surgeons to perform an operation via a small incision under direct vision and still insert a hand easily.

Recent studies have demonstrated the utility of minilaparotomy or hand-assisted gasless laparoscopic surgery for distal gastrectomy with D2 lymph node dissection (9,10), as well as gasless laparoscopic surgery combined with minilaparotomy or transanal excision for colorectal cancer (11–15).

---

aOrigin Medsystems, Inc., San Francisco, CA, currently unavailable.

It has also been reported that low-pressure laparoscopic surgery with abdominal wall lifting is useful for patients with cardiopulmonary dysfunction, advanced obesity, and pregnant women (16–19). Alijani and Cuschieri reported that such surgery was useful for high-risk patients because the addition of abdominal wall lifting gave surgeons a sufficient operating space at a pneumoperitoneum pressure as low as 3 to 4 mmHg and minimized the adverse effects of carbon dioxide pneumoperitoneum (17).

The clinical practice guidelines on pneumoperitoneum for laparoscopic surgery released by the European Association for Endoscopic Surgery also recommend that abdominal wall lifting should be combined with low-pressure pneumoperitoneum in patients who have cardiopulmonary dysfunction (20).

Neck Surgery

Laparoscopic surgery for thyroid and parathyroid diseases involves subcutaneous insufflation of carbon dioxide gas, which causes a problem with gas absorption. Shimizu et al. developed video-assisted thyroid lobectomy with subcutaneous wire lifting in 1998 (21). Subsequently, gasless video-assisted neck surgery has become popular for thyroid adenoma, thyroid cancer, and parathyroid adenoma because it is a less invasive, aesthetically excellent technique without the adverse effects of carbon dioxide (22–24).

Gynecology

Since about 1994, gasless laparoscopic surgery has been applied in the field of gynecology to treat ovarian tumors and uterine myoma (25,26). Gasless laparoscopic methods have also been used for gynecologic surgery via a transvaginal approach because the abdominal wall lifting extends the surgical field and it is therefore unnecessary to care about the leakage of carbon dioxide (27,28).

Urology

Etwaru et al. reported pelvic lymph node dissection by the peritoneal planar lifting method using the Laparolift[®b] in 1994 (29).

Hirsch et al. performed gasless laparoscopic surgery for renal biopsy, varicocelectomy, and pelvic lymph node dissection, reporting that it was useful for renal biopsy and varicocelectomy via the retroperitoneal approach, but was not appropriate for pelvic lymph node dissection because of poor field of view (30). After reviewing additional patients, they reported that gasless laparoscopic surgery only provided a limited field of view, and that new abdominal wall lifting devices were needed (31).

In 1994, Suzuki et al. proposed gasless laparoscopy-assisted radical nephrectomy, in which a small skin incision was first created to remove the renal cancer en bloc and then a planar lifting retractor was inserted through the incision to lift the abdominal wall (32,33).

In the author's experience, gasless laparoscopic surgery combined with the small skin incision was advantageous because there was no need for carbon dioxide pneumoperitoneum, the renal arteries and veins could be safely dissected under direct vision, and the patient could be immediately switched to open surgery if serious complications occurred such as massive bleeding.

The concept of gasless laparoscopy-assisted radical nephrectomy was subsequently extended to gasless laparoscopy-assisted live donor nephrectomy.

Gasless laparoscopic surgery has also been used for Burch bladder neck suspension. Flax performed gasless extraperitoneal laparoscopic Burch bladder neck suspension in 47 patients with Type 2 stress incontinence, and reported that it was necessary to switch to open surgery in three patients (6%), but that previous multiple operations and obesity were not contraindications to the technique (34).

In addition, some Japanese reports have been published on gasless laparoscopic adrenalectomy and partial nephrectomy (35–38).

Live Donor Nephrectomy

Gasless laparoscopic surgery has also been applied to live donor nephrectomy to avoid the effect of carbon dioxide pneumoperitoneum on the kidneys. Yang et al. reported on the performance of minilaparotomy-assisted laparoscopic nephrectomy via the retroperitoneal approach, although they did not state any details of the technique, such as blood loss (39,40). Subsequently, they performed laparoscopy-assisted live donor nephrectomy

The clinical practice guidelines on pneumoperitoneum for laparoscopic surgery released by the European Association for Endoscopic Surgery also recommend that abdominal wall lifting should be combined with low-pressure pneumoperitoneum in patients who have cardiopulmonary dysfunction.

Etwaru et al. reported pelvic lymph node dissection by the peritoneal planar lifting method using the Laparolift® in 1994.

In the author's experience, gasless laparoscopic surgery combined with the small skin incision was advantageous because there was no need for carbon dioxide pneumoperitoneum, the renal arteries and veins could be safely dissected under direct vision, and the patient could be immediately switched to open surgery if serious complications occurred such as massive bleeding.

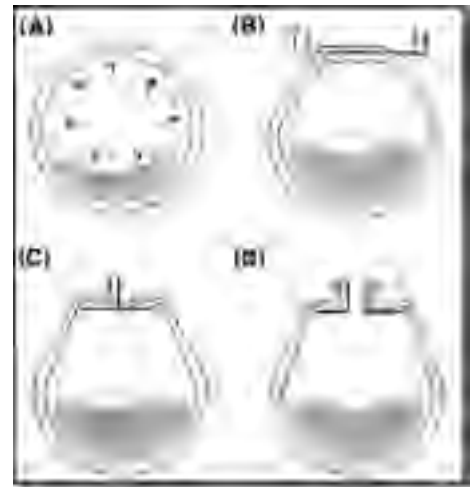
FIGURE 1 ■ Extension of the working space by carbon dioxide pneumoperitoneum and various lifting techniques. **(A)** Carbon dioxide pneumoperitoneum. **(B)** Subcutaneous wire lifting. **(C)** Peritoneal planar lifting. **(D)** Peritoneal planar lifting with minilaparotomy.


in 103 patients with improved retractors and techniques, and reported satisfactory results, with a mean operating time of 130 minutes and blood loss of 100 mL (41).

Suzuki et al. also reported on retroperitoneal laparoscopy-assisted live donor nephrectomy using the abdominal wall lifting method in 1997 (42). Subsequently, they introduced various improvements to reduce the operating time, and concluded that gasless retroperitoneoscopy-assisted live donor nephrectomy was an effective procedure (43).

Advantages of Gasless Retroperitoneoscopic Live Donor Nephrectomy

■ It does not have any adverse effects on cardiopulmonary function and renal blood flow because there is no carbon dioxide pneumoperitoneum.
■ The extraperitoneal approach may be employed.
■ Surgeons can safely dissect the renal vessels under direct vision.
■ The patient can be quickly switched to open surgery by extending the small incision.

Disadvantages of Gasless Retroperitoneoscopic Live Donor Nephrectomy

■ A relatively limited visualization of the operative field.
■ The lifting device may interfere with the use of forceps.
■ Strong traction on the small incision may increase postoperative wound pain (44).

EQUIPMENT AND TECHNIQUE

Gasless laparoscopy creates a working space in the abdominal cavity by lifting the abdominal wall instead of using carbon dioxide. To lift the abdominal wall, the following three methods are available; subcutaneous wire lifting in which a thin steel wire is passed subcutaneously to lift the abdominal wall; peritoneal planar lifting in which by a retractor is inserted into the abdominal cavity to lift the whole abdominal wall; and abdominal wall lifting in which the abdominal wall is lifted by a retractor inserted through a small skin incision (Fig. 1A–D).

Further, gasless laparoscopic surgery can be performed by the following techniques: a pure laparoscopic procedure in which several ports are placed after the abdominal wall is lifted and all surgical procedures are done under video monitoring; gasless laparoscopic minilaparotomy in which abdominal wall lifting is combined with a small skin incision to allow surgery under direct vision; hand-assisted surgery in which one hand of the surgeon is inserted through a small skin incision; and a combination of minilaparotomy and hand-assisted surgery.

Lifting devices for subcutaneous wire lifting that were developed by Nagai et al. and Hashimoto et al. are commercially available in Japan[c] (Fig. 2A and B). The abdominal wall is lifted with a subcutaneous steel wire to create a working space in the peritoneal cavity. Because the space created is relatively small, this method requires some skill when it is used in obese patients or for technically difficult operations.

FIGURE 3 ■ Peritoneal planar lifting device: VarioLift.

However, technically easier operations such as cholecystectomy can be performed as a pure laparoscopic procedure without minilaparotomy.

A device for lifting the whole abdominal wall (Laparofan, Laparolift) was used in Western countries since around 1993, but is no longer being manufactured. The currently available device for peritoneal planar lifting is known as the VarioLift™[d] (Fig. 3).

Peritoneal planar lifting provides a slightly larger working space than the subcutaneous wire method because it raises the whole abdominal wall. However, a Japanese multicenter clinical study compared the peritoneal planar lifting with subcutaneous wire lifting and found that C-reactive protein was significantly increased in the peritoneal planar group postoperatively. This indicates that the peritoneal planar lifting may have a stronger effect on the peritoneum and abdominal wall muscles (45).

Yang et al. developed a mechanical retractor for video-assisted minilaparotomy live donor nephrectomy[e] (Fig. 4). This device requires the insertion of several retractors into the retroperitoneum and a working space created by pulling on the retractors. This technique is generally used under direct vision in live donor nephrectomy. Suzuki et al. have performed hand-assisted, live donor nephrectomy by lifting the abdominal wall with retractors inserted into the retroperitoneum[f] to allow insertion of the

surgeon's hand (Fig. 5). The kidney and ureter are dissected with a hand-assisted technique under video monitoring, while the renal pedicle is managed under direct vision for safety.

GASLESS VS. PNEUMOPERITONEUM

Basic Research

Many basic studies have compared gasless laparoscopic surgery and laparoscopic surgery using pneumoperitoneum in terms of invasiveness and effects on the patient.

Gasless surgery without carbon dioxide pneumoperitoneum is not associated with compression of the inferior vena cava and intestinal vessels, elevation of the diaphragm, and absorption of carbon dioxide gas into the blood. Therefore, the gasless laparoscopic surgery is superior with regard to the effects on hemodynamics and respiratory function (46–48).

The results with respect to several points other than cardiopulmonary effects are described here.

Tumor Seeding, Abdominal Wall and Port Metastases

In 1996, Bouvy et al. reported striking experimental results on tumor seeding and abdominal wall metastases in the *Annals of Surgery* (49). Using rats divided into three experimental groups (carbon dioxide pneumoperitoneum, gasless laparoscopy, and conventional laparotomy groups), they obtained the following results: (i) direct contact between a solid tumor and the port led to an increase of local tumor seeding, (ii) laparoscopy is associated with less intraperitoneal tumor seeding than laparotomy, and (iii) insufflation of carbon dioxide promotes peritoneal tumor seeding and is associated with more abdominal wall metastases than gasless laparoscopy. In response to their results, many other authors have reported data on the relationship between carbon dioxide pneumoperitoneum and tumor cell growth or port metastasis.

It has often been reported that the spread of tumor cells in the abdominal cavity and port metastasis is not due to carbon dioxide gas per se, but arises from widespread tumor cell dissemination and implantation caused by the aspiration or insufflation of gas into the abdominal cavity (50–56). However, port site metastases are considered to result from direct contact between the tumor and port when removing the lesion because these metastases have also been frequently reported after thoracoscopic surgery without carbon dioxide gas insufflation (57,58). In any case, it seems true that insufflating gas at a high pressure and desufflating it increases the risk of tumor cell dissemination to the peritoneum and intraabdominal organs.

Bouvy et al. also reported that carbon dioxide pneumoperitoneum stimulates tumor growth (49). Many subsequent studies have investigated the mechanism of tumor growth associated with pneumoperitoneum. Previously, it was considered that carbon dioxide pneumoperitoneum itself might play a role as a carbon dioxide incubator.

Tumor growth may be attributable not to carbon dioxide gas, but to reduced blood flow in the peritoneum, liver, and renal cortex secondary to high-pressure pneumoperitoneum (59–64).

Immune Response

Several studies have compared immune response between pneumoperitoneum and gasless laparoscopic surgery. Animal experiments have shown the following results: (i) carbon dioxide pneumoperitoneum reduces the activity of T lymphocytes (65); (ii) it reduces the intraperitoneal pH, which decreases macrophage activity and lowers the production of interferon-α (66); and (iii) it reduces splenic and hepatic natural killer cell activity (67). However, clinical data remain controversial: one study showed that carbon dioxide pneumoperitoneum reduced immunocompetence compared with gasless laparoscopic surgery (68), while another found no difference in immunocompetence between the two techniques (69). Buunen et al. (70) reviewed the effect of carbon dioxide pneumoperitoneum on immunocompetence and stated that local (i.e., peritoneal) immune function was affected, but the production of tumor necrosis factor and the phagocytotic capacity of peritoneal macrophages were less impaired. In addition, the systemic stress response, as determined from the delayed-type hypersensitivity response and leukocyte antigen expression by lymphocytes, is preserved after laparoscopic surgery, but is weaker than after conventional surgery. The authors concluded

---

Gasless surgery without carbon dioxide pneumoperitoneum is not associated with compression of the inferior vena cava and intestinal vessels, elevation of the diaphragm, and absorption of carbon dioxide gas into the blood. Therefore, the gasless laparoscopic surgery is superior with regard to the effects on hemodynamics and respiratory function.

Tumor growth may be attributable not to carbon dioxide gas, but to reduced blood flow in the peritoneum, liver, and renal cortex secondary to high-pressure pneumoperitoneum.

that intraperitoneal carbon dioxide insufflation attenuates peritoneal immunity, but laparoscopic surgery is associated with less systemic stress than open surgery.

Renal Function

In 1996, Chiu et al. reported that carbon dioxide pneumoperitoneum reduced the urine output and induced electrolyte abnormalities (71). Subsequent investigations showed that the urine output was reduced because pneumoperitoneum compressed the kidneys, thereby reducing blood flow in the renal cortex (72,73).

Reduction of pneumoperitoneum pressure, should be applied in patients with renal dysfunction or those receiving treatment with angiotensin IIreceptor 1 blockers or angiotensin converting enzyme inhibitors (74,75).

The effect on renal function of live donor nephrectomy with carbon dioxide pneumoperitoneum has been often reported as well. From the results of animal studies, Hazebroek et al. reported that pneumoperitoneum caused transient renal dysfunction, but had little effect on the kidney after transplantation (76–78). Abreu et al. reviewed 100 consecutive cases of laparoscopic live donor nephrectomy and concluded that carbon dioxide pneumoperitoneum had no effect on post-transplant kidney function (79).

Miscellaneous Effects

Other studies have revealed the following results: gasless laparoscopic surgery had less effect on respiratory function and causes fewer postoperative adhesions because of lower peritoneal oxidative stress than carbon dioxide pneumoperitoneum (80,81); gasless laparoscopic surgery does not stimulate bacterial growth (82); and gasless laparoscopic surgery is more appropriate for patients with head injury because it does not increase intracranial pressure (83,84).

Clinical Studies

Since 1996, a number of randomized controlled trials have been performed to compare abdominal wall lifting with carbon dioxide pneumoperitoneum. Gasless laparoscopic surgery had less effect on cardiopulmonary function than pneumoperitoneum.

Major studies on laparoscopic cholecystectomy are listed in Table 1 (45,85–90). Most investigators have reported that gasless laparoscopic surgery provides a small working space and is more technically difficult and time consuming. However, some investigators have found that the difference in operating time compared with pneumoperitoneum becomes negligible as surgeons increase their familiarity with the technique.

Several studies have revealed that gasless laparoscopic surgery is comparable to or better than pneumoperitoneum with respect to postoperative recovery. Some randomized trials have indicated that gasless laparoscopic surgery has less effect on neuroendocrine or hepatic function (91,92).

The randomized controlled trials performed in obstetrics and gynecology patients provided slightly different results from those on cholecystectomy patients (93–97). Many authors have concluded that gasless laparoscopic surgery was most appropriate for patients with serious cardiopulmonary dysfunction because it had little effect on cardiopulmonary function, but that it would be necessary to improve the lifting devices before gasless surgery became popular because it only provided a small working space, was more technically difficult, and often had to be switched to carbon dioxide pneumoperitoneum.

Reduction of pneumoperitoneum pressure, should be applied in patients with renal dysfunction or those receiving treatment with angiotensin II receptor 1 blockers or angiotensin converting enzyme inhibitors.

Gasless laparoscopic surgery had less effect on cardiopulmonary function than pneumoperitoneum.

Several studies have revealed that gasless laparoscopic surgery is comparable to or better than pneumoperitoneum with respect to postoperative recovery. Some randomized trials have indicated that gasless laparoscopic surgery has less effect on neuroendocrine or hepatic function.

TABLE 1 ■ Comparison of Gasless Laparoscopic Cholecystectomy with Pneumoperitoneum

Author	No. of pts.	Adverse effects (cardiopulmonary)	Surgical procedure	Operative time	Convalescence
Nagai H (85)[a]	144	–	–	Same	Same
Koivusalo AM	26	Low	–	–	Fast

SUMMARY

- Deaths that are not directly associated with laparoscopic surgery, but are caused by carbon dioxide pneumoperitoneum (gas embolism or splanchnic vessel thrombosis) have been reported (98–100).
- Sternberg et al. stated that gasless or low-pressure laparoscopic surgery should be considered for patients with preoperative impairment of splanchnic blood flow and/or a hypercoagulable state (98). Gasless laparoscopic surgery is valuable as a less invasive technique for patients with serious cardiopulmonary dysfunction.
- We have performed laparoscopic surgery in about 720 patients at our institution. Gasless minilaparotomy (three radical nephrectomies and one adrenalectomy) was necessary in four patients with serious cardiopulmonary dysfunction contraindicating.
- Gasless laparoscopic surgery has the major merit of little influence on cardiopulmonary function, but has the demerit that it only provides a small working space, particularly when the access site is blocked by the intestines or not.
- Gasless laparoscopic surgery is considered to be more appropriate for surgery at sites that are not severely obstructed by the intestines, such as cholecystectomy, partial hepatectomy, oophorectomy, and adrenalectomy.
- Gasless laparoscopy-assisted minilaparotomy may be useful for technically demanding operations on malignant tumors. Surgeons who aim to be an expert at laparoscopic surgery should master various techniques and approaches, and then select the most appropriate method for each tumor and patient. Abdominal wall lifting may be an option for laparoscopic surgery.

LAPAROSCOPY: DEVELOPING TECHNIQUES

THORACOSCOPIC TRANSDIAPHRAGMATIC ADRENALECTOMY

Massimiliano Spaliviero and Anoop M. Meraney

Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

Many endocrine disorders of the adrenal gland, including primary aldosteronism, Cushing's syndrome, and pheochromocytoma and malignant adrenal disease may be treated surgically with adrenalectomy (1). The large abdominal skin incision employed in past decades to achieve the large open surgical exposure—mandatory to perform adrenal surgery—was dictated by the anatomic characteristics of the adrenal, namely its retroperitoneal high location, small size, friability, and abundant delicate vascularity. For the same very anatomic reasons, minimally invasive approaches, including laparoscopic adrenalectomy, have found rather dramatic application in the field of adrenal surgery since their first description in the early 1990s by Gagner et al. (2)

Laparoscopic adrenalectomy has achieved established status and is increasingly performed at many institutions worldwide in the majority of patients with benign surgical adrenal disease (3).

Although open surgery remains the technique of choice in patients with primary adrenal cancer, the laparoscopic radical dissection of a small, organ confined, solitary adrenal metastasis or primary adrenal carcinoma is associated with acceptable oncological outcomes (4).

Laparoscopic adrenalectomy can be performed either transperitoneally (5) or retroperitoneally (6), and 2 mm needlescopic instruments and optics may be utilized to further minimize the morbidity of conventional laparoscopic adrenalectomy (5).

> Laparoscopic adrenalectomy has achieved established status and is increasingly performed at many institutions worldwide in the majority of patients with benign surgical adrenal disease.

CURRENT INDICATIONS AND CONTRAINDICATIONS OF LAPAROSCOPIC ADRENALECTOMY

Laparoscopic adrenalectomy has become the gold standard approach for the treatment of select patients with aldosteroma, pheochromocytoma, Cushing's disease, nonfunctioning adenoma, and rarely, adrenal cyst or myelolipoma. Laparoscopic radical adrenalectomy for primary or metastatic malignancy, has been reported (4).

Unacceptable cardiopulmonary risk, uncorrected coagulopathy, abdominal sepsis, and bowel obstruction represent general contraindications for laparoscopy. Laparoscopic adrenalectomy is currently contraindicated for the treatment of a large adrenocortical carcinoma with local periadrenal invasion or venous thrombus. Morbid obesity is no longer a contraindication to laparoscopic adrenalectomy (7,8).

TRANSTHORACIC LAPAROSCOPY: EXPERIMENTAL AND CLINICAL DATA

After its first description in the 1920s, thoracoscopy was initially employed as a purely diagnostic tool and, subsequently, as a complex therapeutic procedure for the treatment of pulmonary, mediastinal, spinal, esophageal, and cardiac diseases (9–11).

The first thoracoscopic transdiaphragmatic incisional biopsy of the left adrenal gland was performed by Mack et al. in 1992 (12).

Experimental Data

The porcine model was used by Pompeo et al. to describe transthoracic (TT) left adrenalectomy in 1997 (13). After inserting four 10-mm laparoscopic trocars into the left pleural cavity, left pneumothorax was created insufflating CO_2 at a mean pressure of 10 mmHg. A 6-cm phrenotomy was performed starting from the lateral side of the aorta and retroperitoneal space entry was achieved. Carbon dioxide–induced positive intrapleural pressure facilitated this maneuver. After Gerota's fascia opening and gentle spleen retraction, the adrenal gland was identified and dissected downward. Endoscopic clips were used to control small tributary vessels, which were subsequently divided. Blunt dissection was used to free the inferior pole of the adrenal gland from the renal vein until the main adrenal vein was identified, clipped, and divided. The specimen was retrieved through one of the trocars. Adequate hemostasis was secured and phrenotomy repaired with running nonabsorbable suture placed with endosuture technique. Laparoscopic exit was performed after reexpansion of the ipsilateral lung. Mean operative time was 2.75 hours, mean blood loss was 76 cc. Complications included splenic injury in one pig and difficult diaphragmatic repair in another. However, all the procedures ($n = 5$) were successfully completed. Endoscopic suturing or staples were used to perform thoracoscopic repair of the diaphragmatic incision (13,14).

In 2000, Meraney et al. performed the first thoracoscopic transdiaphragmatic bilateral nephrectomy in an acute porcine model (15). In their study, three ports were used to gain thoracic access and the retroperitoneum was accessed through a diaphragmatic incision. Feasibility of individual control of the renal artery and vein, and circumferential mobilization of the kidney was assessed. Acceptable intraoperative arterial blood gas parameters were maintained in all procedures. The spleen during left-sided nephrectomy, and the liver during right-sided nephrectomy, respectively, were adequately retracted using a TT 10 mm fan retractor. Mean diaphragmatic incision was 7.2 cm. Diaphragm repair was performed placing continuous sutures. Perioperative results showed mean surgical time of 69.3 minutes for left nephrectomy ($n = 4$) and 74.3 minutes for right nephrectomy ($n = 4$), and a mean blood loss of 18.7 cc.

Based on the encouraging results of the porcine study (10), Gill et al. developed and refined the technique for thoracoscopic nephrectomy and extrapolated the approach to adrenal surgery in human cadavers (16). Four human cadavers underwent bilateral thoracoscopic transdiaphragmatic nephrectomy (Table 1).

After access and development of the retroperitoneal space, individual control of the renal artery and vein was feasible in all eight procedures. However, the necessary exposure was achieved only after performing considerable TT retraction of the liver or spleen despite the lateral position in which all the cadavers were placed. Left nephrectomy and right nephrectomy required a mean surgical time of 64.3 minutes and of 82.5 minutes,

TABLE 1 ■ Thoracoscopic Transdiaphragmatic Nephrectomy: Human Cadaver Study

Variables	Left nephrectomy (range)	Right nephrectomy (range)
No. subjects	4	4
Mean surgical time (min)	64.3 (54–76)	82.5 (72–90)
Individual steps (min):		
Diaphragmatic incision	11 (10-13)	11.5 (10-13)
Hilar dissection	26.2 (24–31)	31 (29–36)
Renal vessel control	10.2 (9–11)	13 (11–15)
Diaphragmatic repair	19.2 (16–23)	22.2 (20–25)
Diaphragmatic incision length (cm)	10 (8–12)	9.5 (8–12)
No. inadvertent celiotomy	1	1
Ureteral length (cm)	5.6 (3.5–8)	3.9 (3–4.5)

Source: From Ref. 16.

respectively. Approximately half an hour was necessary to perform hilar dissection on either side, with no injury occurring to the renal vessels. Specimen mobilization resulted in inadvertent peritoneotomy in two instances. However, intraoperative exposure was not compromised by such events. No inadvertent injury to adjacent organs occurred. Suture repair of a mean diaphragmatic incision of 10 cm could be performed adequately.

Clinical Data

The best approach to esophagectomy for benign or malignant disease is still controversial. However, TT and blunt transhiatal esophagectomy remain the two most frequently performed procedures. Safety and feasibility of laparoscopic transhiatal total esophagectomy, and combined thoracoscopic and laparoscopic total esophagectomy assessed by many authors have been confirmed by Nguyen et al. who compared these two procedures with conventional esophagectomy (17,18). In the authors' opinion, the main advantages of thoracoscopy, used for mobilization of the intrathoracic esophagus, included better visualization for nodal clearance, prevention of injury to mediastinal structures during esophageal dissection, and lesser intraoperative blood loss.

The TT approach may be favorable also for the repair of bilateral Morgagni hernia, and for lysis of pericardial adhesions and avoiding complications due to uncontrolled transabdominal dissection of pericardial adhesions. This technique results in shorter hospital stay, lesser postoperative pain, and better cosmetic result (19).

Video-assisted thoracoscopy may be employed to perform radical esophagectomy with three-field lymphadenectomy. In fact, pulmonary function may be better preserved and quality of life improved while achieving equivalent long-term survival (20).

THORACOSCOPIC TRANSDIAPHRAGMATIC ADRENALECTOMY: PATIENT SELECTION

Although a history of major open abdominal surgery is no longer a contraindication to transabdominal laparoscopic adrenalectomy, significant technical difficulty may be encountered in patients with such a history. In fact, the presence of extensive adhesions might preclude transperitoneal laparoscopy in these patients. In these cases, the virgin retroperitoneal space may be directly and successfully accessed using retroperitoneal laparoscopy (6,21). Nevertheless, neither the transperitoneal nor the retroperitoneal laparoscopic approach may be confidently employed in the occasional patient who has had both the transperitoneal and the retroperitoneal spaces already violated by open surgery. An ipsilateral radical, total or partial nephrectomy through an extraperitoneal 11th rib incision, followed by a subsequent staged contralateral renal or adrenal procedure through a transperitoneal Chevron incision for bilateral renal carcinoma or benign end-stage disease, may result in the clinical situation described above in the occasional patient presenting with a metachronous solitary adrenal lesion. The adrenal gland is located high in the retroperitoneum in close juxtaposition to the undersurface of the diaphragm. Thus, TT transdiaphragmatic laparoscopy performed through the virgin thoracic cavity may represent an attractive minimally invasive approach to reach the adrenal gland in such select circumstances.

Gill et al. performed the first thoracoscopic transdiaphragmatic adrenalectomy in three patients (right side two, left side one) (16).

Thoracoscopic transdiaphragmatic right adrenalectomy was performed in a 62-year-old male with a new 3.5 cm irregular, heterogeneous right adrenal mass suspicious for metachronous adrenal metastasis. Prior dense transperitoneal and retroperitoneal postoperative adhesions precluded use of transabdominal laparoscopy. The mass was revealed by abdominal computerized tomography obtained during follow-up after open right radical nephrectomy for cancer performed through an extraperitoneal 11th rib incision and followed by staged open left adrenalectomy through a Chevron incision for adrenal metastasis. In another patient, a 64-year-old male, a 2.4 cm, right adrenal mass suggestive of solitary metachronous adrenal metastasis was identified during follow-up of right partial nephrectomy for cancer through an extraperitoneal 11th rib incision, left radical nephrectomy for cancer through a Chevron incision, open cholecystectomy, and appendectomy. This patient underwent thoracoscopic transdiaphragmatic right adrenalectomy. Finally, a 20-year-old female on hemodialysis who had previously undergone bilateral open nephrectomy for renal failure due to end-stage hypertensive nephropathy, presented with persistent intractable hypertension (resistant to 4 antihypertensive medications) for two years after nephrectomy. Biochemical evaluation of the patient revealed moderately increased dopamine (level = 61 mg/mL; normal, 0–20), and normal plasma

Gill et al. performed the first thoracoscopic transdiaphragmatic adrenalectomy in three patients (right side two, left side one).

FIGURE 1 ■ Abdominal computed tomography scan showing left adrenal mass. *Source*: From Ref. 16.

epinephrine, norepinephrine, and aldosterone, and normal urinary metanephrine, normetanephrine, and vanillylmandelic acid levels. A left adrenal mass increasing in size (from 2.8 to 3 cm) was noted on serial abdominal computed tomography (Fig. 1). The patient underwent thoracoscopic transdiaphragmatic left adrenalectomy.

SURGICAL TECHNIQUE

Patient Preparation and Positioning

Trocar placement can be preoperatively planned with the useful aid of 3-dimensional computed tomography reconstruction of the adrenal gland with vector projection.

> Trocar placement can be preoperatively planned with the useful aid of 3-dimensional computed tomography reconstruction of the adrenal gland with vector projection.

Double lumen endotracheal intubation is performed to obtain general anesthesia. The ipsilateral lung is not inflated and absence of breath sounds in the ipsilateral hemithorax is confirmed by auscultation. After positioning the patient prone on a radiolucent spinal frame table, respiratory excursions of the anterior abdominal wall should be left unrestricted (Fig. 2). Patient's arms are adducted. Preparation and draping of the back should be wide and extending beyond the anterior axillary line on both sides.

Step 1: Laparoscopic Entry

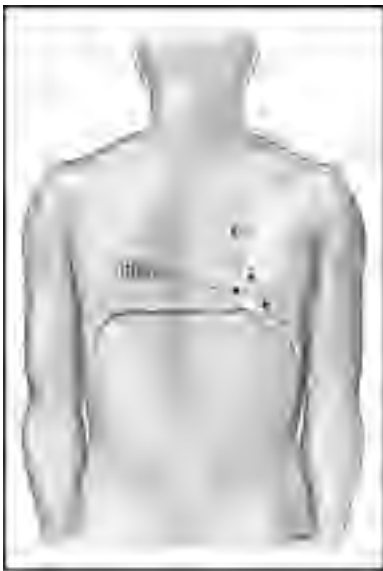
TT approach is performed using four valveless, 12 mm ports (Fig. 3). A 1.5 cm transverse incision is made directly over the underlying seventh rib and the initial port is inserted in the intercostal space at the junction of the posterior axillary line and seventh rib. The incision is bluntly deepened using a Kelly clamp until the rib surface is reached. In the same blunt manner, dissection is then continued immediately along the superior edge of the rib, and blunt entry into the pleural cavity is gained. Careful blunt dissection prevents iatrogenic injury to the intercostal neurovascular bundle or lung. A 10 mm 30° laparoscope inserted through the 10 to 12 mm blunt tipped port is used to inspect the thoracic cavity. Ample working space in the ipsilateral hemithorax is achieved using the double lumen endotracheal tube, which allows the collapse of the ipsilateral lung (Fig. 4A). Active


FIGURE 3 ■ Port placement. *Source*: From Ref. 16.

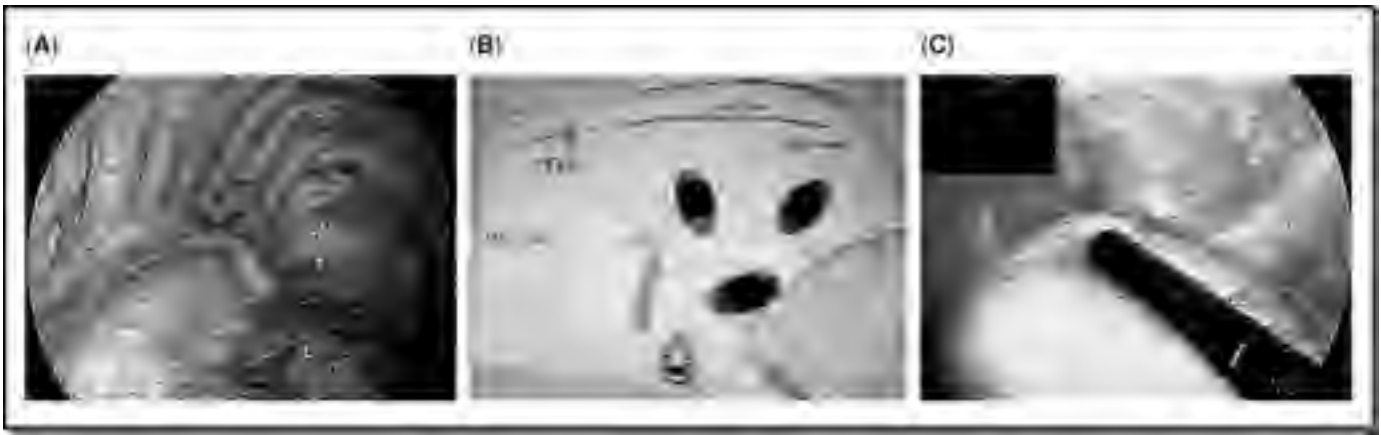
FIGURE 2 ■ Patient positioning. *Source*: From Ref. 16.


FIGURE 4 ■ Laparoscopic entry and secondary port placement. (See text for details.) *Source*: From Ref. 16.

retraction, creation of pneumothorax, or CO_2 insufflation is not necessary because the ipsilateral lung falls out of view spontaneously due to lung deflation and the prone position of the patient.

Step 2: Placement of Secondary Ports
Secondary ports are inserted under laparoscopic guidance and include one 10 mm port in the fifth intercostal space along the anterior axillary line, one 5 mm trocar in the eighth intercostal space along the mid axillary line, and one 5 mm port in the eighth intercostal space approximately 5 cm behind the posterior axillary line.

Step 3: Intraoperative Ultrasound
After securing three secondary ports (Fig. 4B), real-time ultrasound is performed using a flexible, steerable color Doppler ultrasound probe inserted through a lateral port and positioned directly on the pleural surface of the hemidiaphragm. Intraoperative ultrasound allows the precise localization of the adrenal mass on the abdominal side of the diaphragm (Fig. 4C) and its location relative to the adjacent anatomical structures, including the edge of the liver and inferior vena cava on the right side (Fig. 5A), or the edge of the spleen and aorta on the left side. The proposed incision site is radially scored on the thoracic surface of the diaphragm with electrocautery (Fig. 5B). Confirmation of accuracy of the location of the proposed line of diaphragmatic incision directly over the adrenal mass is obtained by repeat ultrasonography (Fig. 5C).

Step 4: Incision of the Diaphragm
Using the ultrasound, the supradiaphragmatic inferior vena cava and aorta are clearly identified and avoided. A 6- to 7 cm, full thickness incision is made through the diaphragm muscular wall using an electrosurgical J-hook to maintain complete hemostasis. The diaphragmatic incision, performed posteriorly in a curvilinear fashion, may be extended as necessary to better expose the adrenal gland. However, a distance of at least 2 cm from the chest wall should be maintained.

Step 5: Access to Retroperitoneum
The full thickness incision of the diaphragm exposes the retroperitoneal fat surrounding the adrenal gland, along with the surface of the liver or spleen on the right or left side, respectively (Fig. 5D). The retroperitoneal fat and fibers of the psoas muscle are visualized along the posterior aspect of the operative field.

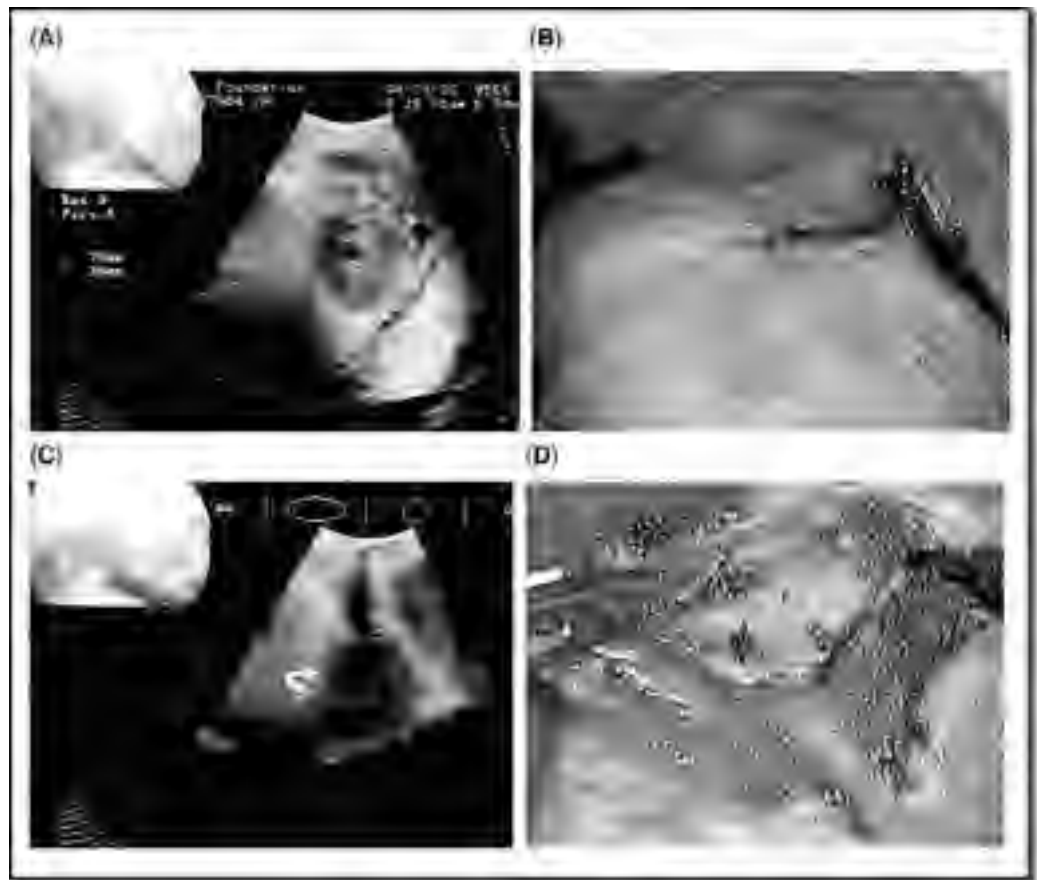
Step 6: Adrenalectomy
The superomedial and superolateral aspects of the adrenal gland are mobilized slowly and in a deliberate manner using an electrosurgical J-hook to ensure meticulous hemostasis, which is critical at all times (Fig. 6A). The inferior phrenic vessels are controlled. During right adrenalectomy, the main right adrenal vein is visualized when performing the dissection between the adrenal gland and inferior vena cava. The main right adrenal vein is secured and precisely transected with an articulating 30 mm cartridge Endo-GIA stapler (vascular). The adrenal gland is completely freed


FIGURE 5 ■ Intraoperative ultrasound. (See text for details.) *Source*: From Ref. 16.

by continuing the dissection caudal, and clipping and dividing multiple adrenal branches arising from the renal hilum. On the left side, the longer, obliquely oriented left main adrenal vein is identified along the inferior–medial aspect of the adrenal gland. After the left main adrenal vein is secured with an Endo-GIA stapler, the adrenal gland is completely freed and is retrieved into the thoracic cavity. The specimen is then entrapped in an Endo Catch bag, and extracted intact through a port site. After confirming hemostasis, the adrenal bed may be filled with a thrombin soaked absorbable hemostatic agent.

Step 7: Closure of the Diaphragmatic Incision

The diaphragm is suture repaired in an airtight manner with a running locking 2-0 polyglactin suture on a computed tomography-1 needle with freehand laparoscopic suturing and intracorporeal knot tying techniques (Fig. 6B).

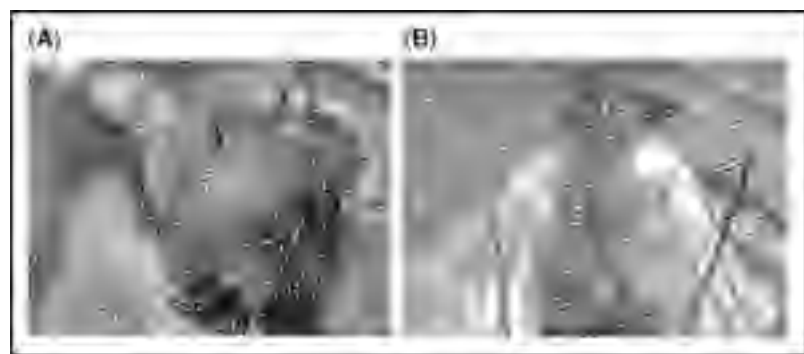
The diaphragm is suture repaired in an airtight manner with a running locking 2-0 polyglactin suture on a computed tomography-1 needle with freehand laparoscopic suturing and intracorporeal knot tying techniques.


FIGURE 6 ■ The adrenalectomy. (See text for details.) *Source*: From Ref. 16.

Hemostasis is confirmed, and the pleural cavity is thoroughly irrigated and cleansed.

Step 8: Laparoscopic Exit

Port removal is performed under thoracoscopic visualization. A 34-French chest tube may be inserted through a lateral port and attached to water seal suction. A figure-of-8 2-0 polyglactin suture in the intercostal muscles is used to close the port sites. After unclamping the double lumen endotracheal tube and maintaining the ipsilateral lung fully inhaled and expanded, each knot is tied down. Skin closure is achieved using 4-0 polyglactin subcuticular sutures.

RESULTS

TT approach for adrenalectomy may represent a unique minimally invasive option for the rare patient with adrenal pathology and concomitant scarring of the intraperitoneal and retroperitoneal spaces due to prior transperitoneal and retroperitoneal

TABLE 2 ■ Thoracoscopic Transdiaphragmatic Adrenalectomy: Clinical Experience

[a]Movement of the postoperative hemidiaphragm was evaluated by fluoroscopic examination of the chest.
Abbreviations: R, right; L, left.
Source: From Ref. 16.

Freehand laparoscopic suturing and intracorporeal knot tying techniques allowed satisfactory airtight suture repair of the diaphragmatic incision in all three cases.

open surgery. In such cases, transabdominal laparoscopic adrenalectomy may be a technically difficult undertaking, and the virgin thoracic cavity may represent a reasonable access route to the pathological adrenal gland.

Table 2 shows demographic, intraoperative and postoperative data of the three clinical cases performed at the author's institution (16).

A considerable history of prior transperitoneal and retroperitoneal open surgery was present in all three patients. The initial two cases required a long operating time of 4.5 and 6.5 hours, respectively. However, the third case was completed in 2.5 hours. Blood loss of 150 and 500 cc in the first two cases, respectively decreased to 50 cc in the third case due to increasing confidence with the novel approach. Histology revealed solitary adrenal metastasis in the initial two cases and adrenal myelolipoma in the third case. Malignant adrenal disease and its periadrenal reaction and neovascularity may explain the high intraoperative blood loss in the first two cases.

Freehand laparoscopic suturing and intracorporeal knot tying techniques allowed satisfactory airtight suture repair of the diaphragmatic incision in all three cases.

As a result, the authors deemed a chest tube not necessary in the third case (Fig. 7). No clinically significant changes of hemodynamic and capnometric parameters occurred in any case. Postoperatively, the patients were offered fluoroscopic examination of the chest and in the two patients who consented to undergo the test, normal respiratory excursions of the ipsilateral hemidiaphragm were documented. No late complications occurred at a mean follow-up of seven months, and follow-up computerized tomography showed no local recurrence in the adrenal bed in the two patients with adrenal malignancy. A total of five patients have undergone transthoracic transdiaphragmatic adrenalectomy at the Cleveland Clinic from December 1999 to date.

TECHNICAL CAVEATS

■ Mastering of thoracic and retroperitoneal anatomy, and considerable prior experience with major laparoscopy and open surgery are prerequisites to perform thoracoscopic transdiaphragmatic procedures (10,22).

■ Thorough familiarity of the anesthesia team with double lumen endotracheal intubation techniques is mandatory for single-lung ventilation.

■ Confirmation of adequate deflation of the appropriate lung on clamping the double lumen tube by auscultation at intubation, after prone positioning, and prior to skin incision is necessary (22). Inadequate functioning of the double lumen tube should be detected immediately by continuous monitoring and promptly addressed intraoperatively by bronchoscopy.

■ Rigid valveless ports (Fig. 4B) allowing free passage of various instruments are employed given no CO_2 pneumo-insufflation is necessary.

■ The need for active retraction of the liver or spleen is minimal due to prone position of the patient, which also allows a direct approach to the adrenal gland, and the related gravity induced anterior displacement of the liver or spleen.

- Diaphragmatic incision directly over the adrenal gland should be precisely planned under real-time ultrasonographic guidance.
- Main adrenal vein control is safely and rapidly performed using an articulating vascular stapler.
- Needle puncture of the lung should be avoided at all times during diaphragmatic repair to prevent inadvertent creation of a bronchopleural fistula.
- Adequate experience and skills with thoracoscopic techniques and team work with an expert minimally invasive thoracic or spine surgeon are strongly recommended.

TECHNICAL LIMITATIONS

Transthoracic transdiaphragmatic surgery is not free of limitations (9,23,24). Preexisting cardiopulmonary disease precluding single-lung ventilation, postoperative pulmonary adhesions due to prior thoracic surgery are contraindications to this technique.

SUMMARY

- Thoracoscopic transdiaphragmatic technique is a novel minimally invasive procedure.
- In patients with a surgically virgin abdomen, laparoscopic adrenalectomy done with the technically simpler transperitoneal or retroperitoneal approaches is recommended and preferred.
- A thoracoscopic transdiaphragmatic approach through the virgin thoracic cavity may be reasonable in the rare patient with surgical adrenal pathology and prior major abdominal surgery precluding transperitoneal and retroperitoneal laparoscopy.
- Necessary requirements for thoracoscopic transdiaphragmatic surgery include anatomical familiarity and considerable experience with thoracoscopic and transabdominal laparoscopy.
- In the future, thoracoscopic and transabdominal laparoscopy could be combined to provide a minimally invasive alternative to open surgical thoracoabdominal incision in patients with larger adrenal (25) or upper pole renal masses.

RENAL HYPOTHERMIA

Anup P. Ramani

Section of Laparoscopy, Department of Urological Surgery, University of Minnesota, Minneapolis, Minnesota, U.S.A.

INTRODUCTION

Laparoscopic partial nephrectomy is emerging as a viable treatment option for select patients who are deemed candidates for nephron-sparing surgery. The laparoscopic option was initially reserved for patients with small, superficial and exophytic tumors. However, with increasing skill and experience, certain centers in the world are now applying laparoscopy to the management of larger and deeper renal tumors.

A clear bloodless field during laparoscopic partial nephrectomy is a pre-requisite for a successful procedure. This allows for optimal visualization of tumor margins as well as tumor depth during resections, which are critical in achieving a negative margin. Although transient hilar control achieves this goal admirably, the attendant warm ischemia may be detrimental to the aerobic metabolism of the kidney. Certainly, the effect is deemed to be more permanent if the warm ischemia period exceeds 30 minutes. Hypothermia induces short-term suspension of renal metabolism, which is necessary for cellular protection and for minimizing post-ischemic renal injury. Thus renal hypothermia is necessary in patients in whom the warm ischemia period is estimated to exceed 30 minutes.

PHYSIOLOGY OF RENAL HYPOTHERMIA

Renal metabolic activities are predominantly aerobic and hence the kidney is susceptible to damage from warm ischemia. Almost immediately after renal arterial occlusion, adenosine triphosphates in the kidney cells break down to monophosphate nucleotides to provide energy for cellular integrity. With increasing duration of ischemia, there is influx of salt and water into the cell resulting in cellular edema and eventually cell death.

Canine studies have shown that warm ischemic intervals of up to 30 minutes can be tolerated by the kidney, with eventual full recovery of function. With greater periods of warm ischemia, there is significant immediate functional loss with either incomplete or absent delayed recovery of renal function. The proximal tubular cells are the most susceptible and show varying degrees of necrosis, while the glomeruli and blood vessels are generally spared. In humans, 30 minutes is the maximum tolerable period of warm ischemia, before permanent damage may ensue (1). Anecdotally, a solitary kidney has been shown to be more resilient to ischemic damage as compared to bilaterally normal kidneys. The exact mechanism remains uncertain.

A variety of techniques have been described to minimize warm ischemic damage due to hilar occlusion. These include preoperative and intraoperative hydration, minimize

traction on the renal artery and intraoperative administration of mannitol. Hypothermia is the most commonly employed technique for protecting the kidneys from ischemic damage (2). Lowering renal temperature reduces energy-dependent metabolic activity of the cortical cells which leads to decreased consumption of oxygen and reduced breakdown of ATP. A negative effect of hypothermia is inactivation of the sodium-potassium pump at the cellular level, which ultimately allows salt and water to enter the cell. These effects are completely reversible at temperatures above 4°C. With further fall in temperature, formation of ice crystals and irreversible cell damage occurs. For practical purposes, a uniform temperature of 20°C to 25°C has been found adequate to maintain renal function even after three hours of arterial occlusion.

TECHNIQUES OF LAPAROSCOPIC RENAL HYPOTHERMIA

Laparoscopic partial nephrectomy is now being performed at a variety of centers in the Unites States and in the world. Duplicating open surgical principles is a key aim of any laparoscopic procedure. Thus various authors have reported their techniques of achieving laparoscopic renal hypothermia, which are modifications of the technique used during open surgery. The critical issue in achieving laparoscopic hypothermia is to ensure that the hypothermia is uniform throughout the kidney surface, cortex and the medulla.

LAPAROSCOPIC ICE SLUSH RENAL HYPOTHERMIA

Based on prevailing open surgical principles, the technique of laparoscopic ice slush for renal hypothermia was first described by Gill et al. (3) from the Cleveland Clinic Foundation. They reported their technique in 12 patients, with a mean tumor size of 3.2 cm (range, 1.5–5). Mean depth of invasion into the parenchyma was 1.5 cm (range, 0.7–2.5). Of these, two patients had a solitary kidney.

A transperitoneal approach was used. A 5 French open ended ureteral catheter was inserted cystoscopically and positioned in the renal pelvis. The renal artery and vein were circumferentially mobilized en bloc, without any attempt to individually dissect the vessels. The kidney was completely mobilized within Gerota's fascia, maintaining the perirenal fat over the tumor. Laparoscopic ultrasonography was now performed to delineate the tumor and circumferentially score the proposed line of resection around the tumor, including an adequate margin of healthy tissue. Mannitol (12.5 g) was administered intravenously and a Satinsky clamp was positioned around the intact, en bloc renal hilum without closing its jaws.

Sterile ice slush was created in an ice slush machine and constantly stirred manually to reduce it to a fine consistency. Five 30 cc syringes were modified by cutting off the nozzle end of the barrel. They were prefilled with ice slush in preparation for rapid injection.

The 12 mm inferior pararectal port was removed and a 15 mm Endocatch II bag inserted through the same skin incision. The bag was opened and carefully positioned around the kidney. The drawstring was pulled, thus, detaching the bag and deploying it around the kidney. The disengaged metal ring of the bag was removed from the abdomen and the inferior pararectal port was reinserted. The drawstring was further cinched with extreme care taken to avoid any trauma to the renal vein and artery. Typically, the drawstring cannot be synched completely, requiring placement of hem-o-lock clips to snug the mouth of the bag gently around the intact renal hilum. Thus, the kidney is completely enclosed by the bag. The jaws of the Satinsky clamp were then securely closed around the renal vessels taking care not to include any part of the bag in the jaws.

The bottom end of the bag was grasped with locking Allis forceps inserted through the inferior pararectal port. This port was removed, delivering the end of the bag outside the abdomen, where it was secured with a hemostat. The port site skin incision was extended by only 2–3 mm and the peritoneal fascia was similarly incised.

Pneumoperitoneum was desufflated and the exteriorized end of the bag was cut open. Using the previously loaded syringes, 600–750 cc of ice slush were rapidly inserted into the bag, thus, completely surrounding the kidney with ice. The opened end of the bag was closed with a tie, the bag reinserted into the abdomen, a 10 mm balloon cuffed blunt tip cannula secured at this port site and pneumoperitoneum was restored. Laparoscopic visualization confirmed that the kidney was properly surrounded by ice slush within the bag. A laparoscopic sponge (4 × 18 inches) was positioned around the bag to prevent bowel from coming in direct contact with the ice filled

bag. After approximately 10 minutes the bag was incised and the ice slush removed from around the tumor site only, leaving the ice in contact with the remainder of the kidney surface. Laparoscopic partial nephrectomy was then completed in the standard fashion.

In the Cleveland clinic series, the median time to deploy the bag was seven minutes (range, 5–20). A nadir renal parenchymal temperature of 5°C to 19.1°C was achieved in the five patients in whom renal parenchymal temperatures were measured using thermocouples. Concomitantly, median systemic esophageal temperature decreased by only 0.6°C.

Median total ischemia time was 43.5 minutes and total operative time was 4.3 hours (range, 3–5.5). Median hospital stay was three days (range, 2–7).

Intraoperative complications occurred in two patients.0 In one, the kidney was not fully mobilized, and the ice slush filled bag partially slipped off the kidney. In the other, part of the bag was caught in the jaws of the Satinsky clamp resulting in inadequate occlusion of the renal pedicle and a 500 cc blood loss during resection of tumor.

Postoperative radionuclide scanning confirmed function in the operated kidney in each instance, although with various degrees of resolving acute tubular necrosis. For the whole group, mean preoperative serum creatinine was 1.1 mg/dL. Mean peak serum creatinine was 1.5 mg/dL an average of 1.2 days after surgery and nadir serum creatinine was 1.2 mg/dL an average of 2.8 days after surgery.

Potential shortcomings of this technique include space limitations to deploy and engage the bag in the retroperitoneal approach, significant perinephric adhesions that may preclude complete mobilization of the kidney, and the theoretical possibility of systemic hypothermia.

The authors concluded that adequate renal cooling can be achieved by purely laparoscopic techniques and the additional studies are required to develop a more efficient ice delivery system.

Wakabayashi et al. (4) recently described a technique for renal hypothermia using ice slush during retroperitoneal laparoscopic partial nephrectomy. They reported their experience in two cases. The renal tumor size was 1.3 cm and 9 mm, respectively.

A 6 French pigtail catheter was inserted into the renal pelvis cystoscopically. A standard retroperitoneal approach was then achieved using a balloon dilator and four trocars. The renal artery was mobilized and vascular tape placed around the renal artery. The kidney was completely mobilized. The primary port site incision was then extended and a cylindrical cannula was then inserted into the retroperitoneum. Ice slush was then introduced through the cylindrical cannula into the retroperitoneum. The device was removed and the skin incision narrowed with a suture. The balloon port was then secured into the retroperitoneum. The ice slush was then evenly distributed over the kidney using an Endo Retractor[a], and Mannitol administered intravenously. A laparoscopic bull dog clamp was placed on the renal artery. Pneumoperitoneum was restored after 15 minutes of cooling. Laparoscopic partial nephrectomy was then completed.

In these two cases, the total operative times were 214 and 233 minutes, respectively. Cold ischemia times were 81 and 47 minutes. Nadir renal temperature was 18.4°C and 25.8°C. The systemic temperature decreased by 0.8°C and 0.6°C, respectively. A total of 1500 cc and 1200 cc ice slush was introduced, respectively, mean time of 10.5 minutes to insert the ice slush. Postoperative isotope renal scans showed good function in the renal remnants. There were no complications. The concern with this technique is the potential for uneven cooling of the kidney due to uneven application of the slush over the entire surface of the kidney. Also any inadvertent peritoneal entry may compromise bowel integrity.

ENDOSCOPIC RETROGRADE COLD SALINE INFUSION

Historically, Jones and Politano initially reported the concept of renal parenchymal cooling using cold saline irrigation of the renal collecting system. However, due to limitations in technology at that time, a ureterotomy was required to gain access to the collecting system.

More recently, Landman et al. (5) described renal cooling using ice cold saline solution for retrograde injection through a pre placed ureteral access sheath. They reported their technique in the porcine model and subsequently in one patient who underwent open radical nephrectomy for renal tumor.

---

[a]U.S. Surgical Corp., Norwalk, CT.

A 12/14 ureteral access sheath was advanced cystoscopically over an Amplatz superstiff guidewire up to the renal pelvis, under fluoroscopic guidance. A side adaptor was twisted into the distal end of the access sheath. A 7.1 French pigtail catheter was passed through the access sheath into the renal pelvis. The access sheath was then secured to the Foley catheter to prevent dislodgement during patient positioning. The kidney was approached and completely mobilized through a flank incision. The renal artery and the vein were individually dissected and then clamped. Ice cold ($-1.7°C$) 0.9% saline from a 3 L bag suspended 120 cm above the kidney was irrigated through the access sheath into the renal pelvis for 35 minutes. The efflux returning from the pigtail catheter in the pelvis was collected. The radical nephrectomy was then completed in standard fashion.

The above technique resulted in the circulation of 85 mL/min of ice-cold saline through the collecting system. The renal cortical and medullary temperatures were measured with thermocouples to be 24°C and 21°C, respectively. The patient's core temperature remained at 37°C throughout the procedure. In this one patient who underwent radical nephrectomy, the cold ischemia was maintained for 35 minutes. As this patient underwent a radical nephrectomy, no follow-up on renal function was available.

A potential concern with this technique is that during laparoscopic partial nephrectomy for an infiltrating tumor, entry into the collecting system occurs early within one to two minutes of initiating resection. This would lead to leakage of the perfusate with potential compromise of renal cooling.

In both their studies, Landman et al. (5) did not perform a partial nephrectomy to evaluate the effect of leakage of the perfusate. Thus additional studies are required to evaluate this technique with radiological follow up of the renal remnant to evaluate residual function.

TRANSARTERIAL RENAL HYPOTHERMIA

Percutaneous transarterial renal hypothermia offers another option of for achieving laparoscopic renal hypothermia. A variety of studies in literature report on the efficacy of this technique. Marberger and Eisenberger (6) in the early 1970s, initially reported that renal artery perfusion cools the kidney three times as rapidly as does surface cooling. They also reported that surface cooling leads to heterogeneous cooling of the kidney, although this has now been shown to be erroneous and that uniform cooling is possible with surface hypothermia with ice slush. They reported on 63 patients who underwent hypothermic nephrolithotomy for extensive stone disease. Percutaneous renal artery access was achieved with a catheter. The renal artery was occluded with either a tourniquet or with a double lumen balloon tipped catheter in the artery. The kidneys were perfused with Ringer lactate or 5% Dextrane solution at 4°C. Rectal temperature was measured simultaneously. A control group of 39 kidneys undergoing the same procedure were cooled with surface ice slush.

The average cold ischemia was 61.3 minutes in the arterial catheter group and 59.8 minutes in the ice slush group. Renal parenchymal temperature was not measured during the procedure. Follow-up consisted of obtaining hippuran clearance. They showed a statistically significant decrease in postoperative renal clearance in the surface cooled kidneys compared to the arterially perfused kidneys. They also reported that poorly functioning kidneys recovered better from the ischemic insult if the hypothermia was arterial as compared to surface cooling.

More recently, Munver et al. (7) reported on a novel technique involving cannulation of the renal artery and infusion of cold lactated ringer's solution in nine patients undergoing open partial nephrectomy.

Following occlusion of the renal artery and vein with vascular clamps, the vessels were cannulated with 14 gauge angiographic catheters. The ice cold perfusate was then run through the arterial catheter and the effluent cleared through the venous catheter.

This led to a rapid (one to two minutes) drop in renal temperature that was uniform throughout the kidney. There were no complications reported in this series. Serial postoperative isotope scans revealed good function in the renal remnants.

Janetschek et al. have reported on their technique of renal artery perfusion for laparoscopic partial nephrectomy. A total of 15 patients underwent laparoscopic partial nephrectomy under cold ischemia induced by renal arterial perfusion. The mean tumor size was 2.7 cm (range 1.5–4). Four of the tumors were completely intra-renal.

An open tipped ureteral catheter was placed in the renal pelvis under fluoroscopic guidance. An angiocatheter was then passed into the main renal artery through a femoral puncture in the operating room by a radiologist. The kidney was approached laparoscopically. The renal artery can be occluded either with the intra-arterial balloon or by

arterial occlusion with a vascular clamp or a tourniquet. In the above series, the intraarterial balloon was used in two patients and the tourniquet in 13 patients. The balloon was unable to occlude the entire lumen that led to bleeding during resection. Intravenous mannitol was administered 15 minutes before arterial occlusion. Hypothermia was achieved by occluding the renal artery and infusing 1000 mL of iced Ringer lactate at 4°C at a rate of 50 mL per minute. Surgery was started immediately following the infusion. Renal temperature was monitored with a thermocouple probe in the parenchyma. When parenchymal temperature of 25°C was attained, perfusion was decreased to maintain steady temperature. Patient was warmed with a warm air blanket and rectal temperature continuously monitored.

The mean time for renal parenchymal temperature to reach 25°C was 10 minutes following initiation of perfusion. Mean operative time was 185 minutes (range, 135–220). The angiocatheter placement required a mean of 16 minutes (range, 10–20). Mean total ischemia time was 40 minutes (range, 27–101). Mean amount of perfusate was 1580 mL (range, 1150–2800). Mean decrease in body temperature was 0.64°C (0.5–1.1). Inadequate occlusion of the artery by the balloon in the initial two patients led to significant blood loss, following which the authors modified their technique to include hilar clamping. One patient required a second look laparoscopy for persistent hemorrhagic drainage from the drain. The cause was found to be a parenchymal suture that had cut through. Hemostasis was achieved with strips of Tachocomb[b]. Of the 15 patients, postoperative renal function was evaluated in eight patients, which revealed decrease of function on isotope scans proportionate to the parenchyma excised.

Although an attractive option, this technique has the potential for injury to the femoral artery as well as the renal artery. This can range from an intimal tear to complete avulsion of the artery. Also this requires an additional procedure with the presence of a radiologist. Thus significant experience with renal artery catheterization is mandatory before this can be attempted.

THE LAPAROSCOPIC COOLING SHEATH

Herrell et al. described the use of a cooling sheath for achieving surface renal hypothermia during laparoscopic surgery. This consisted of a plastic double jacket with inlet and outlet tubings. In a porcine model, 12 animals were divided into three groups. In group I, the kidney was mobilized by open surgery and surface cooling achieved with ice slush after arterial occlusion. In group II, the kidney was mobilized laparoscopically and the renal hilum was clamped for 60 minutes without any hypothermia. In group III, the kidney was mobilized laparoscopically. In three of the four animals in this group, a 4 cm open incision was made to apply the cooling jacket around the kidney. In the last animal the jacket was placed around the kidney through an 18 mm trocar. Mannitol was given intravenously and the renal artery clamped using a bulldog clamp. A tubing pump was then used to initiate flow of cold sterile saline from a chilled bath (3–5°C) through sterile tubing into the sheath. Outflow to the bath through similar sterile tubing created a sterile circuit. Renal and body temperatures were recorded. After 60 minutes, the clamp and the sheath were removed.

The kidney was harvested at seven days after ischemia. The renal temperature in groups I and II dropped to the optimal hypothermic range (5–25°C) within five minutes. Overall surface ice slush cooling resulted in lower temperatures than the sheath, but this was not statistically significant. In one animal, leakage from the sheath, with continued irrigation led to transient drop of body temperature to 34°C with no adverse events. Histology revealed no differences in kidneys from groups I and III (hypothermia) whereas kidneys from group II (no hypothermia) showed expected tubular epithelial necrosis and vacuolization.

ANCILLARY TECHNIQUES FOR ISCHEMIC RENOPROTECTION

The cornerstones of minimizing renal ischemic damage are to achieve copious diuresis before and after hilar clamping, reduce oxidative damage due to free radicals and minimize ischemia time during surgery. Intravenous mannitol given 10–15 minutes prior to and immediately after arterial occlusion ensures adequate diuresis after unclamping.

Protection of renal function by injection of the nucleotide inosine has been well documented in literature. Wickham et al. in 1979 reported the use of inosine in seven

---

[b]Nycomed, Linz, Austria.

patients. Six of these had a staghorn calculus and one had a renal tumor. Ten minutes prior to clamping, 2 g of inosine in 80 mL of diluent Trophycardyl[c] were administered intravenously. The renal artery was then occluded and surgery performed. On differential renography postoperatively patients showed evidence of diminished function, but by one month all had regained preoperative function. Inosine is thought to act by replenishing the adenylic nucleotide pool.

Oxygen free radicals generated as a result of anaerobic metabolism are known to have a toxic effect on cellular architecture. Scavengers of oxygen free radicals may have a renoprotective effect in patients requiring extensive ischemic periods for complicated reconstructive surgeries.

SUMMARY

- Renal hypothermia is infrequently required during the performance of laparoscopic renal procedures today
- Of the variety of techniques available to achieve laparoscopic renal hypothermia, the surface hypothermia achieved with ice slush duplicates open surgical, time-tested principles and represents the preferred option currently.
- Better delivery systems for hypothermic solutions are needed to optimally achieve uniform cooling of the kidney.

INTRODUCTION

Laparoscopic surgery has been shown to reduce postoperative patient morbidity and recovery based on the extensive worldwide clinical experience in the urologic surgical literature. However, the sweeping changes seen in most aspects of urologic laparoscopy have not been paralleled in the area of renovascular surgery. The lack of development in its application to renovascular surgery is primarily due to the high level of technical difficulty in performing meticulous and expeditious vascular reconstruction, in which the intracorporeal suturing and knot-tying skills that are associated with steep learning curve are essential to success.

> To date, three different types of laparoscopic renovascular surgical procedures have been reported in the literature. These include laparoscopic aortorenal bypass, laparoscopic renal autotransplantation, and laparoscopic repair of renal artery aneurysm.

To date, three different types of laparoscopic renovascular surgical procedures have been reported in the literature. These include (i) laparoscopic aortorenal bypass, (ii) laparoscopic renal autotransplantation, and (iii) laparoscopic repair of renal artery aneurysm.

LAPAROSCOPIC AORTORENAL BYPASS

Physiologically significant renal artery stenosis, mostly due to atherosclerosis, has been known to cause hypertension and deterioration of renal function (1–3). Percutaneous transluminal balloon angioplasty and intravascular stenting have evolved as the first-line therapy in recent years; however, they have provided inferior long-term patency (4).

Surgical revascularization remains the gold-standard definitive treatment of renal artery stenosis as well as the salvage treatment of failed endovascular intervention. However, the conventional open revascularization surgery is typically associated with significant patient morbidity and recovery. Laparoscopy was thought to have the potential to reduce the postrevascularization patient morbidity.

> Surgical revascularization remains the gold-standard definitive treatment of renal artery stenosis as well as the salvage treatment of failed endovascular intervention. However, the conventional open revascularization surgery is typically associated with significant patient morbidity and recovery. Laparoscopy was thought to have the potential to reduce the postrevascularization patient morbidity.

Hsu et al. from the Cleveland Clinic investigated the feasibility and the physiologic and pathologic outcomes of laparoscopic aortorenal bypass in the laboratory setting (5,6). Their reports also represented the first attempt to study laparoscopic renovascular surgery in the surgical community.

In the initial report on laparoscopic renovascular surgery, the authors performed an aorta-to-left renal artery bypass using an interposition polyethylene graft in five large farm pigs, following extensive experience with laparoscopic vascular suturing from arduous practice in the in vitro setting as well as in approximately 20 animals (5). In the procedure, five to six trocars were used for transperitoneal access, and intracorporeal free-hand suturing and knot-tying techniques were used exclusively for vascular reconstruction. In this feasiblity study, the mean surgical time was 5.4 hours, and the mean renal ischemia time was 61 minutes. The mean end-to-side graft-to-aorta and end-to-end graft-to-renal artery anastomosis times were 34 and 40 minutes, respectively. The average estimated blood loss was 66 mL. Upon revascularization, there was prompt reperfusion of the kidney and Doppler-confirmed pulsation of the renal artery. On autopsy following the surgical procedure, there was anastomotic patency was present in all five cases.

Following the successful feasiblity study above, the same authors proceeded to investigate the long-term clinical and pathologic outcomes of laparoscopic aortorenal bypass in a survival animal study, in which a total of eight large farm pigs underwent the laparoscopic procedure (6). Again, the aorta-to-left renal artery bypass without graft was performed, involving transection of left renal artery and end-to-side aorta-to-renal artery anastomosis. Again, all steps were performed using totally intracorporeal laparoscopic surgical techniques. Furthermore, a novel method of in situ renal hypothermia was used to achieve intracorporeal renoprotective effects by infusion of ice-cold saline into the renal artery through a balloon catheter. In the study, all eight animals underwent the bypass procedure successfully. The median surgical time and total anastomotic time were 110 and 40 minutes, respectively. The median renal warm ischemic time was nine minutes. The median estimated blood loss was 30 mL. Postoperatively, one animal died of pneumonia, and the remaining seven experienced no postoperative complication and were euthanized at different time points from day 0 to week 6. Physiologically, there was no significant difference between preoperative and postoperative (at euthanasia) serum creatinine values (1.15 mg/dL vs. 1.2 mg/dL; $p = 0.39$). Peripheral renin activity was found to have a transient rise in the immediate postoperative period but normalize by one week postoperatively. On autopsy, a grossly normal left kidney with Doppler confirmation of blood flow in the repaired renal artery was identified in all seven animals. Radiographically, ex vivo angiography confirmed a patent anastomosis in all cases. Histologically, there was gradual resolution of mild acute tubular necrosis in the left kidney within six weeks, and there was gradual endothelialization of the aorto–left renal artery anastomotic site, which was found to be complete by six weeks. In short, durable success with physiologic, radiographic, and pathologic confirmation can be achieved in laparoscopic aortorenal bypass.

Subsequent to these two reports of successful laparoscopic aortorenal bypass, the Cleveland Clinic investigators studied another variation of laparoscopic surgical management of renal artery stenosis—laparoscopic splenorenal bypass (7). In the survival animal study, six dogs underwent the transperitoneal laparoscopic splenorenal bypass successfully, in which end-to-end splenic artery-to-left renal artery anastomosis was performed intracorporeally. Mean total operative time and renal ischemia time were 297 and 71 minutes, respectively. Five of six animals were kept alive from one to two months, and patent anastomoses were found in all animals on autopsy. This chronic canine study further supports that laparoscopic vascular bypass involving the renal artery can provide durable results in the laboratory setting.

LAPAROSCOPIC RENAL AUTOTRANSPLANTATION

Renal autotransplantation has been performed for aortorenal vascular disease, upper ureteral tumors and strictures, ureteral loss, loin pain–hematuria syndrome, and idiopathic retroperitoneal fibrosis (8–13). Renal autotransplantation involving two separate procedures, live donor nephrectomy and autotransplantation, is known to be a morbid open surgical procedure requiring two large skin incisions. Laparoscopy was thought to have the potential to minimize the morbidity of this renovascular surgical procedure.

Meraney et al. from the Cleveland Clinic investigated the feasibility and outcome of laparoscopic renal autotransplantation in the laboratory setting (14). This study represents the initial and only report of a completely laparoscopically performed renal autotransplantation.

In their survival study, six farm pigs underwent the laparoscopic renal autotransplantation procedure (14). Laparoscopic left donor nephrectomy was first performed, following which intracorporeal renal hypothermia was achieved via intra-arterial infusion of ice-cold saline solution through a balloon catheter, the same method described earlier by the same Cleveland Clinic group (6). The renal vessels were then anastomosed to the ipsilateral common iliac vessels in the end-to-side manner using laparoscopic intracorporeal free-hand suturing and knot-tying techniques. All animals underwent the procedure successfully, with return of pink color to the autotransplanted kidney and Doppler-confirmed renal arterial pulsation following revascularization. The mean operative time was 6.2 hours. The mean venous anastomosis time was 33 minutes, and the arterial anastomosis time was 31 minutes. The mean iliac clamping time was 77 minutes. The total renal ischemia time was 68.7 minutes, including warm ischemia of 5.1 minutes, cold ischemia of 33 minutes, and rewarming of 31 minutes. Postoperatively,

Meraney et al. from the Cleveland Clinic investigated the feasibility and outcome of laparoscopic renal autotransplantation in the laboratory setting. This study represents the initial and only report of a completely laparoscopically performed renal autotransplantation.

one animal was found to have atrophic, thrombosed autograft. The remaining five animals had stable serum creatinine levels (mean of 1.6 mg/dL) following staged contralateral nephrectomy after autotransplantation. Just before euthanasia, which was done at various times postoperatively (from one to four months), intravenous pyelography and aortography demonstrated prompt contrast uptake and excretion by the autotransplanted kidneys and patent arterial anastomoses in all five animals, respectively. Following euthanasia, histopathologic examination of the autograft showed normal renal architecture without evidence of ischemia or acute tubular necrosis.

LAPAROSCOPIC REPAIR OF RENAL ARTERY ANEURYSM

Renal artery aneurysms may cause renal function deterioration and renovascular hypertension. Furthermore, large aneurysms (>2 cm) have the increased risk of rupture. When indications for intervention are present, the conventional open surgical renal revascularization is the gold-standard treatment, which is known to be associated with significant postoperative morbidity.

Gill et al. from the Cleveland Clinic reported their initial experience with repair of renal artery aneurysm performed laparoscopically to minimize the patient morbidity associated with renal revascualrization (15). This report represented the initial laparoscopic renovascular surgery in the clinical setting.

The initial clinical laparoscopic renovascular surgery was performed in a 57-year-old woman with 3-cm saccular aneurysm of the distal left main renal artery that was confirmed by selective left renal arteriography. A transperitoneal four-port approach was used. Meticulous dissection led to the identification of the renal artery aneurysm, which was mostly covered by the main renal vein. Following proximal and distal control of the renal artery with respect to the aneurysm using laparoscopic bulldog clamps, the aneurysm was bivalved, and the excess aneurysm sac was meticulously excised. The edges of the excision site were then trimmed and reconstructed using intracorporeal laparoscopic suturing techniques. Following the removal of the vascular clamps, there was prompt return of pink coloration to the kidney and excellent pulsation in the distal main renal and segmental arteries, with no bleeding from the anastomotic suture line or compromise of the caliber of the reconstructed renal artery segment. Total operative time was 4.2 hours, and total blood loss was 100 mL. Total renal artery clamping time was 31 minutes. There was no perioperative complication. Hospital stay was two days. Renal scan on postoperative day 1 showed good perfusion to the left kidney without evidence of acute tubular necrosis, and there was improved relative left renal function (from 37% before the surgery to 43% after the surgery). Postoperative angiography showed normal caliber of the reconstructed artery at one month.

> Gill et al. from the Cleveland Clinic reported their initial experience with repair of renal artery aneurysm performed laparoscopically to minimize the patient morbidity associated with renal revascualrization. This report represented the initial laparoscopic renovascular surgery in the clinical setting.

SUMMARY

- ■ Laparoscopic renovascular surgery is feasible, and its short-term and intermediate-term efficacy has been shown in the laboratory and clinical settings to a limited degree.
- ■ Laparoscopic renal revascularization is technically challenging, especially the free-hand intracorporeal suturing and knot-tying steps, and there is clearly a need for further refinement in surgical instrumentation to minimize the steep learning curve associated with laparoscopic vascular suturing and reconstruction.
- ■ Prior to embarking on laparoscopic renovascular surgery, adequate skills in laparoscopic reconstructive techniques are mandatory for success.
- ■ Atraumatic control and handling of the vascular tissues and precise laparoscopic vascular suturing in a meticulous and time sensitive manner are necessary to achieve successful outcome.

INTRODUCTION

Horseshoe kidney is the most common renal fusion anomaly, occurring in approximately 1 in 400 births (1).

The right and left kidneys are fused in the midline by a parenchymal or fibrous isthmus. During gestation, the metanephric blastema abnormally migrates toward the midline, leading to contact and fusion of the lower poles. The normal ascent of the kidney is arrested by the inferior mesenteric artery at the level of the L3 or L4 vertebra, and the kidney fails to normally rotate. Consequently, the renal pelvis is ventrally placed and the ureters often course over the isthmus.

The vascular supply to the horseshoe kidney may be complex. The isthmus usually has a separate blood supply. The blood supply to the isthmus may arise from the main renal arteries or it may branch from the inferior mesenteric, iliac, or sacral arteries (2,3). In most cases, there are multiple arteries and veins that supply each kidney.

Horseshoe kidneys are frequently associated with other congenital anomalies. Anomalies involving the skeletal, cardiovascular, and central nervous systems are common. The most frequently associated genitourinary anomalies are hypospadias, cryptorchidism, bicornuate uterus, septate vagina, polycystic renal disease, ureteral duplication, and vesicoureteral reflux (4). Horseshoe kidneys are found in 20% of patients with trisomy 18 and 60% of patients with Turner's syndrome (5,6).

Although most horseshoe kidneys do not cause symptoms, nephrolithiasis, ureteropelvic junction obstructions, and renal masses are the most frequent findings that require surgery (7).

The location of the kidney and the isthmus make laparoscopy challenging. However, laparoscopy is becoming the standard for surgical management of many renal diseases, and laparoscopic pyeloplasties and heminephrectomies can be successfully performed in patients with a horseshoe kidney.

PYELOPLASTY

Ureteropelvic junction obstructions occur in approximately 15% to 33% of horseshoe kidneys (8–10).

In the horseshoe kidney, several factors are thought to contribute to the ureteropelvic junction obstruction, including high ureteral insertion, abnormal course of the ureter ventral to the isthmus, and anomalous blood supply to the kidney.

The conventional surgical treatment for a ureteropelvic junction obstruction in a horseshoe kidney is an open dismembered pyeloplasty, isthmectomy, and nephropexy of the involved renal moiety. The success rate for open pyeloplasty in this patient population ranges from 55% to 80% (11,12). Schuessler et al. described the first laparoscopic

pyeloplasty (13). Laparoscopic pyeloplasty offers the advantages of a minimally invasive surgical approach and high success rates associated with open surgery. The reported success rates for laparoscopic pyeloplasty range from 94% to 98% (14,15).

Several authors have reported successfully performing laparoscopic pyeloplasties in horseshoe kidneys (16–20). Bove et al. reported the results of laparoscopic pyeloplasty in 11 patients with upper urinary tract anomalies, including five patients with horseshoe kidneys (16). One of the patients with a horseshoe kidney had previously failed an endopyelotomy. The mean operative time was 3.2 hours and the mean estimated blood loss was 122 mL. No patients required transfusions and there were no operative complications. With a median radiologic follow-up of eight months, all five patients had improvement in renal function on excretory urogram or renal scan.

The medial and ventral location of the ureters in a horseshoe kidney is preferred when performing laparoscopy pyeloplasty.

Although several centers have successfully applied a retroperitoneal approach for horseshoe kidneys when performing extirpative surgery (20–22), the transperitoneal approach provides greater working space for reconstructing the collecting system, which may be dilated and enlarged. However, in select cases a retroperitoneal approach may be feasible. Hsu and Presti reported performing an extraperitoneal laparoscopic pyeloplasty in a horseshoe kidney (19). They used a balloon dilator to extraperitoneally develop 500-mL spaces in multiple directions. The peritoneal sac was bluntly mobilized en bloc to fully expose a dilated left renal pelvis. The surgery time was approximately 6.7 hours. Postoperatively, an excretory urogram was used to document prompt drainage. In both reports, the isthmus was not divided.

Although an isthmectomy is part of the conventional surgery for a ureteropelvic junction obstruction in a horseshoe kidney, these initial reports suggest that the isthmus may be left intact during laparoscopic pyeloplasty.

However, in select cases it may be necessary to divide the isthmus if it contributes to the obstruction at the ureteropelvic junction. Nadler et al. reported performing a hand-assisted laparoscopic pyeloplasty and isthmectomy in a horseshoe kidney (17). Electrocautery was used to score the capsule of the isthmus and the isthmus was divided using an ultrasonic shear. Hemostasis was achieved using manual compression, argon-beam coagulation, thrombin, and fibrin glue. The affected moiety was moved several centimeters laterally before performing the pyeloplasty.

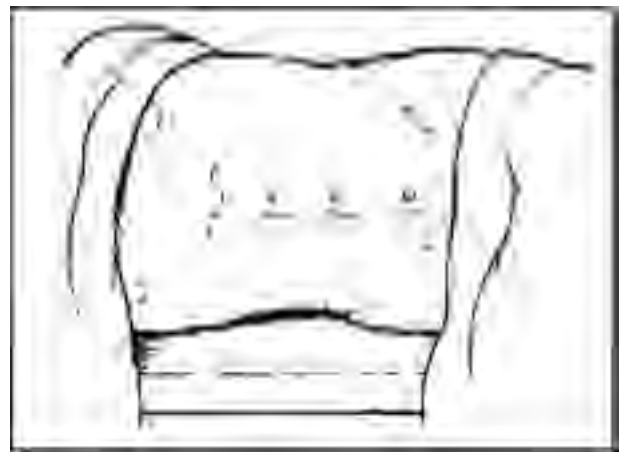
Technique

For patients with horseshoe kidneys, the criteria for diagnosing a ureteropelvic junction obstruction and the indication for surgical intervention are no different than for patients with normally positioned kidneys.

Given the anomalies of the blood supply to the horseshoe kidney, a preoperative angiogram or computed tomography angiogram with three-dimensional volume rendering should be obtained.

Given the anomalies of the blood supply to the horseshoe kidney, a preoperative angiogram or computed tomography angiogram with three-dimensional volume rendering should be obtained.

An understanding of the vascular supply is important when mobilizing the horseshoe kidney and dividing the isthmus. Any crossing vessels should be identified and avoided while mobilizing the proximal ureter.

FIGURE 1 ■ Transperitoneal laparoscopy can be performed using two 12-mm ports and one 5-mm port. The camera is placed through the center port.


Prior to starting the laparoscopic portion of the surgery, flexible cystoscopy is used to place a standard guidewire past the ureteropelvic junction. The guidewire is secured to the Foley catheter in a sterile manner to allow manipulation of the wire by the surgeons during the laparoscopic repair. We prefer to perform the surgery with the patient in a modified flank position using a transperitoneal approach. The surgery can be performed using three midline ports, which include two 12-mm ports and one 5-mm port (Fig. 1). The 5-mm port is the superior-most port and the middle port, used for the camera, is placed through the umbilicus. Depending on the location of the kidney, the three port sites can be adjusted while maintaining the relative position of the three ports.

The colon is reflected medially to expose the kidney and the isthmus.

If a prominent isthmus contributes to the obstruction of the ureteropelvic junction, an isthmectomy should be performed.

To perform the isthmectomy, the isthmus should be separated from the aorta. The involved renal moiety may need to be mobilized to allow the isthmus and aorta to be separated. The isthmus can be divided using electrocautery, ultrasonic shears, or endoscopic staplers. Hemostasis can be achieved at the cut surface using a combination of argon-beam coagulation, fibrin glue, thrombin, cellulose sheet, and intracorporeal sutures.

The involved renal moiety can then be moved several centimeters laterally before performing the ureteropelvic junction repair. However, nephropexy is not necessary (12,23).

A Heineke–Mickulicz repair is well suited for short intrinsic segments of stenosis; a Y–V plasty is well suited in patients with high ureteral insertions. An Anderson–Hynes dismembered pyeloplasty is ideal for patients with a redundant renal pelvis. The ureter and renal pelvis should be transposed over any crossing vessels that may be present. If a renal stone is present, the stone can be removed through the endopyelotomy using a flexible cystoscope and a basket.

The collecting system can be reconstructed using 4-0 Vicryl sutures placed in an interrupted fashion. After performing the posterior half of the ureteropelvic anastomosis, a double-J stent is passed over the previously placed guidewire. The placement of the stent is visually confirmed before completing the anterior portion of the ureteropelvic anastomosis. A surgical drain is placed in the retroperitoneum before repositioning the colon. The drain can be removed on postoperative day one if the drain output remains low following Foley catheter removal. The ureteral stent should be left in place for approximately six weeks.

HEMINEPHRECTOMY

The most common indications for performing a heminephrectomy in a horseshoe kidney are a renal mass and a nonfunctioning moiety, which is usually secondary to a ureteropelvic junction obstruction.

Sidebar notes (left margin):

If a prominent isthmus contributes to the obstruction of the ureteropelvic junction, an isthmectomy should be performed.

The involved renal moiety can then be moved several centimeters laterally before performing the ureteropelvic junction repair. However, nephropexy is not necessary.

TABLE 1 ■ Summary of Selected Reports of Extirpative Surgery in Patients with Horseshoe Kidney

	n	Indication for surgery	Division of isthmus or parenchyma	Approach	Angiogram or CTA	Intraoperature ureter guide
Riedl et al. (24)	1	Nonfunction	Endostapler	Transperitoneal	No	Yes
Ao et al. (25)	1	Nonfunction	Electrocautery[a]	Transperitoneal	No	No
Donovan et al. (26)	1	Nonfunction	Endostapler	Transperitoneal	Yes	Yes
Hayakawa et al. (27)	1	Nonfunction	Microwave coagulator	Transperitoneal	No	No
Hemal et al. (20)[b]	2	Nonfunction	Suture ligature[a]	Retroperitoneal	No	No
Yao and Poppas (28)[b]	1	Nonfunction	Ultrasonic shear	Transperitoneal	No	No
Kitamura et al. (22)	1	3.5-cm renal cell carcinoma	Ultrasonic shear and argon coagulator	Retroperitoneal	No	No
Molina and Gill (21)	1	2-cm cystic renal mass	Intracorporeal suturing	Retroperitoneal partial nephrectomy	Yes	Yes

[a]The isthmus divided extracorporeally.
[b]Includes additional patients with anomalous kidneys undergoing laparoscopic nephrectomy.
Abbreviation: CTA, computed tomography angiogram.

Most reports of laparoscopic heminephrectomy in horseshoe kidneys have been for a nonfunctioning and hydronephrotic renal moiety (Table 1) (20,24–28). There is one report of a heminephrectomy for a 3.5-cm renal cell carcinoma (22) and another report of a partial nephrectomy for a patient with a 2-cm cystic renal mass (21).

When performing an extirpative surgery on a horseshoe kidney, there is no consensus on whether a preoperative angiogram is required or if a ureteral stent should be placed to help identify the ureter during the laparoscopic dissection. Several authors argue that for nonfunctioning kidneys an angiogram is not necessary (20,24,25,27,28). The renal parenchyma is atrophic and the blood supply is minimal. They argue that the magnification provided by laparoscopy makes identification of the vascular supply straightforward.

Laparoscopic heminephrectomy can be performed using a transperitoneal or a retroperitoneal approach, depending on the preference of the surgeon.

When the surgery is being performed for suspected renal cell carcinoma, we feel that the specimen should be extracted intact, using an entrapment bag. A small midline or Pfannenstiel incision can be made. The colon should be repositioned after specimen removal.

If the surgery is performed retroperitoneally, care should be taken to avoid inadvertently opening the thin parietal peritoneum covering the ventral surface of the kidney. Molina and Gill state that when performing a partial nephrectomy in a horseshoe kidney, they prefer a retroperitoneal approach for posterior tumors and a transperitoneal approach for anterior tumors (21). The reported operative times for both retroperitoneal and transperitoneal approaches are approximately 200 to 300 minutes (21,22,25,28).

A variety of techniques have been described for dividing the isthmus (Table 1).

When performing a heminephrectomy for a hydronephrotic, nonfunctioning moiety, the isthmus can be divided extracorporeally (20,25).

A port is placed at the level of the umbilicus, contralateral to the affected side and just off the midline. After the ureter is clipped and the collecting system is decompressed, the port site is extended to approximately 4 cm. The collecting system is then pulled out of the abdomen through the 4-cm incision. Traction is applied extracorporeally as the kidney is mobilized laparoscopically and the blood supply is ligated. The kidney is mobilized to allow the isthmus to be pulled out of the abdomen and be divided extracorporeally.

Molina and Gill make the point that when planning for a partial nephrectomy, a computed tomography scan with three-dimensional volume rendering or an angiogram is crucial (21). A complete understanding of the arterial and venous supply is necessary to achieve vascular control. Molina and Gill report placing an open ended ureteral catheter and injecting dilute methylene blue dye to help identify entry into the collecting system. After repairing the collecting system with 2-0 Vicryl, hemostasis was achieved using a surgical bolster and 0 Vicryl sutures on a CTX needle. The warm ischemia time was 31 minute. The estimated blood loss was 100 mL and the total operative time was 3.3 hours.

Technique

A heminephrectomy may be performed for a nonfunctioning kidney or for a renal mass. We will briefly describe an approach for laparoscopically managing a nonfunctioning moiety of a horseshoe kidney. We feel that for an atrophic kidney with minimal renal parenchyma, a planning angiogram is unnecessary. We prefer to decompress the collecting system at the time of the operation after the kidney is exposed. This avoids the possibility of adhesions resulting from percutaneous drain placement, and the distension of the collecting system facilitates the initial dissection.

For a transperitoneal approach, the port placements are the same as for a laparoscopic pyeloplasty in a horseshoe kidney (Fig. 1). The colon is mobilized medially to expose the kidney. The ureter is identified and ligated between clips. The kidney and isthmus are mobilized and separated from the aorta. The hydronephrotic collecting system is decompressed under direct vision using a percutaneously placed spinal needle. The isthmus can be separated using electrocautery, ultrasonic shears, or an endoscopic stapler. Hemostasis can be achieved at the cut surface using a combination of argon-beam coagulation, manual compression, fibrin glue, thrombin, cellulose sheet, and intracorporeal sutures. Alternatively, the isthmus can be divided using an extracorporeal approach as described above.

Once the affected renal moiety is completely freed, it is placed in an entrapment bag and manually morcellated to allow removal through a 12-mm trocar site.

When the surgery is being performed for suspected renal cell carcinoma, we feel that the specimen should be extracted intact, using an entrapment bag. A small midline or Pfannenstiel incision can be made. The colon should be repositioned after specimen removal.

SUMMARY

- Horseshoe kidneys represent the most common renal fusion anomaly.
- Nephrolithiasis, ureteropelvic junction obstructions, and renal masses are the most common indications for surgical intervention in patients with horseshoe kidneys.
- Ureteropelvic junction obstructions and concurrent stones can be treated by laparoscopic pyeloplasty.
- Nonfunctioning renal moiety and renal masses can be managed by laparoscopic heminephrectomy or a laparoscopic partial nephrectomy.

LAPAROSCOPIC BOARI FLAP URETERONEOCYSTOSTOMY AND ILEAL URETER REPLACEMENT

Amr F. Fergany

Section of Oncology, Laparoscopy and Minimally Invasive Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

LAPAROSCOPIC BOARI FLAP URETERONEOCYSTOSTOMY

Introduction and Indications

Bladder flap (Boari flap) reimplantation is a versatile procedure first described experimentally by Boari in 1894 (1), and clinically by Ockerblad in 1947 (2). This is a useful procedure that can be used to bridge lower and middle ureteric defects when the ureter is of inadequate length to reach the urinary bladder but complete ureteric replacement is not required (3). With shorter ureteric defects of the lower ureter, this procedure can be used interchangeably with the psoas hitch procedure. Properly fashioned bladder flaps can easily extend to the middle portion of the ureter and have been reported to reach as high as the renal pelvis (4). The principles of the technique are simple and reliable, and have been readily incorporated into the wide array of laparoscopic procedures currently performed by urologists.

Contraindications

The presence of malignancy within the urinary bladder is a contraindication to bladder flap reimplantation. Neurogenic bladder dysfunction as well as urinary tract infection should be managed preoperatively. Cases of diminished bladder capacity are unsuitable for this procedure because a healthy flap of adequate length cannot be made.

Preoperative cystogram is advisable in all cases to confirm adequate bladder capacity. Adequate studies of the upper tract to localize the site of ureteric obstruction are also essential to allow accurate operative planning prior to the procedure.

Preparation

A clear liquid diet the day before surgery and a light mechanical bowel preparation (such as oral magnesium citrate) are advisable to avoid bowel distention, which can increase the difficulty of the laparoscopic procedure as well as increase the chances of laparoscopic bowel injury.

Technique

The supine or low lithotomy positions both can be used. Intraoperative sterile access to the genitalia is preferred to allow filling of the bladder or exchange of catheters as needed.

The Trendelenburg position is essential to displace the bowel out of the pelvis, and a contralateral lateral tilt to improve access to the surgical side of the pelvis helps as well.

The patient should be adequately padded and secured to allow positioning in this manner for the duration of the procedure without neuromuscular injury. Although the procedure can be performed through an extraperitoneal or transperitoneal approach

> The Trendelenburg position is essential to displace the bowel out of the pelvis, and a contralateral lateral tilt to improve access to the surgical side of the pelvis helps as well.

using open surgical technique, laparoscopic Boari flap reimplantation has been performed only transperitoneally so far. The principles of the procedure described in the following section apply to the laparoscopic procedure as much as they do the open surgical procedure.

The procedure starts with identification and mobilization of the ureter preserving the periureteral blood supply. The site of obstruction is confirmed, and a final assessment of the length of ureteric defect is made. The ureter is spatulated and carefully inspected to ensure healthy appearance at the site of transection. Adequate mobilization of the urinary bladder is then performed. This is easiest done with the bladder partially filled to help identify the proper tissue planes. Mobilization should be as complete as possible to allow complete mobility in cases requiring longer flaps.

It is critical to avoid dividing the bladder pedicle on the ipsilateral side of the flap because the vascularity of the flap will depend on that pedicle.

This can complicate cases where a full distal ureterectomy is needed as in lower ureteric tumors. In cases requiring a long flap the contralateral bladder pedicle can be divided, allowing added bladder mobility to the side of the flap.

The flap is oriented obliquely based on the superior vesical artery on the ipsilateral side, with the base of the flap being wider than the tip to ensure good vascularity. In cases requiring very long flaps, a spiral flap encompassing most of the anterior bladder wall can be fashioned. The ureter can be anastomosed to the flap in a direct or in an antirefluxing manner depending on the clinical circumstance, and the flap is rolled upon itself to form a tube of bladder, and the suture line is usually continued over the anterior wall of the bladder, closing the cystotomy. Added security can be obtained by suturing the adventitia of the ureter to the distal flap, and suturing the back of the flap to the psoas fascia.

The bladder flap should be outlined on the anterior surface of the filled bladder before incision into the bladder lumen is started to avoid disorientation after the bladder is emptied. This also allows proper judgment of stretched length of the flap.

Laparoscopic Experience

The bladder flap technique of ureteral reimplantation is a fairly simple technique that was readily applied to the laparoscopic field applying all the previously mentioned principles from open surgery. Fergany et al. (5) described the laparoscopic procedure experimentally in a porcine model, performing direct as well as nonrefluxing anastomoses in six animals. No complications were encountered and anastomoses were all patent at the time of sacrifice. In the clinical arena, Boari flap reimplant was first reported by Fugita et al. in 2001 (6). In this report of three patients with various causes of lower ureteric obstruction, laparoscopic Boari flap reimplant was performed without complication and follow up extending to six months confirmed a successful result. All three reimplantations were performed directly without antireflux techniques, and operative time ranged from 120 to 330 minutes. No surgical complications were reported.

Laparoscopic Boari flap ureteric reimplantation is a procedure that has moved from the experimental into the realm of laparoscopic urologic practice. The principles of open surgery can be duplicated with consistent results with a reasonable amount of laparoscopic suturing experience.

In all reported cases, a three or four port transperitoneal technique was used, and the principles learned from the open surgical procedure were applied. Suturing the bladder flap and bladder closure can be performed using freehand suturing, which is probably easiest, or a suturing device. In our experience freehand suturing in this situation is usually straightforward because of the anterior longitudinal orientation of the suture line facilitating exposure and handling.

LAPAROSCOPIC ILEAL URETER REPLACEMENT

Introduction and Indications

Ileal ureter replacement was first described by Shoemaker in 1906, and has proved to be a reliable procedure for urinary reconstruction (7). Replacement of the ureter with ileum is performed in certain clinical indications where a long segment or the entire length of the ureter needs to be replaced. The only other alternative in these cases is the more complicated renal autotransplantation (8,9).

Indications for ileal ureter replacement include long or multiple ureteric strictures (inflammatory, iatrogenic, radiation, retroperitoneal scarring), multifocal tumors, and repeated episodes of stone passage with pain and obstruction.

Ileal ureter replacement is most commonly performed unilaterally, however in cases with bilateral ureteric pathology, a bilateral replacement procedure can be performed with a single loop of small bowel reaching from both renal units to the bladder in an inverted L-fashion.

The shortest possible length of ileum should be used to minimize absorption of urinary components and kinking of the ileum. If the proximal ureter is healthy, it can be spared and anastomosed to the proximal part of the ileal loop.

Healthy distal ureter, however, cannot be used because the ileal peristalsis is not strong enough to pass the urine bolus into distal ureter, and a functional obstruction will result. In other words, the distal extent of the ileum has to be anastomosed to the urinary bladder.

Contraindications

Although ileal ureter replacement can be performed for almost any ureteric pathology, certain conditions of the bowel contraindicate this type of surgery. Among these are short bowel syndrome, inflammatory bowel disease, radiation damage to the bowel, and marked scarring of the mesentery (e.g., desmoid tumors).

Absorption of urinary metabolites occurs across the length of the ileal segment, and normal renal function is essential to avoid systemic metabolic derangement (hyperchloremic metabolic acidosis).

It is generally recommended that segments of bowel not be placed within the urinary tract if the serum creatinine is 2.0 mg/dL or higher. Metabolic complications will occur in more than half of these patients (10).

Even in patients with normal renal function, the shortest length of ileum should be used to minimize absorption. Normal bladder function is an important consideration, and patients with neurogenic bladder dysfunction or decreased bladder capacity or compliance should be managed appropriately before surgery or concomitantly with ileal replacement.

Preparation

A multiday mechanical and chemical bowel preparation for ileal surgery has largely been replaced today by a simplified prep consisting of clear liquids the day before surgery and a mechanical prep taken the night before surgery in the form of 4 L of GoLytely® or until the bowel motions are clear. Antibiotic use can generally be started immediately preoperatively.

Technique

Although the current laparoscopic experience is limited to one case, several important points are necessary during laparoscopic as well as open surgery. Reflection of the ipsilateral colon is the first step in the procedure. This allows exposure of the healthy proximal ureter or renal pelvis in order to estimate the required length of ileum.

Ureterectomy is necessary only in cases where a ureteric tumor is diagnosed. A suitable portion of ileum is chosen of sufficient length to span the length of ureteric defect, and of adequate mobility to reach the renal pelvis as well as the urinary bladder.

Bowel continuity is restored after isolating the ileal segment. The ileal segment is placed in an isoperistaltic direction to avoid functional obstruction. The open end of the ileal segment can be anastomosed to a dilated renal pelvis, to a small renal pelvis opened with an extended pyelotomy into the lower calyx, or even to a dilated lower pole calyx as an ileocalycostomy (11).

Laparoscopic Technique

No tapering of the ileum is needed before reimplantation into the bladder, and no antireflux is needed in most cases.

The urologic literature contains only one description of a laparoscopic ileal ureter replacement (12). The indication for surgery was an upper ureteric tumor in a solitary kidney. The basics of the technique described are the same as the open procedure with certain modifications necessary for the laparoscopic procedure.

In this single case report, the patient was placed in the modified lateral position. A transperitoneal technique was used, which is essential for working with the ileum. The ipsilateral colon was mobilized, and the healthy renal pelvis was identified. The ureter was excised with a bladder cuff, and an appropriate length of ileum was selected. Isolation of the ileal segment and restoration of bowel continuity was performed extracorporeally by

Sidebar notes:

The shortest possible length of ileum should be used to minimize absorption of urinary components and kinking of the ileum. If the proximal ureter is healthy, it can be spared and anastomosed to the proximal part of the ileal loop.

It is generally recommended that segments of bowel not be placed within the urinary tract if the serum creatinine is 2.0 mg/dL or higher. Metabolic complications will occur in more than half of these patients (10).

Ureterectomy is necessary only in cases where a ureteric tumor is diagnosed. A suitable portion of ileum is chosen of sufficient length to span the length of ureteric defect, and of adequate mobility to reach the renal pelvis as well as the urinary bladder.

No tapering of the ileum is needed before reimplantation into the bladder, and no antireflux is needed in most cases.

pulling the ileum to the skin surface through a port site. The bowel and the excluded loop were then returned into the abdominal cavity for the ureteroileal and ileovesical anastomosis. With increasing experience in laparoscopic bowel surgery, a completely intracorporeal ileal exclusion and anastomosis can be performed using the endoscopic GIA stapler with similar results. Freehand intracorporeal suturing was used for both ileal anastomoses in this case described in the literature.

As experience with a wide variety of laparoscopic procedures has shown, moving parts of the bowel or the urinary tract from one region of the abdomen to the other and through or underneath bowel mesentery can be particularly challenging. Ideally, an ileal ureter should pass through the sigmoid mesentery to lie retroperitoneally on the left side although on the right side it can be placed caudal to the cecum. In the previously mentioned case, the ileum was placed anterior to the colon (due to scarring from previous surgery) without any apparent ill effects; and with increased experience with this procedure, it will remain to be seen how the placement of the ileum will be performed and how that would affect the surgical outcome.

The operative time reported for this case was eight hours, which is longer than the expected time for open surgery, but the authors correctly point to several factors that could reduce operating time. In this particular case some time was lost mobilizing adhesions from previous surgery. Additional time was lost shortening the excluded ileal segment to the required length laparoscopically as well as placing a double-J stent cystoscopically. They recommend precise measurement of the ileal length and placement of the stent through the ileum before performing the proximal and distal anastomoses as a method to decrease operative time. Follow up in this case was three months at which time the patient was doing well with normal kidney function and without urinary obstruction.

TRANSVESICAL LAPAROSCOPIC BLADDER DIVERTICULECTOMY

Vito Pansadoro

Vincenzo Pansadoro Foundation, Rome, Italy

INTRODUCTION

Bladder diverticulum, a herniation of the bladder mucosa, occurs through a weak point of a hypertrophied muscular wall caused by bladder outlet obstruction. Bladder diverticula can be congenital but, more frequently, are acquired. The diverticulum wall includes an inner mucosal layer and an outer fibrous reactive layer. In 1922 Geraghty demonstrated that removing the mucosal layer was sufficient to obliterate the cavity delimited by the fibrous layer.

The surgical approach can be extraperitoneal, transperitoneal, or transvesical. The transvesical laparoscopic removal of the inner mucosal layer, followed by intracorporeal suturing of diverticulum neck represents a definite advantage, with a very limited trauma to the patient.

HISTORY OF LAPAROSCOPIC DIVERTICULECTOMY

The first report about laparoscopic bladder diverticulectomy dates back to 1992 when Raul Parra (3) reported the first case. The case was done transperitoneally and the opening in the bladder wall was closed with two successive firings of endostaplers under transurethral endoscopic control. In the following years a few other reports of anecdotal cases have been reported and the surgical technique was always transperitoneal.

In 1994 Nadler and Clayman (7) reported the first extraperitoneal laparoscopic diverticulectomy using a technique popularized years later for the extraperitoneal approach for laparoscopic radical prostatectomy.

Iselin (9) in 1996 and Porpiglia (12) in 2002 addressed the problem of the timing of transurethral resection of the prostate and transperitoneal diverticulectomy stating, although with a limited number of patients, that the two procedures could safely be performed in the same setting. The literature shows that laparoscopic bladder diverticulectomy can easily be performed, either through the transperitoneal or extraperitoneal approach, but the limited number of patients with this pathology does not allow to have significant data.

INDICATIONS AND CONTRAINDICATIONS

Indications are limited to diverticula over 4–5 cm in diameter because diverticula of smaller size can easily be treated through the urethra with a resectoscope. Other indications are persistent urinary infection, large postvoid residual, presence of calculi inside the diverticulum and interference with ureteral drainage. Bladder outlet obstruction should be treated before or at the same time of the diverticulectomy. Proximity to the ureteral meatus is not a limitation. In fact laparoscopy enables better view of these structures. Small bladder capacity can be a limiting factor and the indication in these

cases should be postponed after resolution of the outlet obstruction. Diverticula positioned on the dome and multiple diverticula are a contraindication as it is the presence of neoplasm and vesicoureteral reflux.

Preoperative computed tomography is recommended for posterior and trigonal diverticula and for evaluation of upper tract.

SURGICAL TECHNIQUE

With the patient in general anesthesia a cystoscope is introduced in the bladder, which is distended with saline at his/her maximum capacity. The diverticulum's ostium and its relationship with the ureters are evaluated. Under ultrasound and endoscopic control three spinal needles are introduced in the bladder and then substituted with three Entec[a] 5 mm trocars, with a self-retaining balloon (Fig. 1). Combination of ultrasound and endoscopic control will ensure the appropriate placement of the three trocars avoiding perforation of the peritoneal cavity. The trocar, which will be used for the 0° 5 mm optic is introduced on the abdominal midline and the remaining two on the opposite side of the diverticulum with the axis forming a 90° angle. The use of the Entec trocars, with a self-retaining balloon, allows to fix the bladder dome to the abdominal wall thus avoiding the possibility of losing the bladder in case a deflation occurs (Fig. 2). Care must be taken during this delicate maneuver because if a hole in the bladder is accidentally caused the whole procedure cannot be performed. In fact the bladder cannot be distended anymore and the trocars cannot be introduced.

Water is then substituted with air, laparoscopic forceps and a hook are introduced in the trocars, and the diverticulum orifice is circumscribed. The cleavage plan between mucosa and the fibrous layer is easily developed using a monopolar hook (Fig. 2). Once completely released from the reactive capsule, the intact diverticulum is recovered from the bladder through a transurethral 24 Ch sheath of a resectoscope and a biopsy forceps.

A small 8 French Redon drainage is introduced in the bladder through one of the trocars. At the same time, through an extravesical separate stab wound, a Kelly clamp is introduced in the residual cavity. Using a forceps, introduced through the other trocar, the drainage is positioned in the residual cavity and extracted with the Kelly clamp.

The defect in the bladder wall is sutured with two running sutures, Vicryl 3-0 for the muscle and Vicryl 5-0 for the mucosa. Using a half sheath of a Korth cannula, introduced on a guidewire through the trocars these are substituted with three Foley catheters 14 Ch.

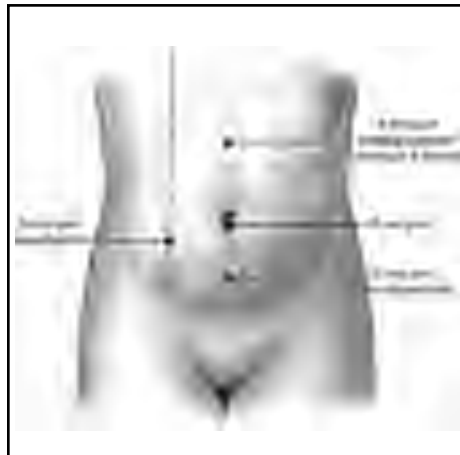
In case of a small prostate a transurethral resection of the prostate is performed in the same setting thanks to the drainage of the three Foley catheters. If the prostate is large the transurethral resection of the prostate is postponed for one week. The suprapubic


FIGURE 1 ■ Pointed troxar with a self-retaining balloon and stopper.

FIGURE 2 ■ Trocars in place fixing the bladder dome to the abdominal wall.

[a]Incision Medical, Brisbane, Australia.

Foley catheters and drainage are removed after 48 hours and urethral catheter 24 hours later. Patients are dismissed the day after.

CURRENT DATA FROM THE LITERATURE

Altogether the number of cases reported in the literature is still very limited with a definite preference for the transperitoneal approach as opposed to the extraperitoneal approach (27 vs. 1). No reports are yet available on the transvesical approach.

COMPLICATIONS

Persistent leakage may occur due, most of the time, to a bladder outlet obstruction. In case of a urinary infection an abscess may occur in the residual cavity.

Ureteral involvement secondary to the suture of the diverticulum neck can be the cause of idronephrosis. Rectal injury is rare and might occur with trigonal and posterior diverticula.

ADVANTAGES AND DISADVANTAGES

The main advantage is the minimal trauma compared to sometimes difficult and complicated procedures for trigonal and posterior diverticula.

The disadvantage is the necessity of two operations if the outlet obstruction cannot be treated at the same time as the diverticulectomy.

SUMMARY

- Transvesical laparoscopic diverticulectomy is an anatomical procedure with a minimal trauma to patients eliminating the need of an open procedure either transperitoneal or extraperitoneal.
- The bladder outlet obstruction, if secondary to a large prostatic hypertrophy, requires a second operation that is a small price to pay, especially in complicated and large posterior diverticula which need a transperitoneal approach.

LAPAROSCOPIC SIMPLE PROSTATECTOMY

Rene Sotelo Noguera and Alejandro Garcia-Segui

Section of Laparoscopic and Minimally Invasive Surgery, Department of Urology, "La Floresta" Medical Institute, Caracas, Venezuela

INTRODUCTION

Open surgery has traditionally been the treatment of choice for benign, symptomatic, large size prostatomegaly (1).

First described in 1945 by Millin (2), retropubic simple prostatectomy achieves complete enucleation of the prostate adenoma through a transverse capsulotomy incision on the anterior surface of the prostate gland. Subsequently, transurethral endoscopic techniques have virtually replaced the open approach in the surgical management of benign prostatic hypertrophy (3–5). Recent modifications of the gold standard transurethral resection (transurethral resection of the prostate) include transurethral needle ablation, thermotherapy, and holmium or "green light" laser enucleation. In general, these techniques are applied for small to moderate sized benign prostatic hypertrophy. More recently, the holmium laser has been employed for "giant" prostatomegaly, even in excess of 100 g (6,7). Nevertheless, at many centers, open prostatectomy remains the technique of choice for the majority of patients with hugely enlarged benign prostatic hypertrophy (8,9).

The size of the prostate gland is an important consideration to select the appropriate surgical approach for the individual patient with symptomatic benign prostatic hypertrophy:

- Transurethral incision of prostate is efficacious for glands up to 30 cc in size (8).
- Transurethral resection of the prostate is the long-established gold standard surgical procedure for the medium-sized adenomas.
- Glands larger than 80–100 g may be better managed with open simple retropubic prostatectomy, especially in the presence of coexisting pathology, such as large vesical diverticulum, large/multiple bladder calculi, or severe hip ankylosis contraindicating a lithotomy position (9).

Operative morbidity of transurethral resection of the prostate increases when performed for prostatic adenoma larger than 45 g, in procedures lasting more than 90 minutes, or patients older than 80 years or with prior history of acute urinary retention (10,11).

A meta-analysis of the literature concluded that open prostatectomy is the most effective method for improving the symptoms of an obstruction caused by benign prostatic hyperplasia, despite being an invasive and expensive procedure. This obstruction is corrected by completely removing the adenoma and this is what guarantees the favorable results (11,12).

Open surgery has traditionally been the treatment of choice for benign, symptomatic, large size prostatomegaly.

Size of the prostate gland is an important consideration to select the appropriate surgical approach for the individual patient with symptomatic benign prostatic hypertrophy.
- Transurethral incision of prostate is efficacious for glands up to 30 cc in size.
- Transurethral resection of the prostate is the long-established gold standard surgical procedure for the medium-sized adenomas.
- Glands larger than 80–100 g may be better managed with open simple retropubic prostatectomy, especially in the presence of coexisting pathology, such as large vesical diverticulum, large/multiple bladder calculi, or severe hip ankylosis contraindicating a lithotomy position.

Considering that improvement of the obstructive symptoms is related to the amount of tissue that has been extracted and that transurethral resection of the prostate may be unable to extract large enough volumes in the case of large prostates (12), transvesical prostatectomy indeed improves obstructive symptoms efficiently. Newer transurethral techniques have been devised and developed to excise the largest possible amount of prostatic tissue. The use of the Holmium laser for this purpose has paved the way for the application of this principle (13,14). Using this technique, the adenoma is precisely dissected from the surgical capsule in the cleavage plane between the adenoma and the capsule in a retrograde direction. Hemostasis is achieved at the bleeding points with the wavelength of the laser beam. The resected fragments are deposited in the bladder, from where they are finally extracted with a transurethral morcellator (7,13–16).

The results of randomized prospective studies comparing transvesical prostate adenomectomy and transurethral prostate enucleation using Holmium laser evidenced a similarly significant improvement in the maximum urinary flow and in the volume of residual urine, as measured using the American Urology Association symptom score. Although surgical time was significantly longer in the Holmium group, blood loss, length of catheterization, and hospital stay were significantly shorter. The volume of extracted tissue was similar in both groups (6,7,15,16).

Persistence of the irritative symptoms due to the presence of residual, heat-damaged prostate tissue occurs more frequently after minimally invasive procedures (11). Chen et al. showed that the reduction of the prostate volume after transurethral resection of the prostate proportionally correlates to the rates of American Urology Association symptomatic score improvement (17). However, as shown by Roehrborn et al. in a cooperative study on the guidelines for the diagnosis and treatment of benign prostatic hypertrophy, the average resected tissue was only 22 g (1). Further, in a comparison between transurethral resection of the prostate and Holmium laser performed by Gilling et al., the estimated resected specimen weight was 15.5 and 21.7 g, respectively (14).

Indications for the laparoscopic surgery are constantly growing and expanding. Indeed, the benefits of this approach, including lower morbidity, limited pain, shorter hospital stay, and earlier return to normal working activities, have been largely proven. Thus, laparoscopic retropubic prostatectomy has the potential to combine the advantages of the minimally invasive techniques with the favorable results of open surgery.

Mariano et al. first reported laparoscopic simple prostatectomy performed in a patient with benign prostatic hypertrophy. A total of four hemostatic sutures were used for vascular control (18). Baumert et al. performed laparoscopic simple prostatectomy in 20 patients (19). van Velthoven et al. reported their initial experience with laparoscopic extraperitoneal Millin's prostatectomy in 18 patients (20). Nadler et al. recently reported preperitoneal laparoscopic approach for resection of a large prostatic adenoma in one patient (21). Sotelo et al. described their technique of laparoscopic simple retropubic prostatectomy in 17 patients with symptomatic significant prostatomegaly ($\geq$60 g on transrectal ultrasonography, mean 93 g) (22).

PATIENT SELECTION

Indications for laparoscopic simple retropubic prostatectomy for benign prostatic hypertrophy are listed in Table 1 (9). Table 2 shows relative and absolute contraindications for laparoscopic simple retropubic prostatectomy.

PREOPERATIVE PREPARATION

The patient should always be informed on the potential for open conversion should technical difficulties or complications not readily manageable by laparoscopic occur. The patient should also be advised of alternatives (open or transurethral surgery). Informed consent must be obtained.

TABLE 1 ■ Indications

Patients with symptomatic BPH with TRUS estimated gland weight of 60 g or more
Patients with obstructive prostatomegaly and associated surgical pathology such as multiple or large bladder calculi, inguinal hernia, large diverticula, a severe ankylosis of the hip that impairs the position of the patient that is required for transurethral resection

Abbreviations: BPH, benign prostatic hypertrophy; TRUS, transrectal ultrasound.

TABLE 2 ■ Relative and Absolute Contraindications

Relative contraindications
    Gross obesity
    Significant previous intraperitoneal or preperitoneal surgery
    Abdominal wall infection
    Bowel obstruction
Absolute contraindications
    Uncorrectable coagulopathy
    Cardiopulmonary contraindication
    Severe obstructive airway disease
    Morbid obesity

TABLE 3 ■ Preoperative Evaluation

History—physical examination
Routine laboratory test
PSA
IPSS and QoL
Uroflowmetry
TRUS

Abbreviations: IPSS and QoL, International Prostate Symptom Score and Quality of Life questionnaires; TRUS, transrectal ultrasound; PSA, prostate specific antigen.

As part of the preoperative workup, all patients should have a complete history and physical examination. Preoperative evaluation includes digital rectal exam, routine laboratory tests including prostate specific antigen, International Prostate Symptom Score and Quality of Life questionnaires, Uroflowmetry, and transrectal ultrasonography with measurement of prostate volume. Blood typing and cross-match should be performed (Table 3). Preoperative preparation is listed in Table 4.

LAPAROSCOPIC TECHNIQUE

The laparoscopic technique comprises nine steps as listed in Table 5.

Step 1: Patient Positioning

In the operating room, the patient is placed in the supine and modified Trendelenburg position. Pneumatic boots are placed on the lower extremities to prevent deep vein thrombosis. The arms are padded and tucked in by the patient's sides. General anesthesia is administered, and an indwelling urethral catheter is placed for bladder decompression.

Step 2: Creation of the Preperitoneal Space

A 1.5 cm subumbilical vertical incision is made, and extended to reach the preperitoneal fat. The index finger of the right hand is inserted, and digital dissection of the preperitoneal space is performed until the pubis is reached. To complete the dissection, a balloon device may be inflated in the preperitoneal space (20–22).

Subsequently, a 10-mm Hassan trocar is inserted in this space, CO_2 is insufflated at a pressure of 15 mmHg, and then a 10 mm, 0° scope is inserted.

Step 3: Trocar Placement

The preperitoneal space is further expanded under direct visualization. After identification of the left anterior–superior iliac spine, a 5 mm port is placed 2 cm medial to this bony landmark. A 5 mm trocar is placed on the left pararectal line, 1–2 cm caudal to an imaginary line extending from the umbilicus to the left anterior–superior iliac spine. In a similar manner, two additional ports are inserted in the contra lateral side of the abdomen. Overall, the port placement duplicates laparoscopic entry during extraperitoneal laparoscopic radical prostatectomy (Fig. 1) (23).

TABLE 4 ■ Preoperative Preparation

Bowel preparation is not routinely performed; but a clear liquid diet is advised for the day prior to the surgery and a bisacodyl suppository the night before surgery
Aspirin and other nonsteroidal analgesic or anticoagulants are discontinued one week before surgery
Low dose subcutaneus heparin low molecular weight in patients at high risk for deep vein thrombosis
Intravenous quinolones (Ciprofloxacin) is administered for antibiotic prophylaxis

TABLE 5 ■ Technical Steps for Laparoscopic Simple Prostatectomy

Patient positioning
Creation of the preperitoneal space
Placement of the tracers
Transverse cystotomy
Retraction of the medial lobe
Development of subcapsular plane
Prostatic adenomectomy
Trigonization of the prostatic fossa
Suture repair of the cystotomy

The space of Retzius is entered and the anterior surface of the prostate capsule is cleared of the overlying fatty tissue. The superficial dorsal vein on the anterior aspect of the prostate is carefully coagulated with the harmonic scalpel.

Step 4: Transverse Cystotomy

A transverse cystotomy is performed 1–2 cm proximal to the junction between the bladder and the prostate using harmonic scalpel or J-hook electrocautery. In this manner, the anterior bladder neck is incised and entry into the bladder lumen is gained. The bulging prostate, with or without median lobe, is now visualized.

Step 5: Retraction of the Median Lobe

If a large bulging median lobe is present, it can be efficaciously retracted anteriorly with a figure-of-eight stitch placed with either a Keith needle or a Carter–Thomason port-closure needle device. Both ends of the stitch are retrieved and anchored to outside the anterior abdominal wall (Fig. 2).

Step 6: Development of the Subcapsular Plane

A transverse (horizontal) incision is made on the bladder mucosa overlying the prostate lobes in the vicinity of the bladder neck area. This semicircular mucosal incision, extending from the 8 o'clock to the 6 o'clock and further extended to the 4 o'clock position, is deepened until the prostate adenoma is identified. Careful blunt and electrocautery dissection is performed to reach the proper subcapsular plane outside the prostate adenoma (Fig. 3).

Step 7: Prostatic Adenomectomy

Semicircular movements using the J-hook electrocautery, harmonic scissors, or the suction–irrigation cannula progressively free the adenoma from the internal surface of the prostate capsule. At this point, the initial mucosal incision is completed circumferentially. The left lateral lobe is dissected first, with the dissection proceeding distally in a largely avascular plane. Simultaneously, one assistant aspirates and countertracts this region with the suction cannula. This enables the surgeon to clearly visualize and further develop the cleavage plane between the adenoma and the capsule. Hemostasis is secured continuously with electrocautery or harmonic scalpel by controlling any perforating tethering blood vessels. Large volume prostate adenomas are divided and extracted piecemeal. Specific care is taken at the prostate apex at its point of transection from the urethra to avoid injury to the external sphincter and possible avulsion (Figs. 4–6).

Every attempt is made to maintain good hemostasis constantly during dissection, such that enucleation proceeds under clear visualization. Adequate control of the main prostatic vessels can be achieved with either the harmonic scalpel and/or hemostatic figure-of-eight sutures placed at 4 and 8 o'clock position at the bladder neck. The contralateral lobe of the prostate is enucleated in a similar manner.

Step 8: Trigonization of the Prostatic Fossa

Whenever there is a redundant or hypermobile incised edge of bladder neck mucosa, it is suture approximated to the floor of the prostatic fossa or to the posterior wall of the urethra in an attempt to trigonize the fossa (Fig. 7).

Step 9: Suture Repair of the Cystotomy

Once enucleation is completed and adequate hemostasis is obtained, a 22 to 24 French Foley catheter is inserted and its balloon inflated to 25–30 cc. The transverse cystotomy incision is closed in a watertight manner with a running 2-0 Vicryl stitch on a CT-1 needle. Bladder irrigation with saline solution is performed to assess watertightness of the incision. A Jackson–Pratt drain is inserted, the specimen is entrapped and extracted, and laparoscopic exit completed (Fig. 8).

TECHNICAL MODIFICATIONS

Mariano et al. performed an intraperitoneal technique in one patient (18). The prostatic capsule and the bladder neck were opened in the midline. Two hemostatic sutures of 2-0 polyglactin were used to control the dorsal vein complex and the puboprostatic liga-

FIGURE 2 ■ Retraction of the medial lobe with the Carter–Thomason port-closure device. The stitch is retrieved and anchored outside the abdominal wall.

FIGURE 3 ■ Developing the subcapsular plane with a transverse incision made back on the bladder mucosa overlying the prostate lobes in the vicinity of the bladder neck.

FIGURE 5 ■ The adenoma enucleation is continued.

ments, and two additional sutures were placed to secure the lateral pedicles of the prostate (near the bladder neck). Blood loss was 800 cc, and operative time was 3.8 hours.

van Velthoven et al. reported their initial experience with laparoscopic extraperitoneal Millin's prostatectomy in 18 patients (20). Their technique, which included hemostatic control of lateral venous vesicoprostatic pedicles, transverse

FIGURE 6 ■ The adenoma enucle-
ation is completed.

anterior incision of the prostate capsule, adenoma enucleation, and reconstruction of the posterior bladder neck and prostate capsule, is similar to the original technique described by Millin (2). In their series, mean operative time was 2.4 hours, and mean blood loss 192 cc.

An important technical modification by the authors consists of a transverse cystotomy incision proximal to the junction between the bladder and the prostate, instead of incising the prostate capsule itself. This cystotomy is created by using a harmonic scalpel or J-hook electrocautery. In our early cases, we attempted various technical maneuvers to minimize intraoperative hemorrhage, such as suture ligation of the dorsal vein complex after incising the endopelvic fascia, and extravesical suture ligation of the lateral prostate pedicles bilaterally. Later, a transverse or longitudinal anterior capsulotomy of the prostate gland was attempted. In our experience, none of these maneuvers reliably provided a bloodless field. In fact, it is now our impression that performing a capsulotomy directly over the anterior surface of the prostate gland may transgress the subcapsular venous plexus, contributing to increased blood loss. Incising the bladder neck just proximal cephalad to the prostatovesical junction to gain entry into the urinary bladder, thereafter entering the subcapsular plane posteriorly and posterolaterally, and its subsequent circumferential development is effective in decreasing blood loss.

Several maneuvers had been described to facilitate the enucleation of the adenoma. Njinou Ngninkeu et al. described an extraperitoneal laparoscopic prostatic adenomectomy assisted by the index finger inserted through the abdominal wall for digital enucleation of the adenoma after the removal of the medial port and a 2-cm enlargement of the port (24). Nadler et al. used a fan retractor and laparoscopic shears to enucleate the adenoma (21). We perform the enucleation with the "Sotelo Prostatotome," a device designed by the senior author. It is similar to a curette or an osteotome and facilitates the enucleation of the adenoma during laparoscopic simple prostatectomy. Its metallic, curvilinear tip with a sharp cold-knife on the distal side of the forceps divides the adherence between the adenoma and its capsule during circumferential dissection of the gland (Fig. 9; Tables 6 and 7).

PROS AND CONS OF VARIOUS TECHNIQUES

Compared to open surgery, all laparoscopic techniques mentioned above have limitations, including a steep learning curve and the requirement of significant laparoscopic expertise. In all the reported series, operative time was significantly longer than the conventional open surgical adenomectomy. Compared to open surgery, laparoscopic techniques may result in decreased blood loss, shorter hospital stay, shorter postoperative length of catheterization (range 3–10 days), less postoperative pain, lower morbidity, and shorter convalescence. The ability to precisely transect the prostate adenoma at its apex under magnified laparoscopic visualization, while maintaining the integrity of the sphincteric zone of the membranous urethra, is superior compared to open surgery. Unlike open surgery, the surgeon does not insert the index finger in the open capsule nor are any intravesical retractors placed, thus decreasing the risk of capsular trauma and potential capsular avulsion (18–21).

FIGURE 8 ■ The prostate capsule is suture approximated anteriorly.

FIGURE 7 ■ Trigonization. The trigone is advanced into the floor of the prostate fossa or into the posterior wall of the urethra.

Bladder entry also allows the concomitant management of any coexistent intravesical disease such as bladder calculi. A benefit of this technique, similar to open surgery, is the nearly complete removal of the entire adenoma thus achieving complete clearance of the obstructive symptoms. Complications of transurethral surgery, such as the transurethral resection syndrome, which occur due to prolonged resection times frequently noted with the larger glands do not occur during laparoscopic simple prostatectomy.

Advantages of the technique proposed by van Velthoven's include its preperitoneal nature, the relatively short operative time (2.4 hours), and limited blood loss (192 mL). However, it is our feeling that a direct capsulotomy over the anterior surface of the prostate gland potentially transgresses the subcapsular venous plexus and contributes to increased blood loss. In van Valthoven's series, the average specimen weight of the excised prostate was equal to only 50% of the gland weight estimated on preoperative transrectal ultrasonography (20).

We described an extraperitoneal technique for laparoscopic simple prostatectomy in 17 patients. Blood loss was 516 mL, operative time 156 minutes, and average specimen weight was 72 g, representing 77% of the preoperative transrectal ultrasonography estimated weight.

TECHNICAL CAVEATS AND TIPS

An important technical caveat is that subcapsular dissection should proceed in close contact with the whitish surface of the prostatic adenoma, with this plane being further developed bluntly with a combination of J-hook electrocautery, harmonic scalpel, Sotelo prostatome, or suction–irrigation cannula tip. Small vessels entering the adenoma can thus be precisely identified and electrocoagulated.

Maintaining a thick prostate capsule is important to minimize violation of the subcapsular venous plexus. Using this technique we have not encountered significant hemorrhage from the prostatic vessels entering the prostatic capsule at the 4 o'clock and 8 o'clock positions.

Attempting to extract the entire prostatic lobe intact may actually impair visualization, contributing to increased blood loss. Hence, piecemeal excision of the already mobilized part of the adenoma provides superior visualization of the remaining part of the adenoma, allowing better hemostasis.

SPECIFIC MEASURES TAKEN TO PREVENT COMPLICATIONS

The transverse cystotomy incision should not be extended onto the prostate capsule, but must remain limited to the bladder wall exclusively. The adequate plane for incision may be identified by laparoscopic sense of touch over the surface of the prostate and the bladder using a laparoscopic forceps to appreciate the different consistency of the two tissues; the edge of the prostate is easily recognized moving the catheter inside the lumen of the prostatic urethra and the bladder.

Special attention should be directed to avoid any comprise of the ureteral orifices. Any source of bleeding in the prostate bed should be definitively controlled with the J-hook, the harmonic scalpel, or a hemostatic stitch.

INTRODUCTION

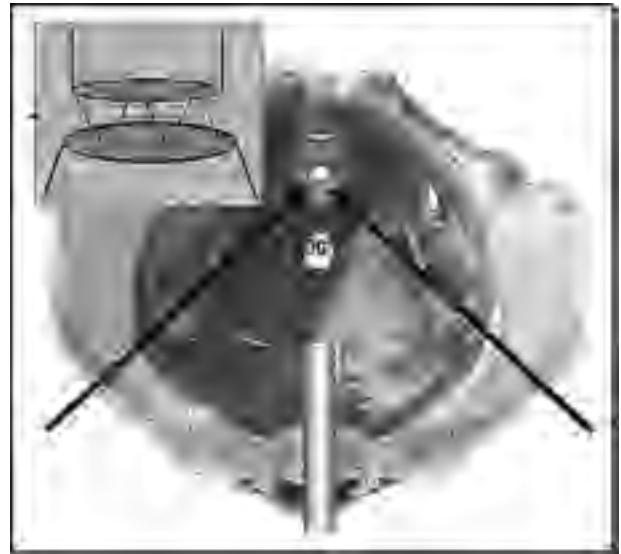
Laparoscopic radical prostatectomy represents a "minimally invasive approach" to conventional retropubic radical prostatectomy (1). The technique, however, requires a significant learning curve even for experienced laparoscopic surgeons (1–3). Indeed, it is estimated that the steep part of the learning curve extends over 40 to 50 cases (4). One area of difficulty is mastering laparoscopic suturing techniques in order to perform the urethrovesical anastomosis, which is one of the most demanding steps of the whole procedure. According to Schuessler et al., it represents the part of the procedure requiring the greatest time, taking twice as long as the removal of the prostate (1). However, this technique needs to be standardized at the very beginning of the laparoscopic experience in order to improve its ergonomics and accuracy.

It is trivially obvious to say that urethrovesical anastomosis comes at the end of the radical prostatectomy itself. When the prostate is removed through a laparoscopic approach, the difficulty inherent to this maneuver may be increased by the variable length of the former technical steps, with a direct impact on the surgeon's fatigue and hence on eventual shortcomings compromising the suture's quality. Suturing in the deep pelvis is moreover submitted to anatomical variations able to disturb the suturing technique.

Laparoscopic technique offers optimal light conditions under the pubic symphysis and the 10- to 12-fold magnifications permits accurate placement of the sutures which was never approached with open techniques (5). Nevertheless, the reduction of the work space, the distance from the bladder neck to the urethral stump, the weight of a filled bladder in Trendelenburg position, the impaired axial vision in a two-dimensional space, all these usual conditions may lead urologists with limited laparoscopic experience to face severe problems at the end of a demanding procedure. Several technical prerequisites, which are inherent to the whole operative protocol, may yet improve this situation.

PATIENT POSITIONING

At the moment of the suture, steep Trendelenburg is less contributive than during the antegrade dissection of a transperitoneal approach. The reduction of this inclination may ease the ascension of the bladder.

FIGURE 1 ■ View of the pelvis, the working axes of the needle holders are represented with respect to the anatomical position of the urethrovesical anastomosis.


SURGEON POSITIONING

The urethrovesical anastomosis is generally carried out with preferably two needle holders, eventually with one needle holder in the dominant surgeon's hand, assisted by a straight or Maryland forceps. The choice of the trocars defines the spatial relationship between the needle holders and hence has also a direct impact on the suturing technique.

It has been described by Frede et al. (6) that the angles between the instruments and the suture line are of outmost importance. Acute angles between instruments of 25° and 45° maximize the efficiency of suturing and knotting. This statement is adopted by several teams, irrespectively of the trocar placement. In addition, angles inferior to 55° between needle holders and the horizontal plane simplify also these maneuvers. If the latter sentence seems quite obvious in order to reduce surgeon's fatigue and frustration, the former appears more questionable.

As the urethrovesical suture line is anatomically oriented in the horizontal plane, suturing maneuvers and appropriate needle direction may be eased by needles working as much as possible in a vertical plane, that is perpendicular to the suture plane (Fig. 1). Taking into account the respective orientations of the needle and of the needle holder tip, this is hardly feasible if the main needle holder works through a midline port. In this situation, the needle should work rather parallel to the suture line and this might compromise the achievement and the quality of some stitches with respect to the position of the urethral stump.

In the author's view, needle holders should work preferably with an angulation between 60° and 90°, through the lateral or the pararectal ports.

As a matter of fact, this favorable situation is reproduced when the suture is "robot-assisted." It is well known that the working arms of the "slave system" work through the lateral iliac ports, reproducing as such an ideal isosceles triangulation shape with "the eyes of the surgeon" materialized by the lens, located on the midline port.

> In the author's view, needle holders should work preferably with an angulation between 60° and 90°, through the lateral or the pararectal ports.

PREPARATION OF THE URETHRAL STUMP

The preserved length of the urethra is essential to the quality of the urethrovesical anastomosis.

As the urethra is classically sharply cut in a stretched position, with the assistance of a cephalad traction on the prostate, a subsequent retraction of the urethra is expected after section (7). The presence of an 18-French catheter or of a urethral dilator facilitates the exposition of the stump with eventual assistance of a gentle push on the perineum at the level of the bulbar urethra.

> The preserved length of the urethra is essential to the quality of the urethrovesical anastomosis.

PREPARATION OF THE BLADDER NECK

Complete resection of the prostate unavoidably removes a significant length of urethra, according to the prostate's size.

Relative preservation of the bladder neck contributes to the feasibility of the anastomosis not only in terms of smooth muscle preservation but also by the saving of available centimeters of tissue to fill the prostate gap.

A wider opening of the bladder neck, in case of the presence of a large median prostatic lobe has only reduced impact on the anastomotic technique (8).

The posterior lip of the bladder neck is generally approximated first to the posterior urethra. In case of excessive discrepancy between the diameters of both organs, an anterior vesicoplasty will be carried out at the end of the anastomosis in most of the cases. A posterior vesicoplasty, performed prior to the anastomosis, is generally not necessary but must be achieved only when the ureteric orifices are at 5 mm or less from the bladder limit; this suture is carried out with either interrupted or running stitches; it allows for a larger safety distance between orifices and suture line but may also enable the anastomotic technique by reducing and tubulizing the diameter of the bladder neck. This latter artifice becomes mandatory in case of previous transurethral resection of the prostate or of Millin's adenomectomy; in these instances, both the ureters are at high risk of obstructive stretching if the bladder is simply pulled down toward the urethra.

Three main techniques are presented in the literature to achieve the vesicourethral anastomosis: the Montsouris technique (8) for interrupted sutures; the running suture, popularized by Gaston in Bordeaux and described in 2000 by the group of Creteil (France) (5); and the modified running suture, described by our group (9–11).

URETHROVESICAL ANASTOMOSIS IN THE MONTSOURIS TECHNIQUE

This protocol was described by Guillonneau and Vallancien (8) after a continuous cohort of 260 patients operated in 23 months. According to these authors, when compared to the technique described by Walsh (12), it is not necessary to evert the bladder mucosa or to narrow the bladder neck. Knots may be formed inside or outside of the anastomotic lumen. The surgeon works with two needle holders all along this step.

Anastomosis is performed with interrupted 3-0 resorbable 4/8 or 5/8 sutures on a No. 26 needle.

All sutures are tied intracorporeally, although the assistance of a knot pusher may ease the maneuver for beginners. For internally tied interrupted sutures a 6-in. length is sufficient. A metal Benique dilator with a depressed tip allows for the placement of the needle into the urethra and the metal sheet can also help by allowing the needle to slide along the dilator.

The first suture is placed at the 5 o'clock position, running inside-out on the urethra (right hand, forehand) and outside-in on the bladder neck (right hand, forehand). The knot is tied inside the urethral lumen (Fig. 2). Then four sutures are placed symmetrically at the 2, 4, 8, and 10 o'clock positions, the knots are tied outside the lumen.

For a right-handed surgeon, the right-sided sutures run outside-in on the bladder (right hand, forehand) and inside-out on the urethra (left hand, backhand). The left-sided stitches run outside-in on the urethra (right hand, forehand) and inside-out on the bladder neck (right hand, forehand). Finally two sutures are placed at the 11 and 1 o'clock positions, running outside-in on the urethra (right hand, forehand) and inside-out on the bladder neck (right hand, forehand, on the left; left hand forehand, on the right) (Fig. 3). These two last sutures are tied only when the Foley catheter has been correctly positioned in the bladder and checked. The knots are tied outside the lumen, without any risk of balloon injury. The balloon is inflated with 8–10 cc and the bladder is irrigated with 120–200 mL of saline to assess the watertightness of the anastomosis.

Türk et al. described a similar approach in 2001 (13) without major modifications; for these authors, the anastomosis requires 8 to 10 single stitches of 2-0 Vicryl. The same year, Gill and Zippe reported the same attitude; moreover, they described carefully the choreographed sequence of planning and placing the interrupted sutures (Table 1) (7).

Stitch placement is performed using both hands, because more than 50% of the sutures are passed with the left hand.

These authors also address the possible difficulties encountered when starting the sutures. Per Türk et al., to facilitate placement of the initial two stitches, a sponge stick can be employed to place perineal pressure, thereby presenting the urethral stump somewhat more clearly. Difficulties encountered with the placement of the Foley catheter may be

FIGURE 2 ■ Urethrovesical anastomosis in the Montsouris technique. The first suture is placed at the 5 o'clock position, running inside-out on the urethra (right hand, forehand) and outside-in on the bladder neck (right hand, forehand). The knot is tied inside the urethral lumen.

FIGURE 3 ■ Urethrovesical anastomosis in the Montsouris technique. Finally two sutures are placed at the 11 and 1 o'clock positions, running outside-in on the urethra (right hand, forehand) and inside-out on the bladder neck (right hand, forehand, on the left; left hand forehand, on the right).

> If the posterior stitches are too distant to each other, a "fausse route" may develop during catheter insertion. This gap may also cause delayed healing of the anastomosis at the 6 o'clock level, which may require considerable additional catheter time.

solved by a finger placed into the rectum to lift the bulbar urethra anteriorly; alternatively a catheter insertion mandrin (Guyon) can be employed (7).

If the posterior stitches are too distant to each other, a "fausse route" may develop during catheter insertion. This gap may also cause delayed healing of the anastomosis at the 6 o'clock level, which may require considerable additional catheter time.

RUNNING SUTURE TECHNIQUE FOR VESICOURETHRAL ANASTOMOSIS

Hoznek et al. started their own laparoscopic experience with prostatectomy about six months later than the Montsouris group. One will notice that these authors moved very early to a running suture to deal with the urethrovesical anastomosis. This attitude aimed at sparing the time devoted to knots on interrupted stitches as well as to avoid any intraluminal knotting (5).

The patient is positioned in dorsal decubitus, with the legs slightly spread to allow intraoperative rectal examination. Five trocars are used; as already mentioned, trocar disposition has primary importance in the anastomotic technique, because they determine the axis of the needle holder, plane of the needle, and angle between the instruments. Once the prostate is excised, there is usually no need to perform a racket

TABLE 1 ■ Choreographed Sequence of Successive Stitches in Interrupted Vesicourethral Anastomosis

FIGURE 4 ■ The running suture technique. A starter knot is done at the 3 o'clock position, the suture is conducted from outside-in on the bladder, then from inside of the urethra to the outside. For both needle passages, we use the right needle holder. The suture is then tightened with intracorporeal technique.

FIGURE 5 ■ The running suture technique. One or two sutures are then placed near the 6 o'clock position of the bladder and urethra. The sutures at the bladder side are easier to perform with the more horizontal left needle holder.

The vesicourethral anastomosis consists in a posterior and an anterior hemicircumferential running suture. Two needle holders are used simultaneously.

handle bladder neck reconstruction. Indeed, due to improved visibility and identification of anatomic landmarks during laparoscopy, the bladder neck is often sectioned in the optimal plane.

The vesicourethral anastomosis consists in a posterior and an anterior hemicircumferential running suture. Two needle holders are used simultaneously.

The right needle holder is inserted through the 12-mm disposable trocar situated at the right margin of the rectus sheath. This trocar allows also the passage of the suturing material: a 3-0 Vicryl suture with a 26-mm needle, where the optimal length of the suture is about 20 cm. The left needle holder is passed through the 5-mm port near the left anterior superior iliac spine. One will notice here again that this implies an angle of at least 60° between the needle holders axes. The surgeon manipulates these two needle holders. The first assistant holds the 0° lens which is passed through the 12-mm trocar at the umbilicus. In the other hand, he holds the suction–irrigation device, passed through the left 12-mm trocar. The suction–irrigation device allows exposing the bladder neck and removing the accumulated urine from the operating field. A second assistant or the instrumentalist uses a narrow forceps to hold the long tail of the running suture. On the urethral side, the long tail is maintained under traction in the direction of the symphysis, while on the bladder side it is pulled cephalad.

A starter knot is done at the 3 o'clock position. The suture is placed from outside in on the bladder, then from inside of the urethra to the outside. For both needle passages we use the right needle holder. The suture is then tightened with intracorporeal technique (Fig. 4). Next, the needle is passed from outside to inside of the bladder, below the starter knot, at the lower margin of the bladder neck in the 4 o'clock position. This is done with the right needle holder. One or two sutures are then placed near the 6 o'clock position of the bladder and urethra. The sutures at the bladder side are easier to perform with the more horizontal left needle holder (Fig. 5). For the left lateral zone of the bladder neck and urethra, we use the right needle holder (Fig. 6).

For the terminal knot of the posterior hemicircumferential suture, a closed loop is prepared at the 9 o'clock position. The needle is passed from inside to outside on the bladder, then from outside to inside on the urethra, thus forming a loop, and again from inside to outside on the bladder side. The suture line is thus ended extramurally with a three-legged. The Foley catheter is pushed without any difficulty into the bladder.

Then, a second running suture is realized on the anterior margin of the bladder and urethra, beginning at the 2 o'clock position on the bladder side, then in the urethra with the help of the right needle holder (Fig. 7). Two or three needle passages

FIGURE 6 ■ The running suture technique. For the left lateral zone of the bladder neck and urethra, we use the right needle holder.

FIGURE 7 ■ The running suture technique. Then, a second running suture is realized on the anterior margin of the bladder and urethra, beginning at the 2 o'clock position on the bladder side, then in the urethra with the help of the right needle holder. Two or three needle passages are sufficient to close entirely the anterior aspect of the anastomosis.

are sufficient to close entirely the anterior aspect of the anastomosis. A loop is again formed at the 10 o'clock position and the knot is tied. These different sutures are performed with deliberate structured and error-free choreography, which has evolved progressively during the developmental phase of laparoscopic radical prostatectomies.

SINGLE KNOT METHOD FOR THE LAPAROSCOPIC RUNNING URETHROVESICAL ANASTOMOSIS

This protocol was developed in Brussels in December 2000, after a continuing cohort of 85 patients operated in 20 months, of whom 75 underwent an interrupted suture tied extracorporeally for the very first, then intracorporeally according to the Montsouris technique, and 10 patients had a running suture for the anastomosis.

Since 2000, about 265 consecutive patients have been treated with this modified running suture consisting of one single intracorporeal knot (9–11).

After laparoscopic removal of the prostate has been accomplished, the bladder neck is identified. The running suture is prepared by tying together the ends of two 5–7 in. sutures of 3-0 or 2-0 monolayer polyglycolic acid; when available one thread is dyed and the other is not dyed, for easy identification purposes. The running stitch is initiated by placing both needles (SH or UR-5) outside in through the bladder neck and inside out on the urethra, one at 5:30 position and the other needle at 6:30 (Fig. 8). The sutures are run from the 6:30 and 5:30 positions to the 9 o'clock and 3 o'clock positions, respectively, approximating the bladder and urethra at each pass. The posterior lip of the bladder neck is left apart from the posterior urethra as long as the two first runs on the urethra and the three first runs on the bladder are not completed (Fig. 9). When this is achieved, a gentle traction is exerted on each thread simultaneously or alternatively, and the system of loops acts as a "whinch" to bring the bladder in contact with the urethra without any excessive traction on the latter. For that purpose, the presence of the knot at 6 o'clock position allows to keep two equal suture branches when pulling and forces the bladder to move as the fixed point of the whinch. At this point, the 16-French silastic catheter used during the whole procedure is placed into the bladder. Proceeding in this manner, both knots might reside on the bladder side of the anastomosis, this is

Since 2000, about 265 consecutive patients have been treated with this modified running suture consisting of one single intracorporeal knotch.

FIGURE 8 ■ The "single knot" running suture technique (all stitches are labeled according to Table 2). The running stitch is initiated by placing both needles (SH or UR-5) outside in through the bladder neck and inside out on the urethra, one at 5:30 position and the other needle at 6:30.

FIGURE 9 ■ The "single knot" running suture technique (all stitches are labeled according to Table 2). The sutures are run from the 6:30 and 5:30 positions to the 9 and 3 o'clock positions, respectively, approximating the bladder and urethra at each pass. The posterior lip of the bladder neck is left apart from the posterior urethra as long as the two first runs on the urethra and the three first runs on the bladder are not completed.

avoided between sutures 7 and 8 to end on the urethral side with the right thread and on the bladder side with the left one (Fig. 10). Carrying the suturing up to the 12 o'clock position on both sides, going outside in on the urethra and inside out on the bladder completes the remaining closure (Fig. 11). At 12 o'clock, the ends of the running sutures are tied to one another on the outside of the bladder (Fig. 12). The choreographed

FIGURE 10 ■ The "single knot" running suture technique (all stitches are labeled according to Table 2). As such, going on this way, both knots might reside on the bladder side of the anastomosis, this is avoided between sutures 7 and 8 to end on the urethral side with the right thread and on the bladder side with the left one.

FIGURE 11 ■ The "single knot" running suture technique (all stitches are labeled according to Table 2). Carrying the suturing up to the 12 o'clock position on both sides, going outside in on the urethra and inside out on the bladder completes the remaining closure.

FIGURE 12 ■ The "single knot" running suture technique (all stitches are labeled according to Table 2). At 12 o'clock, the ends of the running sutures are tied to one another, intracorporeally, on the outside of the bladder.

sequence of all sutures are described in Table 2. This table also illustrates the reduced need to sew with the left or nondominant hand although ambidextrous skills remain useful to some extent.

If some discrepancy persists between the diameters of the urethra and of the bladder neck, some residual anterior opening of the bladder is closed at that moment in two layers with the same sutures; in that case, both lengths of threads are increased accordingly to about 20 cm. The balloon on the 20-French silastic catheter is filled with 10 cc of water; the bladder is irrigated until clear with approximately 60 cc of sterile water. A drain is placed and is usually removed on the first postoperative day. The catheter is normally left in place for five to six days, and removed after a retrograde cystogram.

One of the major advantages of laparoscopic radical prostatectomy is its potential to perform all the sutures under total visual control. However, knotting of the sutures is time consuming and contributes to prolonged operating time (1). In open surgery, in fact, a half-knot necessitates less than two seconds, whereas the same requires 15 to 20 seconds during laparoscopy.

DISCUSSION

As stated by Hoznek et al., in open retropubic radical prostatectomy, the pubic bone impairs the visibility and the access to the urethral stump making the placement of the sutures difficult. In addition, the surgeon must tie the knots in a blind field and must rely on tactile sensation only. Therefore, there is a risk of inadequate suture knot positioning. Moreover, if the knot is pulled too strongly it may tear out of the urethra, whereas if it is too loose, the vesical neck and the urethral stump will not be correctly aligned (5).

One of the major advantages of laparoscopic radical prostatectomy is its potential to perform all the sutures under total visual control. However, knotting of the sutures is time consuming and contributes to prolonged operating time (1). In open surgery, in

fact, a half-knot necessitates less than two seconds, whereas the same requires 15 to 20 seconds during laparoscopy (14).

The difficulties inherent to vesicourethral anastomosis are illustrated in conventional open retropubic prostatectomy where several authors developed maneuvers designated to ease the approximation of the bladder to the urethra or the suture technique itself, some of these tips might be transposed to laparoscopy.

The exposition of the urethra may be eased by a Benique dilator, held by the assistant at the edge of the cut urethra; the manipulation of its tip opens the urethral stump according to the various orientation of the needles requested for the four to seven stitches generally used for the anastomosis (8). Currently, the dilator may be replaced by a Foley catheter, put in tension by a traction on its tip combined by a counter-traction on a forceps placed at the urethral meatus. These artifices are used in open and in laparoscopic surgery.

For tying the knots after an open procedure, surgeons may temporarily "hire the assistance" of a laparoscopic instrument like a knot pusher, combined with a Reuder knot, to ease the maneuver when tactile control seems insufficient (15). Approximation of the bladder to the pelvic floor may be eased by additional sutures, sometimes placed through the perineum (16) in case of morbid obesity (17). Novicki et al. consider even the modified Vest suture as a valid alternative to direct anastomosis, providing similar results in terms of long-term continence (18). Anchoring the bladder to the pelvic wall near the urethra is also realized by modified sutures tying the surface of bladder neck to the base of the urethral stump (19). Beyond anecdotical reports, none of these artifices where ever described in laparoscopy where the visual advantage of a direct approach and the magnification factor seem to solve most of the technical problems, in conjunction with a relatively wider perivesical dissection allowing for a direct anastomosis.

Assistance to the open suturing procedure is brought either by a Foley catheter leading the needle to the urethral lumen (20) or by several suturing devices such as Maniceps® (21,22) or Endostitch® (23). It seems here again that skilled laparoscopic surgeon solved most of the suture technique problems with straight or slightly curved needle holders combined to 4/8 or 5/8 22–26 mm needles.

In laparoscopic vesicourethral anastomosis, the main difficulty may still reside in the tying of the first knot. In fact, this step must successfully achieve two main goals, as the approximation of the bladder as well as the adequate start point of an immediately watertight anastomosis.

Quality control problems with interrupted sutures are illustrated by the complication rates observed even on large cohorts; however, one must yet remain aware of the fact that these cumulative series also describe forever the discovery-learning curve of these protocols. Guillonneau and Rozet reported about 57 cases out of 567 (10%) with early urine leakage resulting in aspiration of urine by the suction drain (24). In 43 patients, the diagnosis occurred before the removal of the catheter and healing followed spontaneously with longer catheter drainage. Two patients requested percutaneous aspiration of urine, while one patient had to be reoperated laparoscopically. In 11 cases, catheter removal was followed by a status of acute pain, acute urinary retention, and peritoneal irritation syndrome, leading to the diagnosis of secondary anastomotic leakage requiring continuous bladder drainage for another week.

The reported difficulties encountered in vesicourethral reconstruction during laparoscopic prostatectomy prompted the group of Creteil to use two hemicircumferential running sutures for the anastomosis instead of interrupted sutures, which so far, were used in all of the reported series (3,4,25). The authors also observed four cases of intraperitoneal urine extravasation in the beginning of their experience; these patients requested open or laparoscopic repair, for three and one of them, respectively. No reoperation was necessary for the second half of the experience in Creteil, although postoperative cystography, performed at postoperative days 4 to 5, demonstrates that about 15% of patients have at least some degree of anastomotic leak (26).

To ensure the quality of the direct anastomosis, Türk et al. emphasize the importance of an atraumatic and precise dissection of the bladder neck. They observed 13.6% anastomotic leakage in their series of 125 patients, almost all of them gathered during the learning curve; overzealous use of diathermy around the bladder neck was estimated responsible for these relatively poor results (13).

Beside the arguments in favor of running techniques to increase the watertightness of anastomoses, several experimental studies on small bowel demonstrate, that the time required is significantly shorter with running sutures compared to interrupted sutures. However, interrupted sutures are often preferred on small bowel, because running sutures may lead to anastomotic stenosis when the suture line is tightened (27). In

spite of this, stenosis almost never occurs on urethrovesical anastomosis with running sutures, because the Foley catheter prevents early narrowing of the anastomotic circumference and because reduced extravasation prevents subsequent fibrosis.

Increased surgical precision may reduce the risk of postoperative urethral strictures. Catalona et al. reported 4% urethral strictures in his series of 1870 open prostatec-tomies (28). Furthermore, as reported for the Medicare population, transurethral incision in 3.3%, transurethral resection in 2.9%, and urethral dilation in 7.3% were performed, respectively, after radical retropubic prostatectomy, for the relief of urethral or bladder neck strictures (29). Vesicourethral anastomosis stricture is reported as high as 0.48% to 32% in the literature; several comorbidity conditions may influence this outcome of surgery through the mechanism of microvascular disease having a direct impact on oxygenation and tissue healing (30,31).

Strictures after laparoscopic prostatectomy were reported in 2.8% only by Rassweiler et al. (32) and in only 0.5% during the further experience of Abbou and coworkers (33).

In the author's own experience, only 4/265 (1.5%) anastomotic or urethral strictures with a mean follow-up above 18 months (range, 1–43 months) were observed. This compares favorably with the 4/85 cases (4.7%) observed with our initial series of patients. The difficulties already mentioned with the first knot remain true with the technique of two hemirunning sutures, where the anastomosis is initiated by approximating the bladder neck to the urethra at the 3 o'clock position with one suture only.

Our technique described herein as the single knot method, offers further simplification of the running suture technique. The first knot is prepared extracorporeally by joining the two ends of the threads together. After both needles are passed through the posterior bladder neck and urethra, the bladder neck is easily moved into position at the 6 o'clock position where the knot sits. So, the entire bladder neck from the 5:30 to 6:30 position is moved as a unit toward the urethra, acting much as a mattress suture. After one suture is run from the 5:30 position to the 3 o'clock position, the other suture is run from the 6:30 to 9 o'clock position. We believe this latter method may decrease the chances of pulling through the initial suture. The catheter is then placed into the bladder. The transition suture allows the stitch to now exit the bladder on its outer surface. The sutures are continued to the 12 o'clock position and tied to each other. This solitary intracorporeal knot now, like the initial extracorporeal knot, rests on the bladder side of the anastomosis.

This simplification of the running suture technique has now been adopted by several teams. For example, Menon et al. moved from the two hemicircle running suture to the single knot technique during their experience with robot-assisted prostatectomy (34,35). This technique was also firstly adopted by Ahlering et al. during the development of his own robot-assisted protocol of laparoscopic prostatectomy (36,37).

The impact of the suturing technique on the days before catheter removal was nicely illustrated by Gill and coworkers (38); they showed that mean catheter time after interrupted, two hemirunning, and single knot running suture at one institution were 14.4 ± 8.4, 9.0 ± 9.2, and 7.6 ± 6.7 days, respectively.

Contrary to our initial concerns with an interrupted suture anastomosis, there have been few problems with bladder neck contractures that have come to our clinical attention. However, we have not been routinely performing cystoscopy on our patients to assess for this problem. Not surprisingly, symptomatic postoperative urinary extravasation has not occurred. Based on a retrograde cystogram, 17/265 patients operated at our center or during mentoring of coworking teams requested additional catheter time beyond days 5 to 7 postoperatively. We believe the initiating mattress-type stitch at the 5:30 to 6:30 position area effectively buttresses and seals this area while the running nature of the closure further results in a urine-tight anastomosis. Referring to our personal experience, we believe also that the avoidance of even minimal urine leak between the suture points may reduce the rate of anastomotic strictures observed by other authors with separated stitches.

It may seem meaningless to compare these running techniques whose results are rather comparable in skilled hands; reduction of operative time was certainly obtained through the development of a stepwise standardized protocol for the whole laparoscopic prostatectomy.

The choreographic sequence of technical steps is closely linked to a thoughful reflexion about suturing ergonomy. The best and easiest anastomoses are obtained through an iterative sequence of maneuvers, ensuring an optimal management of the needle exchange between both needle holders.

Strictures after laparoscopic prostatectomy were reported in 2.8% only by Rassweiler et al. and in only 0.5% during the further experience of Abbou and coworkers.

The choreographic sequence of technical steps is closely linked to a thorough reflexion about suturing ergonomics. The best and easiest anastomoses are obtained through an iterative sequence of maneuvers, ensuring an optimal management of the needle exchange between both needle holders.

Not surprisingly are these maneuvers accomplished in an improved ergonomic environment when the prostatectomy is robot-assisted.

Currently, daily conventional laparoscopic practice may be enabled by the respect of a strict spatial organization of the needle holders in the working space. The axes of the instruments should work at an angle of 60° to 90°; through pararectal or lateral ports. In this position, when the needle is prepared for stitching, its curve is situated in a vertical plane, hence the jaws of the working needle holder belong to an horizontal plane, perpendicular to the needle plane. If the second needle holder is moved to place its jaws in the same plane as the needle, then when the latter will be pulled through the stitch, a slight rotation of the wrist will replace it immediately ready to be caught for another stitch. This rule works irrespectively of the right or left side of the working hand and with either forehand or backhand maneuvers and of course with interrupted or running sutures. This type of ergonomic rule may be reproduced for any type of suture such as for pyeloplasty or in case of robot-assisted procedures. In our experience, this technique brought our suturing time for urethrovesical anastomosis around 20 minutes during a whole prostatectomy lasting 2 to 2.5 hours.

Basic suturing principles should always be taught in dry boxes where these ergonomic rules are easily illustrated; thereafter, their application to tissues could be extended to still and live animal models such as simple chicken skin models (39,40), chicken breast models (41,42) or in surgery on the pig or on human cadavers (43,44). The chicken thoraco-abdominal cavity reproduces very nicely the human pelvis hollow cavity. The esophagus dissection starts at the joint with the glandular stomach releasing it basically, from the surrounding fat; the esophagus-gastric junction is then divided sharply.

In the chicken model, the "intrapelvic perspective" on the esophagal stump and on the gastric lumen will easily reproduce the vesicourethral picture. This model is easily adapted to learn interrupted or running suture techniques, and is undebatably cost-effective when compared to other sophisticated models available.

This model is easily adapted to learn interrupted or running suture techniques, and is undebatably cost-effective when compared to other sophisticated models available.

SUMMARY

■ Urethrovesical anastomosis is one of the most demanding steps of the whole laparoscopic prostatectomy.
■ The pubic bone impairs the visibility and the access to the urethral stump making the placement of the sutures difficult.
■ The preserved length of the urethra is essential to the quality of the urethrovesical anastomosis.
■ Relative preservation of the bladder neck contributes to the feasibility of the anastomosis.
■ The best and easiest anastomoses are obtained through an iterative sequence of maneuvers, ensuring an optimal management of the needle exchange between both needle holders.
■ In laparoscopic vesicourethral anastomosis, the main difficulty may still reside in the tying of the first knot; this step must successfully achieve two main goals, as the approximation of the bladder as well as the adequate start point of an immediately watertight anastomosis. The use of two hemicircumferential running sutures instead of interrupted sutures greatly simplified a crucial part of laparoscopic radical prostatectomy. Such technical advances made laparoscopic prostatectomy coming closer to the operating times of open radical prostatectomy while reducing postoperative morbidity.
■ The "single knot" running urethrovesical anastomosis described offers another simplifying step to the laparoscopic surgeon interested in performing laparoscopic radical prostatectomy. The method is easy to learn and perform, is watertight and appears to have a low risk of bladder neck contracture. This may enable surgeons with limited suturing experience to master this difficult technical step, unavoidably located at the end of a very challenging procedure.

MINILAPAROSCOPIC UROLOGIC SURGERY

Anoop M. Meraney

Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

Technologic innovations constantly influence current surgical practice. Minimally invasive surgery has been particularly influenced by the development of newer technology and refinement of existing technology. Development of sophisticated and miniaturized optical systems led to the beginnings of minilaparoscopic surgery. Initially, minilaparoscopy was used primarily as a diagnostic tool in gynecologic surgery. Amongst the initial minilaparoscopes was a system developed by Medical Dynamics[a] in Englewood, Colorado. The system consisted of optical fibers, incorporated in fiber-optic bundles known as "optical catheters." Utilizing this technology, Dorsey and Tabb reported their experience with minilaparoscopic myomectomy, adhesiolysis, and biopsy and laser coagulation of endometriosis tissue in 1991 (1). More recently, numerous therapeutic applications of minilaparoscopy have been described in general surgery, endocrine surgery, gynecology, thoracic surgery, and urology.

Various terms have been used in the literature to describe laparoscopic surgery that is performed utilizing small caliber laparoscopic instruments. These include microlaparoscopy, needlescopy, and minilaparoscopy. There appears to be a lack of clarity in the literature regarding the precise definition of these terms. Commonly, the terms have been used interchangeably to denote instruments that are of smaller caliber than conventional laparoscopic instruments. Within this chapter the term "needlescopic" is utilized to denote instruments with an outer diameter of 2 mm or lesser. As such, needlescopic ports have an outer diameter of 2 mm, which is similar to the diameter of a 14-gauge angiocatheter needle, hence the term "needlescopic." The term "minilaparoscopic instruments" includes all devices that are smaller than conventional laparoscopic instrumentation, which have an outer diameter lesser than 5 mm. The term "minilaparoscopy" includes procedures performed employing needlescopic instruments.

In a pure sense, minilaparoscopic procedures are those that are performed exclusively utilizing minilaparoscopic instruments. However, more commonly, during procedures involving the use of minilaparoscopic instruments, conventional laparoscopic instruments, especially conventional 5 or 10 mm laparoscopes, are also utilized to effectively obtain the most optimal surgical result. This has resulted from deficiencies in minilaparoscopic instrumentation and optics.

> In a pure sense, minilaparoscopic procedures are those that are performed exclusively utilizing minilaparoscopic instruments. However, more commonly, during procedures involving the use of minilaparoscopic instruments, conventional laparoscopic instruments, especially conventional 5 or 10 mm laparoscopes, are also utilized to effectively obtain the most optimal surgical result.

MINILAPAROSCOPIC INSTRUMENTS

Conventional laparoscopes typically incorporate the Hopkins rod lens image transmission systems. The image relay system occupies the center of the laparoscope, while the light illumination fibers are located peripherally. Image transfer is facilitated by a series of lenses and glass rods, which was invented by Harold Hopkins in 1960 (2). This

technology is also utilized in the manufacture of rigid minilaparoscopes. Further miniaturization of the minilaparoscopes has been facilitated by employing fiber-optic imaging technology. Each fiber-optic quartz fiber measures 6 μm in diameter. A needle-scope typically contains 30,000 to 50,000 quartz fibers arranged in a bundle. The fiber-optic tele-scopes are flexible. Because image transfer occurs via individual optical fibers, the image obtained appears pixilated. Overall, images obtained through rod lens systems are of improved quality compared to images obtained from fiber-optic systems. Also, the fiber-optic laparoscopes are delicate and damage to individual fibers impacts image quality. Further, unlike the rod lens minilaparoscopes, the fiber-optic minilaparoscopes cannot be autoclaved and need to be gas sterilized.

Minilaparoscopes currently available include Storz microendoscope[a], diameter 1 mm; Medical Dynamics microendoscope[b], diameter 1.8 mm; Pixie microendoscope[c], diameter 1.9 mm; Minisite[d], diameter 2 mm; and Hopkins II[b], diameter 3.3 mm.

Both reusable and disposable trocars for 3 mm minilaparoscopic instruments are available. Disposable trocars utilized for needlescopic surgery have an outer diameter of 2 mm (Miniport[d]), and are similar to Veress needles. The needle ports are valveless, although they have roughened outer surfaces, which minimizes leakage of gas.

Given the narrow port diameter, inflow of insufflation gas occurs at a low flow of approximately 1 L/min. This results in slow filling and evacuation of insufflation gas. Evacuation of smoke following the use of electrocautery is also slow, which may prolong the operative time.

Various reusable and disposable minilaparoscopic instruments are available for clinical use. Reusable instruments include scissors, hook scissors, single-action and double-action graspers, needle drivers, and suction–irrigation cannulas. Disposable insulated 2 mm shears (Minisite[d]) designed for monopolar electrocautery are also available. The shears are equipped with only a thin layer of insulation, and the manufacturers recommend that electrosurgical power be limited to 30 W to prevent damage to the insulation and inadvertent thermal injury to adjacent tissues. Instruments of larger diameter (3 mm) are sturdier than needlescopic instruments (2 mm). Also, wider selections of instruments are available in the former category, including needle drivers and a selection of tissue graspers.

MINILAPAROSCOPIC UROLOGIC PROCEDURES
Needlescopic Urologic Procedures
Adrenalectomy
Technique
Left Adrenalectomy.   The procedure is performed with the patient in the lateral position with a 45° tilt. A 2 mm Minisite port is utilized to gain initial peritoneal access. The 2 mm trocar serves as a Veress needle and is inserted lateral to the lateral border of rectus abdominus muscle (anterior axillary line) 3 fingerbreadths inferior to the costal margin. Initial peritoneal entry is confirmed utilizing the needlescope. Pneumoperitoneum is then established. Additional ports that are inserted subsequently include a 10 mm port at the umbilicus, a 5-mm port in the midclavicular line 2 fingerbreadths inferior to the costal margin, and a 2 mm port along the lateral border of the rectus at the costal margin. Except for the initial 2 mm port, all ports are placed under direct visual guidance. A 10 mm 45° laparoscope is inserted through the umbilical port. The surgeon operates through the medial 2 mm port and the 5 mm port. The lateral 2 mm port is utilized by the assistant to place traction on the kidney in an inferior and lateral direction, in order to facilitate tissue dissection. Initially, the line of Toldt is incised, and the left colon is reflected medially. The left renal vein is identified. Dissection along the superior margin of the left renal vein facilitates identification of the adrenal vein. The vein is controlled utilizing 5 mm hemoclips and divided. Next, adrenal vessels arising from the renal artery and aorta are individually controlled with hemoclips and divided. The gland is then circumferentially mobilized. A 10 mm endocatch bag is inserted through the umbilical port

for specimen entrapment. Insertion of the needlescope through the lateral 2 mm port facilitates this maneuver. Hemostasis is reconfirmed. The fascia underlying the 10 mm port site is closed with a 0 Vicryl suture utilizing a Carter–Thomason closure device.

The steps of the procedure are similar to those of a transperitoneal laparoscopic adrenalectomy. The differences between conventional laparoscopic and needlescopic adrenalectomy include (i) the utilization of a 45° laparoscope at the umbilicus instead of a 30° laparoscope inserted through a more laterally placed port; (ii) the utilization of 2 mm instruments for dissection, utilization of 5 mm hemoclips; and (iii) the need to switch to a needlescope during insertion of secondary ports, specimen extraction, and fascial closure of the umbilical port site.

Right Adrenalectomy.   Initial peritoneal access is achieved with a 2 mm port placed in the anterior axillary line 3 fingerbreadths inferior to the costal margin. A 10-mm port is placed at the umbilicus, a 2-mm port is placed lateral to the xiphoid at the costal margin, and a 5-mm port is placed at the lateral border of the rectus 3 fingerbreadths inferior to the costal margin. The assistant retracts the liver superiorly with a 2 mm grasper inserted through the medial 2 mm port. The surgeon operates utilizing the lateral 2 mm port and the 5 mm port. Initially, the line of Toldt is incised and the right colon is reflected medially. Following this, the posterior parietal peritoneum inferior to the inferior margin of the liver is incised. The inferior vena cava is then identified. Dissection between the adrenal gland and the inferior vena cava facilitates identification of the adrenal vein, which is controlled with 5 mm hemoclips and divided. The specimen is then circumferentially mobilized, entrapped in an endocatch bag, and extracted through the umbilical port site.

Results

Gill et al. compared needlescopic adrenalectomy ($n = 15$) to conventional laparoscopic adrenalectomy ($n = 21$) (3). Within this retrospective review, patients in the needlescopic group were older than patients in the conventional laparoscopic group (60.4 ± 11.3 years vs. 52 ± 12.7 years; $p = 0.06$). The needlescopic group was associated with shorter operative time (2.8 hours vs. 3.7 hours; $p = 0.05$), lesser estimated blood loss (61.4 mL vs. 183.1 mL; $p = 0.002$), and shorter length of stay in the hospital (1.1 days vs. 2.7 days; $p < 0.001$). The average specimen weight for the needle-scopic group was 41.6 g (range, 6.8–108 g) and was 15.7 g (range, 6.6–55 g) for the laparoscopic group. Convalescence was shorter for the needlescopic group (2.1 ± 1.02 weeks vs. 3.1 ± 1.9 weeks; $p < 0.001$). Four of the needlescopic cases were converted to conventional laparoscopy for various reasons including: morbid obesity with a body mass index of 34.1 ($n = 1$); large tumor size (6 cm) ($n = 1$); and hemorrhage ($n = 2$). None of the cases required open conversion.

Orchiopexy
Technique

Initially, a 2 mm needle port is inserted at the umbilicus. The normal side is inspected first. The internal ring is identified lateral to the medial umbilical ligament. The vas and testicular vessels are identified entering the ring. Next, the internal ring of the affected side is identified. Blind ending testicular vessels are indicative of anorchia obviating the need for any further intervention. In the rare case with a blind ending vas, identification of the testicular vessels should still be performed as an undescended testis may still be present and may be identified at the termination of the testicular vessels. Alternatively, intra-abdominal testis peeping into the inguinal canal or inguinal testis may be identified. At times, identification of the abdominal testis may require medial reflection of the right colon. Two secondary 2 mm ports are inserted and the line of Toldt is incised, and the right colon is reflected medially. Following identification of intra-abdominal testis therapeutic options include orchiectomy, one-stage or two-stage orchiopexy. For inguinal testis, inguinal exploration may be performed needlescopically or open surgically. The testicular vessels are mobilized, and the gubernaculum is divided. A scrotal incision is then made and the testis is transferred into the scrotum where it is inserted into a subdartos pouch. A stay stitch placed on the testis facilitates its transfer into the scrotum. A hemostat inserted through the scrotal incision grasps the stay suture and the testis is then delivered into the scrotum. Alternatively, a laparoscopic port may be introduced through the scrotal incision to facilitate transfer of the testis. During needlescopic dissection, the internal ring may be enlarged medially in order to achieve a more direct course to the scrotum. If needed, a Stephen Fowler orchiopexy or a two-staged orchiopexy may also be performed.

Results

Gill et al. reported their results following 12 needlescopic procedures for cryptorchidism with nonpalpable testis (4). Following 12 diagnostic needlescopic explorations therapeutic interventions were performed in select cases. These included bilateral orchiopexy ($n = 2$), orchiectomy ($n = 2$), and excision of testicular remnant ($n = 2$). The average operative time was 1.8 hours (range, one to two hours), and the estimated blood loss was 6 mL (range, 0–20 mL).

Bladder Cuff Excision During Laparoscopic Radical Nephroureterectomy
Technique

To begin with, a thorough cystoscopic examination is performed to rule out the presence of any concomitant bladder tumors. Two needlescopic ports are then inserted into the bladder suprapubically. A 2 mm endoloop tie is inserted through one of the ports and is placed over the targeted ureteral orifice. Following this, a ureteric catheter is inserted through the cystoscope. The catheter is inserted through the endoloop tie, into the targeted ureteral orifice. Now, the cystoscope is exchanged for a resectoscope with a Collins knife, and the 2 mm ports are hooked to wall suction to minimize the possibility of extravasation. Glycine is used as the irrigant. A 2 mm grasper is inserted through one of the suprapubic ports in order to retract the ureteral orifice anteromedially. The resectoscope with the Collins knife is then utilized to detach a full thickness bladder cuff. Traction applied by the suprapubically inserted 2 mm grasper facilitates dissection of 3–4 cm of distal ureter in this fashion. The detached ureteral orifice is then occluded with the previously positioned endoloop tie. The bladder is emptied, the 2 mm ports are removed, and a Foley catheter is left indwelling in the bladder. Formal closure of the bladder is not performed. Following this, the patient is positioned in the flank position for a retroperitoneoscopic radical nephrectomy.

Results

The above technique was reported by Gill et al. (5). The procedure was performed in 20 patients undergoing laparoscopic nephroureterectomy. The operative time for this maneuver was 59 minutes (range, 35–120 minutes). In one patient, extravesical extravasation was noted during the case, and the endoscopic procedure was aborted. Postoperative cystograms were obtained by one week. Mild extravasation was noted in one of the 20 patients, which resolved following catheter drainage of the bladder for an additional week.

Lymphocele Drainage
Technique

Pelvic lymphoceles that are symptomatic and recur following percutaneous drainage are best treated by marsupialization into the peritoneal cavity. Laparoscopic lymphocele drainage entails a three-port transperitoneal approach. Large lymphocele are easily identified laparoscopically and appear as a visible bulge. Surface or intra-abdominal intraoperative ultrasound may be employed to facilitate precise localization of lymphoceles. The lymphocele wall is excised to facilitate a wide communication between the lymphocele and peritoneum. Lymphoceles that are superficially located, and those that are not associated with significant adhesions can be easily treated utilizing needlescopic instruments.

Results

Gill and colleagues reported their results following needlescopic lymphocele drainage in three patients (6). The procedures were performed on an outpatient basis. Mean operative time was 118.3 minutes, and estimated blood loss ranged from 10–50 mL.

Renal Cyst Drainage
Technique

Marsupialization of simple renal cysts may be offered to patients with symptomatic renal cysts. For cysts that are anteriorly located, needlescopic techniques may be employed. The procedure is performed through a three- or four-port transperitoneal approach. A 5 mm port is inserted at the umbilicus from the outset of the procedure and a 5 mm laparoscope is inserted through the umbilical port. The other ports are of needlescopic size. The colon is reflected medially, and the Gerota's fascia is incised to expose

the cyst. The cyst is drained and the cyst wall is excised. Occasionally, bleeding may be encountered from the residual cyst wall. A 5 mm argon beam coagulator inserted through the 5 mm port is utilized to achieve hemostasis. Next, a 2 mm needlescope is inserted through one of the lateral ports, and the excised cyst wall is extracted through the umbilical port.

Results
Gill and Colleagues reported their experience following three procedures (6). Average operative time was 1.7 hours, and mean estimated blood loss ranged from 10–200 mL. One case was converted to conventional laparoscopy to facilitate better hemostasis. Over a six-month period, one of the three patients developed a recurrent renal cyst, which was subsequently treated utilizing conventional laparoscopic techniques.

Minilaparoscopic Pyeloplasty
Minilaparoscopic pyeloplasty was reported by Tan (7). The procedure is performed utilizing 3 mm instruments inserted through 3.8 mm ports, and a 5 mm laparoscope. The procedure is performed utilizing a transperitoneal approach, and initial peritoneal access is obtained with a 6 mm Hasson cannula, which is inserted through the supraumbilical skin crease. An Anderson-Hynes dismembered pyeloplasty is performed utilizing a 6-0-polydiaxone suture on a 3/8 circle round body needle. Initially, the posterior layer of the anastomosis is completed in a running fashion. Next, an antegrade ureteral stent is introduced and the suture is continued to complete the anterior layer of the anastomosis. In this manner, a running ureteropelvic anastomosis is performed. No drains are placed, and the fascia underlying the 5 mm port is closed. The bladder is drained with a catheter for a period of 24 hours. The procedure was performed in 18 patients. Average patient age was 17 months (range, 3 months to 15 years). Mean operative time was 1.5 hours. Complications included a trocar injury resulting in a hematoma, and a case of postoperative stent migration, which necessitated ureteroscopic extraction at six weeks. None of the cases were converted to open. During follow-up, 2 of the 18 patients needed to undergo repeat laparoscopic pyeloplasty for persistent ureteropelvic unction obstruction. Both these patients were less than three months of age at the time of the primary laparoscopic procedure.

BENEFITS AND LIMITATIONS

Minilaparoscopy is associated with a cosmetic advantage compared to conventional laparoscopy in which, port site incisions vary from 5–15 mm. A retrospective study comparing needlescopic and conventional laparoscopic adrenalectomy demonstrated lesser postoperative pain, decreased length of stay in the hospital, and a shorter convalescence associated with needlescopic surgery. Also, patients undergoing minilaparoscopic procedures can often be treated on an outpatient basis or in an office setting (8). Moreover, diagnostic minilaparoscopic procedures may be performed under local anesthesia, making this a versatile tool in the office or emergency/trauma room.

Minilaparoscopic instruments are ideally suited for handling finer structures and fine sutures, making them optimal for performance of delicate reconstructive laparoscopic procedures.

Compared to 5 and 10 mm laparoscopes utilized for conventional laparoscopy, image resolution with the minilaparoscopes is inferior. The minilaparoscopes have a short focal distance, and as a result need to be placed closer to the target object compared to conventional laparoscopes. This results in transmission of an image that is too bright. Minilaparoscopic instruments lack tensile strength and are not as sturdy as conventional laparoscopic instruments. As a result, this makes the performance of major ablative procedures rather cumbersome. Another limitation with minilaparoscopy is the limited selection of instruments presently available. These include the lack of some instruments that are essential to effectively performing any laparoscopic case including clip applicators, energy-based hemostatic devices, effective suction–irrigation systems, tissue retractors, and improved tissue-handling graspers.

CURRENT STATUS AND FUTURE POTENTIAL

Until date, numerous urologic procedures have been performed utilizing minilaparoscopic instruments. Minilaparoscopy is uniquely suited for the performance of procedures involving delicate tissue reconstruction, pediatric urologic procedures, and also

> Minilaparoscopic instruments are ideally suited for handling finer structures and fine sutures, making them optimal for performance of delicate reconstructive laparoscopic procedures.

to obtain a superior cosmetic result. The size and tissue handling characteristics of mini-laparoscopic instruments make them ideal for handling delicate tissues and fine sutures. These instruments are akin to microsurgical instruments utilized during open surgery. It has been our observation from experience in the laboratory that complex urologic vascular reconstructive procedures can be successfully performed utilizing mini-laparoscopic instruments (9). With the aid of 3 mm instruments we demonstrated the feasibility of performing laparoscopic renal autotransplantation in a porcine survival model. Vascular anastomoses were performed utilizing 5-0 prolene sutures. In addition to facilitating manipulation of delicate vascular tissue, the 3 mm grasper and needle driver permit precise suture placement and suture handling. There is minimal suture fraying as often encountered with the use of conventional laparoscopic instruments.

SUMMARY

- The role of laparoscopy in pediatric urology is, at present, limited. The ability to perform major abdominal surgery through small-sized open surgical incisions has resulted in limited application of laparoscopy in pediatric urology. Incisions measuring 5–10 mm for each port site are rather large in the pediatric population. Utilization of minilaparoscopic instrumentation in this scenario would be cosmetically advantageous and also would afford appropriate handling of delicate pediatric tissues.
- Performance of fine reconstructive laparoscopic procedures will require the development of finer instruments, in the minilaparoscopic range.
- Continued development of minilaparoscopic technology and growing laparoscopic experience are likely to result in more widespread application of minilaparoscopy, either exclusively or in conjunction with conventional and robotic laparoscopic procedures to provide increased precision during laparoscopic tissue reconstruction and to improve cosmetic outcomes.

ROBOTIC SURGERY: OTHER APPLICATIONS

Amy E. Krambeck and Matthew T. Gettman

Department of Urology, Mayo Clinic College of Medicine, Rochester, Minnesota, U.S.A.

INTRODUCTION

The development and increased acceptance of laparoscopic techniques for a variety of extirpative and reconstructive procedures have revolutionized the practice of urology. As highlighted in multiple chapters of this text, urologic laparoscopy has provided multiple patient-related benefits including decreased pain, shortened convalescence, earlier return to work, and improved cosmesis. Conventional laparoscopy can limit surgical performance secondary to visualization of three-dimensional images on a flat two-dimensional screen, limited instrument maneuverability, and reduced dexterity in comparison to open surgery. Furthermore, training opportunities to learn laparoscopic urology are relatively limited. In addition, laparoscopic techniques such as intracorporeal suturing can be more difficult to perform than corresponding tasks in open surgery. The increased difficulty of conventional laparoscopy has prompted a variety of technologic enhancements designed to address performance deficiencies of the standard techniques and possibly increase clinical applicability.

As previously discussed elsewhere in the text, surgical robots can address the performance limitations of standard laparoscopy. In addition, surgical robots may increasingly provide an opportunity for "untrained" urologists to perform complex urologic techniques. While telesurgical robots such as the *da Vinci*® Surgical System[a] have been utilized predominantly for radical prostatectomy, other robotic applications have been described and increasingly performed for indications in the upper and lower urinary tract. Unfortunately, a common thread to essentially all of these other robotic techniques is limited clinical experience. This chapter will review the current status of robotics for other urologic applications in the upper and lower urinary tract.

UPPER URINARY TRACT

Robotic Pyeloplasty

There are a myriad of treatments for ureteropelvic junction obstruction. Open pyeloplasty is associated with the highest success rate, up to 95% (1). Unfortunately, it requires a sizeable muscle incision and is associated with considerable postoperative pain and convalescence. Since the 1980s, various techniques of antegrade and retrograde endopyelotomy were introduced as less invasive treatment options for primary and secondary ureteropelvic junction obstruction. While these techniques are faster and less morbid than open surgery, overall success rates for all endopyelotomy techniques remain lower than those for open pyeloplasty (2).

---

[a]Intuitive Surgical, Sunnyvale, CA.

In an attempt to merge the high success rates of pyeloplasty with the advantages of minimally invasive surgery, the techniques of laparoscopic pyeloplasty were developed. These techniques report success rates comparable to open pyeloplasty without the morbidity of a large flank incision (3). Unfortunately, there is a steep learning curve associated with this approach and despite advancements in instrumentation, laparoscopic pyeloplasty remains one of the more difficult procedures performed by urologists. Robotics has been applied to pyeloplasty in an attempt to simplify the laparoscopic technique yet maintain the benefits of minimally invasive surgery.

Telerobotic laparoscopic pyeloplasty has been performed in the animal model and clinically. Sung et al. first evaluated efficacy and feasibility of robotic dismembered pyeloplasty in the animal model (4). In the study, five female farm pigs were prospectively randomized and laparoscopic pyeloplasty performed with or without the Zeus robotic system. When comparing robotic procedures to conventional laparoscopy, no significant differences in operative time, suturing time, or total number of suture bites per ureter were reported (4). Sung et al. concluded that the Zeus-assisted robotic approach was feasible and could be used for clinical application. In the experimental model, Sung and Gill subsequently compared laparoscopic pyeloplasty performed with either the Zeus robotic system or the *da Vinci* robotic system. They found that *da Vinci*–assisted pyeloplasties were associated with shorter overall operative times, shorter anastomotic times, and an increased number of suture bites per ureter (5). The conclusion was either system could be used for robotic pyeloplasty; however, the researchers thought that the *da Vinci* robotic system was more intuitive. These early experimental studies at Cleveland Clinic provided a foundation for clinic application of robotic pyeloplasty.

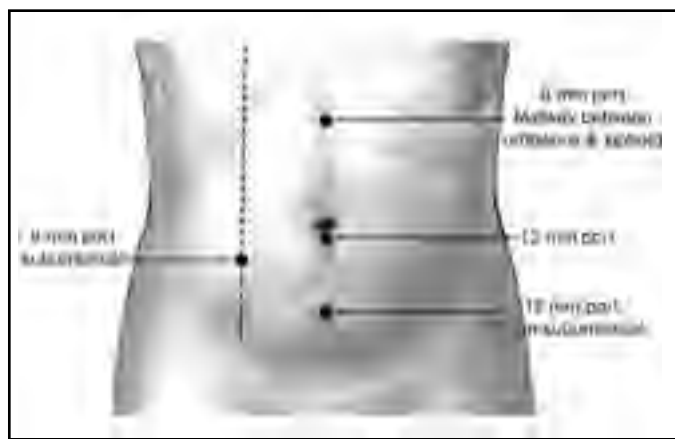
Robot-assisted laparoscopic pyeloplasty has been performed clinically using either the *da Vinci* robotic system or the Zeus robotic system (6–9). The only system currently supported for performance of robotic pyeloplasty is the *da Vinci* robotic system. The indications for robotic pyeloplasty are the same as those described for the conventional laparoscopic technique. Robotic pyeloplasty can be performed for patients with both primary and secondary ureteropelvic junction obstruction. In addition, robotic pyeloplasty can be safely performed in the presence of crossing vessels, a redundant renal pelvis, and intrinsic or extrinsic obstruction (6–9). Patients that have previously failed open pyeloplasty are not ideal candidates for this procedure. In addition, patients with poorly functioning obstructed kidney and those with a relatively small intrarenal pelvis are not ideal candidates.

The most commonly performed technique for robotic pyeloplasty utilizes the *da Vinci* robotic system. The procedure is performed using four transperitoneal ports with the patient in a 45° lateral decubitus position (Fig. 1). A standard 12 mm port is inserted at the umbilicus for placement of the laparoscope. Two 8 mm robotic ports are then placed as well as another standard 12 mm laparoscopic port for the assistant surgeon. The robotic system is then installed, and all operative steps are performed solely using the *da Vinci* robotic system.

For renal exposure, the line of Toldt is incised and the large intestine is retracted medially. While mobilization of the descending colon is commonly preferred for exposure of the left ureteropelvic junction obstruction, a transmesenteric approach has also been described for thin patients. Exposure of the ureteropelvic junction obstruction is commonly performed using a Prograsp or Cadiere forceps on the left robotic arm and the hook electrode on the right robotic arm. Next, either a nondismembered Fenger-plasty or an Anderson–Hynes-dismembered pyeloplasty is performed based on the type of ureteropelvic junction obstruction encountered. Regardless of the technique utilized, the surgical indication and the operative steps of robotic pyeloplasty mirror the steps described for conventional laparoscopic pyeloplasty. During the pyeloplasty procedure, a 7 French double pigtail stent is placed in an antegrade fashion over a guidewire into the ureter via the 12 mm assistant port (6,7).

Once the ureteropelvic junction repair is completed, displaced bowel is then repositioned anatomically and secured using 4-0 vicryl suture. Placement of a surgical drain is recommended only in certain surgical situations and is up to the discretion of the individual surgeon. The ureteral stents are left in place for six weeks, at which time they are removed via a cystoscopic approach.

Clinical experience with robotic pyeloplasty is limited but encouraging. Based on an initial report of nine patients undergoing laparoscopic Anderson–Hynes pyeloplasty with the *da Vinci* system, Gettman et al. reported a mean operative time of 139 minutes, mean suturing time of 62 minutes, and a 100% success rate at short-term follow-up (6).

FIGURE 1 ■ Port placement for robotic-assisted pyeloplasty. The 12-mm port for the camera is placed at the umbilicus. The 8-mm robotic ports are placed midway between the umbilicus and xiphoid in the midline and pararectally just below the level of the umbilicus. The 12-mm assistant port is placed at least 5 cm below the umbilicus in the midline.


Robot-assisted procedures have also been reported as advantageous when compared to traditional laparoscopic pyeloplasty with regards to mean operative time and mean suturing time (7). When patients undergoing *da Vinci*–assisted laparoscopic Fenger-plasty or Anderson–Hynes pyeloplasty were compared to patients undergoing purely laparoscopic procedure, the *da Vinci*–assisted procedures were associated with shorter operative times and decreased suturing times. Furthermore, the magnitude of improvement was greatest for patients treated with the more difficult Anderson–Hynes repair (7). A report by Bentas et al. further supports the clinical applicability of robotic pyeloplasty. In this series, 11 patients underwent a *da Vinci*–assisted laparoscopic Anderson–Hynes pyeloplasty with no intraoperative complications or open conversions (8). At one-year follow-up, the group reported 100% success rate. Interestingly, the group from Frankfurt had no formal training in laparoscopic surgery before successfully embarking on these types of robotic procedures.

Robotic pyeloplasty appears to be gaining momentum as a definitive treatment of ureteropelvic junction obstruction. The use of robotics negates most of the technical disadvantages associated with the traditional laparoscopic procedure, yet still provides a successful, minimally invasive treatment. Additional clinical experience, however, is needed from investigators at multiple centers with varying degrees of laparoscopic experience to define the exact role of robotic pyeloplasty among other treatment options for ureteropelvic junction obstruction.

Robotic Adrenalectomy

Adrenalectomy has historically been a significantly morbid procedure due to the deep location of the adrenal glands in the retroperitoneum. Laparoscopy has significantly decreased the morbidity associated with this operation, and laparoscopic adrenalectomy is now the recommended gold standard for the majority of adrenal disorders requiring surgery. Despite this transition to minimally invasive surgery, the incidence of disease processes requiring laparoscopic adrenalectomy is quite low and can potentially limit acquisition of skills necessary to perform the procedure. Laparoscopic adrenalectomy requires a delicate dissection of the adrenal gland as well as the adrenal veins and arteries. Given the somewhat restricted location of the adrenal gland and the careful dissection needed for successful removal, techniques of robot-assisted laparoscopic adrenalectomy have been reported in experimental models and clinically.

Gill et al. demonstrated the feasibility of robotic adrenalectomy using the porcine model in 2000 (10). Using the Zeus robotic system, the Cleveland Clinic group successfully performed four robotic adrenalectomies. During one robotic adrenalectomy, an injury to the inferior vena cava required telerobotic suturing with 5-0 prolene suture. None of the remaining procedures were associated with complications, but the operative time for robotic adrenalectomy was roughly double the time required to perform the conventional laparoscopic procedure. In another experimental study comparing the Zeus robotic system to the *da Vinci* robotic system, Sung and Gill reported that robotic adrenalectomy was more intuitive with the *da Vinci* system, and that operative times using this system were significantly shorter than those reported with the Zeus robotic system (5).

The first clinical use of the *da Vinci* robotic system for robotic adrenalectomy was reported by Kim et al. in August, 2000 (11). Shortly thereafter, the first bilateral *da Vinci*–assisted adrenalectomy was reported in a human by Horgan and Vanuno (12). They reported their overall experience using the *da Vinci* system in 34 patients including the one patient in whom successful bilateral adrenalectomies were performed (12). Others have since reported their experience in performing robot-assisted adrenalectomy, yet overall available clinical data is limited (13,14). Given the limited clinical experience with robotic adrenalectomy, specific indications have not been clearly defined. It would be anticipated, however, that the indications for robotic adrenalectomy would be the same as the current indications for traditional laparoscopic adrenalectomy. Currently, robotic adrenalectomy has been limited to tumors <6 cm in diameter. The specific indications for the reported cases have included pheochromocytoma, active and inactive adenomas, and adrenal metastasis.

The technique of robotic adrenalectomy has been performed through a four or five port transperitoneal approach with the patient placed in a 45° lateral decubitus position. Port placement and the operative steps of robotic adrenalectomy are very similar to those performed for conventional laparoscopic adrenalectomy.

Bentas et al. reported one of the initial clinical experiences with *da Vinci*–assisted adrenalectomy in 2002 (13). Among the series of four patients undergoing robotic adrenalectomy, the mean tumor size was 3.8 cm, blood loss was minimal, and operative time ranged from 160 to 330 minutes. No intraoperative complication or open conversions were reported (13). Desai et al. also reported their experience with two patients and again noted minimal blood loss during the *da Vinci*–assisted procedures (14). However, they did report an adrenal capsular tear secondary to lack of tactile feedback with the *da Vinci* robot system and concluded that this was a technical disadvantage of the robotic technique when compared to the conventional laparoscopic or open adrenalectomy technique.

Perhaps the largest series to date on robotic adrenalectomy was published by Brunaud et al. (15). This prospective randomized study compared *da Vinci* unilateral adrenalectomy with the standard laparoscopic procedure. Fourteen patients were enrolled in each arm of the study for a total of 28 unilateral adrenalectomies. Mean operative time was longer with the *da Vinci* system (111 minutes vs. 83 minutes). Interestingly, operative time required for conventional laparoscopic procedures correlated with body mass index, whereas operative time required for robotic adrenalectomy did not correlate with body mass index. Additionally, operating time with the *da Vinci* system decreased later in the study as the surgeon's experience with the procedure increased. There were no significant differences between the two procedures with regards to open conversion rate (7% for both), morbidity, or duration of hospitalization (6.8 days) (15). Despite early reports showing feasibility of robotic adrenalectomy, further study is needed with greater patient enrollment to assess the true benefit of robotic versus laparoscopic adrenalectomy and specific indications for the robotic procedure.

Robotic Nephrectomy

Advanced robotic technology has previously been utilized for nephrectomy in clinical and experimental studies (5,10,16). Bowersox and Cornum initially evaluated a prototype master–slave robotic system for open nephrectomy, cystotomy closures, and ureteroureterostomies (16). Using the experimental system, all procedures were successful, and no intraoperative complications were encountered. Prolonged operative times were one disadvantage suggested by the authors for the experimental robotic system. Using the Zeus robotic system, Gill et al. first reported feasibility of laparoscopic telerobotic nephrectomy and adrenalectomy in the animal model (10). In the study, the performance of standard laparoscopic nephrectomy and adrenalectomy was compared to that of the corresponding telerobotic procedures in five farm pigs. The robot-assisted techniques required longer operative times, but the adequacy of surgical dissection and blood loss were equivalent.

The initial report of a telerobotic laparoscopic nephrectomy in humans was reported by Guillonneau et al. using the Zeus robotic system in 2001 (17). All steps of telerobotic nephrectomy were successfully performed with the robotic system. The procedure was safely performed with an operative time of 200 minutes and an estimated blood loss of <100 cc (17). To date, there remains a paucity of published results for robotic nephrectomy performed with either the *da Vinci* robotic system or the Zeus robotic system. Robotic nephrectomy has been slow to gain wide clinical acceptance, possibly related to the complexity of the procedure. The procedure requires that the

assistant surgeon perform essential steps of the operation including ligation of the renal vessels and placing the specimen in the retrieval bag. Thus, the assistant surgeon must possess advanced laparoscopic skills to perform the procedure.

Robotic Donor Nephrectomy

Laparoscopic donor nephrectomy is the new gold standard for kidney donation at many transplant centers. The development of laparoscopic donor nephrectomy has been revolutionary, yet increased operating room time and retrieval of shorter donor vessels especially in the early learning curve have been suggested as technical concerns (18,19). With the introduction of telerobotic surgical systems, some investigators have hypothesized that the enhanced dexterity and improved optics of systems like *da Vinci* may remedy reported technical concerns and thereby improve operative performance of laparoscopic donor nephrectomy. Using this premise, the initial clinical series of robot-assisted donor nephrectomies were reported by Horgan et al. in 2002 (18).

The indications and operative techniques for robotic donor nephrectomy are similar to those used for the standard laparoscopic procedure; however, to date the robotic technique has been utilized only for left donor nephrectomies. Robotic donor nephrectomy also utilizes both the *da Vinci* robotic system and the laparoscopic hand-assist device (18,19). After placing the patient in a 45° lateral decubitus position, a 7 cm infraumbilical incision is first made for the hand-port device, and four trocars (two reusable robotic trocars and two 10 mm standard trocars) are then positioned on the left side of the abdomen. During the robotic procedure, the assistant surgeon performs important standard laparoscopic maneuvers including retraction and exposure, division of the renal artery and vein, and removal of the kidney through the hand-port device.

In the initial report of 10 patients undergoing robot-assisted laparoscopic donor nephrectomy, Horgan et al. reported a mean operative time of 166 minutes and a mean estimated blood loss of 68 mL (18). The mean warm ischemia time was 85 seconds and all kidneys were functional upon transplantation. There were no intraoperative complications and no open conversions. In a related report, Horgan et al. compared the results of 12 robotic donor nephrectomies to 23 standard laparoscopic donor nephrectomies and 25 open donor nephrectomies (19). While the mean operative time was 50 minutes longer using the robotic technique, the authors reported multiple technical advantages including a three-dimensional view of the operative field and enhanced dexterity, which improved dissection of the vessels and allowed early identification of the ureter. The authors also reported that dissection of the upper pole was simplified by the articulating wrists of the *da Vinci* system (19).

LOWER URINARY TRACT

Robotic Radical Cystectomy and Urinary Diversion

Building on the clinical experience with *da Vinci*–assisted laparoscopic radical prostatectomy, the use of robotics has expanded to include extended pelvic lymph node dissections and radical cystectomy with urinary diversion. The current indications for robotic cystectomy are the same as those reported for laparoscopic radical cystectomy. Patients with large bulky tumors and obvious extravesical disease are not ideal candidates. Robotic cystectomy has now been reported in both men and women with or without a concurrent nerve-sparing technique using either an ileal conduit or an ileal neobladder urinary diversion (20–23).

Although minor variations have been reported among institutions, the technique of robotic cystectomy closely follows the operative steps of conventional laparoscopic radical cystectomy. After the patient is placed in dorsal lithotomy position and then steep Trendelenburg, five or six transabdominal ports are placed in similar fashion as for robotic prostatectomy. All steps of extended bilateral lymph node dissection and radical cystectomy can be performed solely with the *da Vinci* robotic system. The urinary diversion can then be performed entirely in an open fashion via the specimen extraction incision, entirely intracorporeally using only the *da Vinci* robot, or in combination with open and minimally invasive techniques (20–23).

Beecken et al. reported the first case of *da Vinci*–assisted laparoscopic cystectomy with intracorporeal formation of the ileal neobladder (20). The procedure was performed with an overall operative time of 510 minutes and an estimated blood loss was <200 cc. The *da Vinci* robot facilitated intracorporeal suturing for the urethral

anastomosis, construction of the neobladder, and the ureteroileal anastomosis (20). Bowel continuity was reestablished after a minilaparotomy was performed for specimen removal. Yohannes et al. reported some of the first cases of laparoscopy-assisted robotic cystoprostatectomy with ileal conduit urinary diversion for organ-confined urothelial carcinoma (21). The *da Vinci* robot was employed to perform bilateral lymph node dissection, cystoprostatectomy, and ileoureteral anastomosis. Total operative times were 600 and 720 minutes with blood loss of 435 and 1800 mL, respectively (21).

With a larger clinical experience, operative times and estimated blood loss have improved. Menon et al. reported a series of 14 nerve-sparing robot-assisted radical cystoprostatectomies with urinary diversion (22). The *da Vinci* system was utilized to perform all aspects of the surgery except for the urinary diversion, which was performed extracorporeally. For those undergoing an orthotopic neobladder, the *da Vinci* was also utilized to perform the urethroneovesical anastomosis. Mean operative time for the nerve-sparing cystoprostatectomy was 140 minutes and average blood loss for the entire procedure less than 150 mL. One complication of unexplained blood loss requiring exploration was reported (22). Results are currently not available in regard to postoperative continence and erectile function.

Robot-assisted female cystectomy with preservation of the uterus and vagina has been recently reported (23). Menon et al. published their series of three patients, for which the *da Vinci* robot was utilized to perform the cystectomy and urethroneovesical anastomosis. Posterior mobilization of the bladder via the cul-de-sac of Douglas facilitated preservation of the uterus and vagina. Urinary reconstruction was performed extracorporeally through a small midline incision. Average operating time for the cystectomy was 160 minutes with mean blood loss of less than 100 mL (23). It is known that the pneumoperitoneum created during laparoscopic and robotic procedures helps to reduce vascular bleeding. The group reasoned that the superior hemostasis afforded by the robotic system allowed them to avoid the significant vaginal bleeding that often accompanies reproductive sparing female cystectomies (23).

Although the procedure has yet to demonstrate a decrease in length of hospitalization or length of overall procedure time, robot-assisted cystectomy appears to have a favorable clinical future. Those that perform this procedure have sited it to be technically much simpler than laparoscopic cystectomy or even robot-assisted radical prostatectomy. Additionally, the benefits of limited patient morbidity, cosmesis, and superb hemostasis as well as visualization provided by the robotic system cannot be ignored. We anticipate robot-assisted cystectomy to become more widely performed now that a standard technique has been described and demonstrated to be safe and effective.

Sacrocolpopexy

The current gold standard treatment for posthysterectomy vaginal vault prolapse is abdominal sacrocolpopexy. This technique involves suspending the vaginal vault anteriorly, posteriorly, or by closing the levator hiatus by an abdominoperineal approach. These open procedures are associated with significant morbidity and extended hospital stays. A vaginal approach was developed in an attempt to decrease morbidity associated with sacrocolpopexy; however, the success rates are consistently less than the abdominal technique (24). Laparoscopic sacrocolpopexy was developed to mimic the open procedure while decreasing the accompanying morbidity. Unfortunately, these procedures have been performed with significant difficulty and lengthy operating times, especially early in the learning curve (25). DiMarco et al. reported the first series of five robot-assisted laparoscopic sacrocolpopexies (24). The attempt was to reap the minimal invasive benefits of laparoscopic sacrocolpopexy while simplifying the procedure and decreasing operating room time.

Robotic sacrocolpopexy is indicated for vaginal vault prolapse after hysterectomy. Currently, the procedure has only been performed in grade 3–4 apical prolapse and grade 2–4 anterior prolapse. The preferred patient has had no or minimal prior abdominal surgeries. A transperitoneal approach is utilized after placement of five laparoscopic ports (Fig. 2). Robotic sacrocolpopexy follows similar operative steps as those performed with laparoscopic sacrocolpopexy (25). Retraction of the sigmoid colon and a steep Trendelenburg position provide exposure of the sacral promontory and vagina. Using the Cadiere forceps and the hook electrocautery, the anterior vagina is dissected from the bladder. A customized vaginal retractor aids in dissection (24). Next, the peritoneal reflection is incised posteriorly to further mobilize the

FIGURE 2 ■ Port placement for robotic-assisted sacrocolpopexy. The 12-mm port for the camera is placed at the umbilicus. A 12-mm assistant port is placed subcostally lateral to the rectus and a 5-mm assistant port is placed one handbreadth inferior-laterally. The 8-mm robotic ports are placed lateral to the rectus two fingerbreadths superior to the iliac crest.

vagina. Anterior and posterior dissection is then carried out distally toward the introitus. The sacral promontory is now exposed by incision of the posterior peritoneum. Care should be taken to avoid injury to the sacral veins. A Silastic Y-graft is brought into the abdomen through a 10 mm port. Using the *da Vinci* robot system, the graft is sutured to the posterior vagina and then the anterior vagina using 1.0 Gore-Tex suture. The use of a 30° lens maximizes visualization. The tail of the graft is then sutured to the sacral promontory. There should be minimal tension on the vagina. The ureterosacral ligaments are then plicated and the posterior peritoneum closed over the graft.

In the initial series of five patients, DiMarco et al. reported an average operating time of 225 minutes. Hospital stay was 24 hours for all patients and none had recurrent prolapse at four-month follow-up (24). One complication of persistent vaginal bleeding was reported; however, this was attributed to a concurrently performed pubovaginal sling. While the technique of robotic sacrocolpopexy is now standardized, additional clinical experience is needed to fully understand the indications and limitations of the technique. This procedure is still in its infancy and as of yet long-term results are not available. Nonetheless, initial results have shown promise for robotic sacrocolpopexy and the technique appears to have important clinical implications in the future.

CONCLUSION

Aside from robot-assisted laparoscopic radical prostatectomy, clinical utilization of robotic systems for a variety of procedures in the upper and lower urinary tract is still in its infancy. Surgical techniques and feasibility of multiple robotic procedures have been described, but the data currently available is limited to small case series with little long-term follow-up. Telerobotic surgical systems were introduced to address the technical limitations of standard laparoscopy. The current robotic systems provide three-dimensional visualization of the operative field, improved dexterity (with tremor filtering and motion scaling software), and increased range of motion compared to standard laparoscopy. The benefit of these performance features appears greatest when performing advanced laparoscopic dissection techniques (i.e., prostatectomy and cystectomy) or intracorporeal suturing (i.e., pyeloplasty, prostatectomy, urinary diversion, and sacrocolpopexy); however, a clinical advantage remains scientifically unproven at this time.

In the skills laboratory, Yohannes et al. have previously shown that learning how to suture is faster with *da Vinci* than with standard laparoscopy (26). Furthermore, the investigators reported novice laparoscopists learned suturing with the robot quicker than experienced laparoscopists. Clinically, multiple centers have also successfully used robotics to perform complex laparoscopic tasks without any formal training in minimally invasive surgery (8,22,23). For instance, Bentas et al. had no experience with laparoscopic pyeloplasty before successfully embarking on their *da Vinci*–assisted procedures (8). In general, they concluded that telerobotics enabled inexperienced urologists to perform complex reconstructive procedures with more confidence and better results than could be obtained with standard laparoscopy. Nonetheless, a paucity of prospective randomized trials is currently

available to compare outcomes of laparoscopic surgery performed with or without telerobotics (15). This information would be helpful in defining the role of robotics for "trained" and "untrained" laparoscopists.

Limits are also currently present with telerobotics. Critical performance features are lacking with robotic surgery including even gross tissue palpation and force feedback. So, robotic surgery must be performed with increased reliance on visual versus tactile inputs. Telerobotic surgery is also associated with a significant learning curve not only for the operating surgeon but also more significantly for the operating room staff. An attempt should be made to establish a robotics "team" when embarking on these surgical procedures. In contrast to standard laparoscopy, the importance of the surgical assistant is critical to the flow of robotic surgery. Using standard laparoscopic instruments, the assistant surgeon is depended on to provide traction/countertraction, apply hemostatic clips, and introduce and remove suture. For this reason, the assistant surgeon must be proficient with at least basic laparoscopic tasks. At the present time, robotic surgery also utilizes more resources than standard laparoscopy. For instance, two surgeons are needed when performing robotic surgery: one at the remote control unit and one scrubbed at the operating table. Initial capital expenditures and per case costs are also more expensive at the present time for robotic surgery.

Robotic technologies have been recently introduced with fanfare, but increased clinical application and critical evaluation are needed. Robotics appears best targeted for complex laparoscopic tasks requiring delicate dissection or intracorporeal suturing. Robotics has already succeeded in increasing clinical applicability by permitting "untrained" open surgeons to perform complex laparoscopic tasks (8,22,23). Nonetheless, deficiencies currently exist for robotics, and the learning curve is not insignificant. With the anticipated introduction of improved robotic technologies and other technologies in the information age, the ongoing value of robotics must be carefully evaluated and proven to optimally benefit patient care.

LAPAROSCOPIC COMPLICATIONS: ETIOLOGY, PREVENTION, MANAGEMENT

VASCULAR COMPLICATIONS DURING UROLOGIC LAPAROSCOPY

James R. Porter

Of the major complications associated with urologic laparoscopic surgery, vascular injuries are the most common. They can also become the most devastating complications during laparoscopic procedures resulting in significant morbidity and death.

INTRODUCTION

Of the major complications associated with urologic laparoscopic surgery, vascular injuries are the most common (1–3). They can also become the most devastating complications during laparoscopic procedures resulting in significant morbidity and death.

These injuries often attract legal attention, and in one report, 62% of legal cases involving vascular injuries were settled in favor of the plaintiff (4). Too often, however, fear of litigation eliminates the opportunity to assess the cause and learn from the experience of others, and therefore many vascular injuries go unreported making the true incidence higher than that reported in the literature (5,6).

FREQUENCY OF LAPAROSCOPIC VASCULAR INJURY

Vascular injuries may occur due to errors in dissection or from access-related injures and have been reported in 1.6% to 4.7% of urologic laparoscopic procedures (Table 1). Several series have reported their experience with vascular injury during urologic laparoscopic procedures; however, some studies have failed to distinguish vascular injury due to dissection from that due to access injuries.

Gill et al. noted vascular injuries in 3 (1.6%) of 185 patients undergoing laparoscopic nephrectomy with two of the three injuries due to error in dissection (7). Fahlenkamp et al. reviewed the German experience with laparoscopic complications and found 40 vascular injuries in 2407 patients, making vascular injuries the most frequent complication in that report (1). Thiel noted six major vascular injuries during 274 transperitoneal laparoscopic cases for an incidence of 1.7% (8). All were venous dissection injuries, and the authors noted that vessel injury was more likely to occur during complex laparoscopic procedures in patients who had undergone previous surgery in the region. This concept was supported by a report by Meraney et al. who reviewed the complications of retroperitoneal laparoscopic surgery and noted seven vascular injuries in 404 patients for an incidence of 1.7% (9). Five of seven vascular injuries occurred during dissection and the majority of vascular injuries in this series occurred in patients who had previous abdominal surgery. Rassweiler et al. reported 22 vascular injuries out of 482 laparoscopic nephrectomies for a rate of 4.6% (10). Vascular complications during laparoscopic donor nephrectomy were recognized in 2.3% of cases and included stapler misfire in two, laparoscopic clip dislodgement in two, and vessel laceration during dissection in four patients (11). In a review of the Mayo Clinic experience with laparoscopic nephrectomy, vascular injury was the most common intraoperative complication (2). Four patients sustained dissection injuries and all required open conversion for control. There was one epigastric artery injury that was managed conservatively, bringing the total number of vascular injuries to 5 (1.8%). Finally, Siqueria et al. compiled their experience with major complications in 213 laparoscopic nephrectomies and reported 10 (4.7%) vascular injuries (3). Seven of the injuries were due to dissection errors

TABLE 1 ■ Laparoscopic Vascular Injuries from Urologic Series

Series (Ref.)	Procedure	Cases	Vascular injury	Type
Gill et al. (7)	Laparoscopic nephrectomy	185	3 (1.6%)	2-Dissection injury 1-Access injury
Thiel et al. (8)	Transperitoneal laparoscopy	274	6 (1.7%)	6-Dissection injury
Rassweiler et al. (9)	Laparoscopic nephrectomy	482	22 (4.6%)	Not reported
Fahlenkamp et al. (1)	Multiple	2407	40 (1.7%)	40-Dissection injury
Meraney et al. (10)	Retroperitoneal laparoscopy	404	7 (1.7%)	5-Dissection injury
Hsu et al. (11)	Donor nephrectomy	353	8 (2.3%)	4-Dissection injury 2-Stapler misfire 2-Clip dislodgment
Siqueira et al. (3)	Laparoscopic nephrectomy	213	10 (4.7%)	4-Dissection injury 3-Access injury 2-Stapler misfire 1-Clip dislodgement
Simon et al. (2)	Laparoscopic nephrectomy	285	5 (1.8%)	4-Dissection injury 1-Access injury

and three were related to problems with access. Five of the seven dissection injuries resulted in emergent open conversion.

In nonurologic laparoscopy, vascular injury appears to be less frequent and is usually associated with access-related injuries as compared to errors during dissection (Table 2). In a review by Usal et al., vascular injury was noted in 0.11% to 0.25% of laparoscopic general surgery procedures, and the majority of these injuries were due to trocar misplacement (12). Saville and Woods noted four (0.1%) vascular complications out of 3591 laparoscopic procedures and all were due to trocar injury (13). Another review of laparoscopic cholecystectomy and appendectomy revealed nine (0.07%) vascular injuries and all were due to either trocar or insufflation needle injury (14). In the gynecologic literature, vascular injury complicating laparoscopic procedures were reported in 0.68% to 1.2% of cases (5). Fruhwirth et al. reported nine vascular injuries during gynecological procedures for a vascular injury rate of 0.8%, and all were due to access injuries (15). Chapron et al. reviewed 17 reported cases of major vascular injury in the French Society of Gynecological Endoscopy, and 76% of the injuries occurred while gaining access (16). Of the four cases of dissection injury, three occurred during dissection around vascular structures. Like the general surgery experience, most vascular injuries reported by gynecologic surgeons were due to trocar-related events and not errors of dissection. However, Nezhat et al. reviewed eight case reports of vascular injuries due to errors of dissection, and four of the eight were associated with laparoscopic lymphadenectomy while three injuries were attributed to distorted anatomy (17).

TABLE 2 ■ Laparoscopic Vascular Injuries from Nonurologic Series

Series (Ref.)	Procedure	Cases	Vascular injury	Type
Usal et al. (12)	Laparoscopic choley, appy	1372	3 (0.11%)	1-Access injury 2-Dissection injury
Saville and Woods (13)	Laparoscopic choley, appy Laparoscopic hernia	3591	4 (0.1%)	4-Access injury
Guloglu et al. (14)	Laparoscopic choley, appy		9 (0.07%)	9-Access injury
Fruhwirth et al. (15)	Laparoscopic gynecologic		9 (0.8%)	9-Access injury
Chapron et al. (16)	Laparoscopic gynecologic	Review	17	13-Access injury 4-Dissection injury
Nezhat et al. (17)	Laparoscopic lymphadenec-tomy Laparoscopic adhesiolysis	Review	8	8-Dissection injury

A comparison of nonurologic vascular injuries to that in the urologic literature reveals two important distinctions between the two experiences.

- Vascular injuries due to access-related events are present in all specialties, but the higher overall occurrence of vascular injuries in the urologic literature is probably due to a greater number of dissection injuries.
- The greater number of dissection injuries in the urologic literature and select gynecologic reports are due to procedures that demand dissection around major vascular structures such as laparoscopic nephrectomy and laparoscopic lymphadenectomy.

Vascular injury during dissection is the most frequent cause for emergent open conversion.

Although the rate of vascular injury is relatively low, these injuries tend to be the most common intraoperative complication (1,3,7,10,18,19).

Vascular injury during dissection is the most frequent cause for emergent open conversion (3,7,9,10,20).

Vascular injury during dissection tend to occur during procedures where dissection is required around large vessels as in laparoscopic nephrectomy or laparoscopic retroperitonealymph node dissection (20), but are rare in cases such as laparoscopic prostatectomy where large arteries are rarely encountered. Guillonneau et al. noted only three bleeding episodes significant enough to require open conversion out of 567 laparoscopic prostatectomies (21). While this appears to be the trend, there are exceptions. In a multicenter study by Cadeddu et al. involving 157 laparoscopic radical nephrectomies, there was not a single vascular injury due to errors dissection (22).

The majority of vascular injuries during urologic laparoscopy are due to errors in dissection. Most commonly, this is due to inadequate exposure of the vascular structure leading to either direct sharp injury or thermal injury to the vessel. The principle of dissecting from superficial to deep structures (from known to unknown) must be followed in order to avoid this type of injury. In addition, anatomic knowledge of the proximity of major vascular structures is essential to avoid inadvertent vascular injury. Disorientation during laparoscopic procedures can occur and has been associated with injury to the inferior vena cava (23) and the superior mesenteric artery (3). If the surgeon becomes disoriented during the procedure due to bleeding or unusual anatomy, it is best to visually scan the abdomen for available landmarks. If landmarks cannot be established, then consultation with a colleague may be helpful. If proper orientation is still unable to be obtained, then conversion to open surgery should be performed.

Once a dissection injury has occurred, control of the bleeding vessel may be a challenge due to several factors. First, bleeding from a vessel quickly obscures the source because blood pools around the injured vessel. Second, the injured vessel is often not completely exposed because the dissection injury often occurs during exposure of the vessel. Third, unlike open surgery, the application of manual direct pressure is difficult, and depending on the laparoscopic instrument in the abdomen, the quick application of pressure to the bleeding vessel may be impossible.

Once a vascular injury has occurred, an immediate assessment is required to determine whether an attempt at laparoscopic repair should be performed or if open conversion is necessary. If the surgeon is inexperienced, or if this is a case early in the learning curve, then immediate open conversion should be performed. However, if the surgeon is more experienced and the necessary instrumentation is available, then a laparoscopic repair may be attempted. The first principle is to provide tamponade to the bleeding area with the available instrument that is in the abdomen at the time of injury. Additional ports may be required to provide exposure and suction as needed.

The pneumoperitoneum should be maintained because this may decrease venous bleeding.

The pneumoperitoneum should be maintained because this may decrease venous bleeding (8).

Once the area of bleeding has been identified, further exposure of surrounding structures should be carefully performed to allow complete visualization of the region. After adequate exposure has been obtained, the area of injury may be identified and repaired either with intracorporeal suturing or by judicious placement of clips. On occasion, an injury may be repaired by firing a vascular stapling device (9). Failure to control hemorrhage by any of these measures, or the occurrence of hemodynamic instability in the patient, should prompt immediate open conversion.

It is essential in any laparoscopic procedure to have an open laparotomy tray open and available in the room in the event that emergent laparotomy is required.

It is essential in any laparoscopic procedure to have an open laparotomy tray open and available in the room in the event that emergent laparotomy is required.

The need for open conversion to control vascular injury appears to occur early in the laparoscopic experience of the surgeon. Meraney et al. noted that open conversion was required in three of their first four vascular injuries; however, three subsequent vascular injuries were controlled using laparoscopic techniques, and open conversion was not required to control vascular complications during their last 200 cases (9). Guillonneau et al. reported seven open conversions for laparoscopic prostatectomy in the first 70 patients, with three due to bleeding, but no conversions in the subsequent 497 cases (21). Thiel et al. noted successful laparoscopic repair of four consecutive venous injuries after open repair of the first (8).

In addition to dissection injuries, vascular injuries have also been reported due to malfunctioning of endoscopic stapling devices. These injuries may be caused by application of the stapling device over previously placed metal clips on adjacent branch vessels. This may result in bleeding from the divided vessel due to lack of staple closure, or a jammed stapling device that cannot be easily removed from the vessel. Chan et al. reported 10 occurrences of stapler malfunction in 565 cases for an incidence of 1.7% (24). In 5 of the 10 cases, malfunctioning of the staple device was due to operator error with application of the stapler over previously placed metal clips causing the stapler to misfire. Others have reported similar problems with the endoscopic stapling device (3,7,25).

There have been recent reports of major vascular injury due to inadvertent endoscopic stapler application across the vena cava (23) and the aorta (26). All injuries occurred during retroperitoneal laparoscopic nephrectomy. In one report, two patients suffered vena caval injury when the vena cava was thought to be the right renal vein (23). Both injuries were recognized intraoperatively with conversion to open laparotomy. Vascular surgical consultation lead to a successful outcome in each case. Disorientation of the surgeon due to unfamiliar landmarks was thought to contribute to ligation of the vena cava. Sautter et al. reported an aortic ligation during retroperitoneoscopic nephrectomy that resulted from application of an endoscopic clip in the renal hilum during bleeding (26). Limited visibility of the hilum was noted. The patient presented postoperatively with neurologic symptoms, and complete occlusion of the aorta was diagnosed on angiography. The occlusion was successfully bypassed with an aortic tube graft. These cases demonstrate the importance of remaining oriented during laparoscopic procedures, especially when bleeding may obscure the operative field.

If bleeding cannot be controlled and is compromising operative visibility, then open conversion should be favored over blind application of vascular closure devices.

If bleeding cannot be controlled and is compromising operative visibility, then open conversion should be favored over blind application of vascular closure devices.

ACCESS-RELATED INJURY

Access-related injuries to abdominal viscera or retroperitoneal vascular structures are estimated to occur between 0.05% and 2.8% of laparoscopic procedures (27,28). While these are rare injuries, when they do occur, the consequences can be devastating with a mortality rate reported from 5% to 13% (6).

A review by Chadler et al. of insurance claims and Food and Drug Administration Medical Device Reports of access-related injuries over a two-year period revealed bowel and retroperitoneal vascular injury comprised 76% of all injuries incurred in the process of establishing a primary port (6). The small bowel was the most common organ injured and nearly 50% of both large and small bowel injuries were unrecognized for 24 hours or longer. Delayed recognition, along with age greater that 59 years and major vascular injury, was an independent predictor of death. Shielded pyramidal cutting trocars were the most common trocar type associated with access injuries, and trauma from insufflation needles accounted for 18% of the injuries. Injuries were also observed with open, Hasson-type, blunt cannulas, which were associated with two deaths: one from unrecognized bowel injury and another from retroperitoneal vascular injury. The authors concluded that no entry technique or device is absolutely safe, and that access injuries to abdominal viscera and vessels may be more common than is currently reported in the literature.

Other reports of trocar injury have confirmed that delayed recognition is a predictor of death, and the most common vascular structures injured with an insufflation needle or primary trocar are the distal aorta, vena cava, iliac arteries, and iliac veins (17,29). A detailed review of the injuries caused by "safety" shielded trocars revealed 32 deaths out of 629 trocar injuries reported to the Food and Drug

Access-related injuries to abdominal viscera or retroperitoneal vascular structures are estimated to occur between 0.05% and 2.8% of laparoscopic procedures. While these are rare injuries, when they do occur, the consequences can be devastating with a mortality rate reported from 5% to 13%.

Administration over a four year period (30). Twenty-six (81%) of deaths resulted from vascular injuries and six (19%) were due to bowel injuries. Eighty-seven percent of deaths from vascular injuries involved the use of shielded trocars and 9% involved optical access trocars. When the diagnosis of bowel injury was delayed, the mortality rate increased to 21%. In fact, the Food and Drug Administration mandated that trocar manufactures remove the word "safety" to describe disposable shielded trocars.

Laparoscopic access injuries in the urologic literature are reported as one of three injuries: visceral organ or vascular trauma, abdominal wall vessel laceration, or port site herniation. Kavoussi et al. reported 10 (2.7%) trocar-related injuries in 372 patients treated with laparoscopic pelvic lymph node dissection (18). Four of the injuries were due to laceration of the epigastric vessels, three were bladder injuries, two were due to injury to a superficial abdominal wall vessel, and one was a small bowel injury. Gill et al. noted four (2.2%) trocar injuries in 185 laparoscopic nephrectomy patients (7). There were two port-site hernias, one abdominal wall hematoma, and one trocar injury to the kidney resulting in open laparotomy. In a survey of pediatric urological laparoscopy, Peters noted abdominal wall herniations in 0.15% of patients (31). He also noted that significant complications occurred more frequently in patients in whom the Veress needle was used (2.55%) compared to the Hasson technique (1.19%, $p < 0.006$). While the type of access technique was found to be significant, the most important factor in predicting the occurrence of complications in this study was the experience of the practitioner.

A recent review of laparoscopic nephrectomy revealed the potential risks involved in using optical trocars to gain primary port access into the peritoneal cavity. After insufflation is performed with a Veress needle, an optical trocar is used to visually pass through each layer of the abdominal wall. The proposed advantage of the optical trocar is that direct visualization while passing the trocar should allow identification of intra-abdominal structures and thereby decrease the risk of injury to viscera. Thomas reviewed 1283 urological laparoscopic procedures and found four (0.31%) injuries due to optical trocars (32). Two injuries involved the epigastric vessels, one involved bowel mesentery, and one involved bowel. Siqueira et al. reported three (1.4%) access-related injuries from optical trocars in the series of 213 patients (3). One injury involved laceration of the inferior epigastric artery, which resolved with conservative treatment. The other two injuries involved the liver while passing an optical trocar. Both injuries were managed conservatively. Orvieto et al. recently reported an aortic injury from an optical trocar during laparoscopic radical nephrectomy (33). There was no pneumoperitoneum prior to placement of the optical trocar and the patient recovered uneventfully after the injury was treated by placing an aortic vascular stent.

Injury while using optical trocars has also been confirmed in the gynecologic literature. Sharp et al. reviewed Medline, the Food and Drug Administration Medical Device Reporting, and the User Facility Device Experience databases for reports of complications from optical-access trocars (34). They found only two case reports in the medical literature of serious complications from optical-access trocars, but 79 serious complications in the Medical Device Reporting and User Facility Device Experience databases. These injuries included 37 major vascular injuries, 18 bowel perforations, 20 cases of significant bleeding from other sites, three liver lacerations, and one stomach perforation. Four deaths resulted from these complications. Clearly, this report demonstrates that optical trocars are associated with significant injuries despite the ability to see tissues during insertion, and these injuries are underreported in the medical literature.

> The open technique of gaining laparoscopic access is not without complication as noted in a report by Peters and coworkers.

The open technique of gaining laparoscopic access is not without complication as noted in a report by Peters and coworkers (35). The injury involved a segment of small bowel, which had been included in the purse-string suture placed around the access incision. Inspection of the primary access site from a secondary trocar identified the trapped bowel and the serosal defect was repaired. The conclusions of this case report were that care must be used when placing a purse-string suture, and the initial access site should be inspected from a secondary trocar site to look for injury. Two aortic injuries have also been reported during placement of Hasson-type cannulas: one occurred due to the scalpel injury during the initial skin incision and the other due to a sharp metal burr on the tip of the cannula (36).

> There is no perfect access technique and no method is risk free. The management of access injuries should focus on prevention and recognition.

There is no perfect access technique and no method is risk free. The management of access injuries should focus on prevention and recognition.

FIGURE 1 ■ Proximity of the umbilicus to the aortic bifurcation during Veress needle placement. *Source*: From Ref. 38.

The distance from the abdominal skin surface at the umbilicus to the ventral surface of the aorta can be less than 1 cm in a thin woman and children.

Prevention of primary trocar injury requires knowledge and control of the axial forces at work during application of the trocar.

Risk factors for intra-abdominal injury during closed entry techniques include thin patients, patients with previous abdominal surgery with adhesions, and application of excess axial force. Another important factor that influences trocar-related injury is the experience of the surgeon (31). Dixon reported seven iliac vascular injuries due to trocars or Veress needles during general surgical procedures, and inexperience on the part of the operating surgeon was demonstrated in all cases (37).

If a closed entry technique is employed using a Veress needle and blind primary trocar, then prevention requires clear knowledge of the underlying anatomy and their proximity to landmarks on the skin (Fig. 1).

The distance from the abdominal skin surface at the umbilicus to the ventral surface of the aorta can be less than 1 cm in a thin woman and children (39).

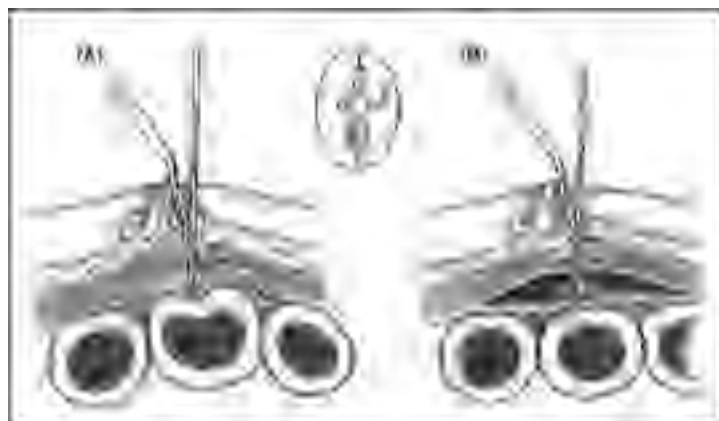
Some have abandoned the use of the Veress needle in thin patients and recommend an open Hasson technique (5). Others have suggested avoiding midline access altogether because of the potential risks, and advocate primary access in the left upper quadrant (40). If a patient has an incision from previous surgery, this area should be avoided and primary access should be obtained in a location remote from the incision, or an open access technique should be employed.

While the Veress needle may be smaller than a trocar, complications can occur with this device, and the Veress needle accounted for 18% of access-related injuries in a report by Chandler et al. (6). Veress needle placement was perceived as the most difficult aspect of laparoscopy as noted in a review by See et al. (41). Some have proposed that because of the smaller size of the Veress needle, injuries caused by these needles may be observed. However, Dixon and Carrillo reported three Veress needle injuries and all required immediate exploration and vascular control for resolution (37). He also notes that there may be multiple unrecognized injuries to surrounding structures and this warrants exploration.

When a Veress needle is passed, the abdominal wall should be elevated with penetrating towel clips and the Veress needle should be left open to permit air to enter the peritoneal space and allow the bowel and omentum to fall away (Fig. 2). Before CO_2 insufflation, aspiration, irrigation, reaspiration, and drop test should confirm the location of the needle. Any question as to the location of the needle should prompt removal. Once the needle is felt to be in the correct position, CO_2 insufflation should be started at low flow (1–3 L/min) and the initial pressure reading from the needle should be noted. A pressure reading greater than 8 to 10 mmHg or an occlusion reading from the insufflator should prompt the slow retraction of the needle until the pressure reading is acceptable. It is also important to communicate with the anesthesiologist at this time to inform them that insufflation is underway so that close monitoring can be performed. Any sudden change in the hemodynamics of the patient or end-tidal CO_2 reading should lead to cessation of insufflation.

Prevention of primary trocar injury requires knowledge and control of the axial forces at work during application of the trocar.

Some have suggested temporary overinflation of the abdomen with the Veress needle to 20 to 25 mmHg to maximize the space between abdominal wall and viscera as well as increase abdominal wall resistance (42). If a shielded, cutting-type trocar is

FIGURE 2 ■ Visceral deformation of displacement (A), and the importance of having an open stopcock for air entry (B) to allow omentum and bowel to drop away from the elevated ventral abdominal wall. *Source*: From Ref. 6.


used then the skin incision must be wide enough to allow the trocar to pass easily. The abdominal wall should be stabilized with towel clips and the angle of passage should take into account the underlying anatomy. Axial force control at this point is key and can be degraded by positioning that requires more muscle recruitment to exert a given amount of force, i.e., having the table too high, or reaching across the patient to put in a lateral port. Once the primary trocar is placed, its position should be confirmed immediately by passing the laparoscope through and observing for underlying injury. Secondary trocars are passed under direct vision, but care must be exercised during this procedure because injuries have occurred with secondary trocars, including injury to retroperitoneal vascular structures (6). Once a secondary trocar is in place, the primary entry site should be viewed to look for injury. In an effort to redirect axial force during trocar placement, radially expanding trocars (Fig. 3) have been developed and have been shown to be safe with a very low incidence of injury (6,43).

If the open, or Hasson, technique is used to gain access, care must be taken to avoid underlying bowel during the creation of the incision because exposure is limited. One of the criticisms of the Hasson technique is that there is loss of CO_2 from the cannula site, which can decrease the working space. Some surgeons have attempted to solve this problem by placing a purse-string suture around the cannula site. However, care must be exercised because complications have been reported with this technique as noted previously (35).

If vascular of bowel injury is suspected during Veress needle or primary trocar placement, immediate conversion to an open procedure should be performed. While a bowel injury may be recognized laparoscopically, the full extent of injury may be underappreciated by the view from the laparoscope and combined injury of bowel and vascular structures are well documented (6).

A high index of suspicion is required to recognize bowel injury due to trocar placement, because nearly half of all bowel injuries (47% for small bowel and 49% for colon) went undetected for 24 hours of greater, and delayed recognition of injury was an independent predictor of mortality (6). Vascular injuries due to trocar or Veress needle misplacement may go unrecognized for some time because of overlying mesentery and bowel, and the retroperitoneal position of major vascular structures. In addition, intraperitoneal CO_2 may compress the bleeding site and a steep Trendelenburg position may decrease venous bleeding as well (5). Therefore, it is important to assess all clinical signs of the patient if access injury is suspected. Consultation with the anesthesiologist should be performed to determine blood pressure, heart rate, and end-tidal CO_2. In young patients, blood pressure and heart rate may be maintained in the normal range for sometime before bleeding is apparent, and a change in end-tidal CO_2 may be the best indicator of vascular insult.

A thorough understanding of the anatomy of the anterior abdominal wall can minimize injury to abdominal wall vasculature during trocar placement.

The inferior epigastric artery courses on the posterior surface of the rectus muscle, upward and medially on a line from the midpoint of the inguinal ligament toward the umbilicus. At the level of the semilunar line, it changes course and heads

> If vascular of bowel injury is suspected during Veress needle or primary trocar placement, immediate conversion to an open procedure should be performed. If the epigastric artery is injured attempts at cautery are usually unsuccessful and the best method of control is suture ligation.

cephalad, running between the midline and lateral boarder of the rectus muscle (Fig. 4). Saber et al. determined the position of the inferior and superior epigastric vessels relative to the midline by evaluation of computed tomography scans in 100 patients (45). They found the epigastrics were between 4 and 8 cm from the midline at five different locations along the anterior abdominal wall, and described a "safe zone" outside of this range. While these findings may be anatomically correct and useful for patients in the supine position, this may have limited application in urologic laparoscopy when many patients are placed in a modified flank position. Clearly, the midline shifts toward the downward side in the flank position and even more so in obese patients. This makes using the midline as a reference point for trocar placement problematic.

The inferior epigastric vessels can be avoided by placing trocars in the midline, lateral to the boarder of the rectus muscle, or with direct visualization of the vessel from inside the abdomen. In thin patients, transillumination of the abdominal wall may allow the inferior epigastric vessels to be seen and this maneuver is also helpful to identify and avoid superficial vessels. In obese patients, the costal margin and iliac crest are usually palpable and can be used as reference points for trocar placement, because the midline is not a reliable landmark as mentioned above.

If the epigastric artery is injured attempts at cautery are usually unsuccessful and the best method of control is suture ligation.

This can be performed laparoscopically using a small-caliber piercing needle such as a Carter–Thomasen needle or a Stamey needle (44). The suture is passed on both sides of the bleeding site, perpendicular to the vessel. The suture may be tied on the skin over a gauze bolster or under the skin surface if the suture was passed within the trocar incision.

SUMMARY

■ Vascular injury during laparoscopic is a rare complication, but is the most common major complication in many urologic procedures.

■ Vascular injury may be due to errors of dissection or access-related trocar injury. These injuries can have devastating consequences resulting in significant morbidity and death.

■ Vascular injuries are probably under-reported in the literature, and the true incidence is higher than realized.

■ Avoiding dissection injuries requires strict adherence to principles of dissection such as working from superficial to deep structures.

■ Successful management requires prompt control of the bleeding vessel and exposure, but early open conversion should be performed if control cannot be established or the surgeon has limited laparoscopic experience.

■ There is no one completely safe method of gaining laparoscopic access, and great care must be employed in whatever technique is used.

■ The successful management of laparoscopic access injuries rests on prevention, early recognition of injury, and immediate open conversion if injury is identified or suspected.

INTRODUCTION

Intestinal injury is a rare but potentially fatal complication of abdominal laparoscopy.

Intestinal injury is a rare but potentially fatal complication of abdominal laparoscopy. Review of large multi-institutional studies of urologic laparoscopy over the last decade reveals an overall complication rate from 4.4% to 16%, a conversion rate of 0.8% to 5%, and a mortality rate up to 0.9% (1–5). The combined incidence of reported bowel injury from the general surgical, gynecologic, and urologic literature is 1.3 per 1000 cases (6).

Gastrointestinal complications of urologic laparoscopy can occur intraoperatively while obtaining abdominal access, during dissection of viscera, or from an unrecognized intraoperative bowel injury. Postoperative bowel complications include a prolonged ileus or bowel obstruction from a trocar site or internal herniation.

ABDOMINAL ACCESS-RELATED BOWEL INJURIES

The reported incidence of bowel injuries due to Veress needle and trocar insertion is 0.03% to 0.3%. Veress needle injuries are more common than trocar injuries.

The reported incidence of bowel injuries due to Veress needle and trocar insertion is 0.03% to 0.3% (7–10). Veress needle injuries are more common than trocar injuries.

Correct Veress needle placement should be confirmed before proceeding with insufflation of the abdomen (Table 1). Bowel insufflation through a Veress needle may produce asymmetrical abdominal distension, insufflation of only a small amount of CO_2 (less than 2 L) before high intra-abdominal pressures are reached, and passage of flatus during insufflation. If these signs are identified, insufflation should be immediately terminated. A pneumoperitoneum may then be established using a second Veress needle or an open Hasson technique at a different site.

During Veress needle or trocar insertion, the stomach or bowel may be entered. Typically, transgression into a hollow viscus is immediately apparent because of aspiration of gastrointestinal contents.

During Veress needle or trocar insertion, the stomach or bowel may be entered. Typically, transgression into a hollow viscus is immediately apparent because of aspiration of gastrointestinal contents.

Rarely, patients with urachal abnormalities, i.e., cysts or sinuses, may be encountered with a history of umbilical discharge, which should alert the surgeon to this possibility and high risk for viscus perforation. Once identified, the Veress needle bowel injury is managed based on the level of severity. If the Veress needle perforates any intra-abdominal hollow viscus and no leakage of enteric content is noted, conservative management can be undertaken. If the bowel defect appears to be a small puncture, a simple suture may be placed to close the needle hole. However, larger defects that may result from the Veress needle or from a trocar require formal repair. Formal repair of

TABLE 1 ■ Safe Veress Needle and Trocar Insertion

Place patient in Trendelenburg position, make a 12 mm incision at the site of desired needle entry,
   spread the underlying fat with a Kelly clamp, and grasp the underlying fascia with two Allis clamps
Pass Veress needle (midline two "pops") into the peritoneal cavity
Aspirate Veress needle for blood/bowel content
Irrigate needle with 5 cc of saline: fluid should inject without any force
Aspirate: there should be no return
Inject another 2–3 cc of saline (to push any aspirated fat, omentum, etc. away from the needle)
Drop test: fluid in the hub of the needle should flow into the peritoneal cavity
Advancement test: needle should be able to be advanced 1–2 cm without encountering any resistance
   (i.e., indicator in the hub of the needle should not move)
Ensure intra-abdominal pressure is low (<10 mmHg) when connected to the insufflator
Place first trocar after the intra-abdomenal pressure reaches 15–25 mmHg
Use visual dilating obturator trocar for primary trocar insertion
Always insert secondary trocars under vision
Visually inspect each site of trocar entry (including that of the primary trocar) for bleeding or
   visceral injury

Source: From Ref. 11.

significant bowel injuries may be performed via open or laparoscopic technique based on the level of experience of the operating surgeon. A general surgeon should be consulted to help determine the level of injury and to help establish an intraoperative management strategy. Trocar-induced bowel injuries should typically occur only during insertion of the primary trocar; the primary trocar is the only access that is generally not placed under direct vision.

When a trocar-induced bowel injury is suspected, the surgeon should resist the temptation to remove the trocar, because the offending trocar can be used to identify the site of bowel injury expeditiously and minimize the leakage of bowel contents into the peritoneal cavity.

The site of primary trocar passage should always be considered as a suspect for injury, and after additional access is gained, the primary access site should be inspected to rule out a bowel injury. During upper abdominal trocar deployment, gastric perforation may occur as a result of trocar insertion into a distended stomach. Keeping patients without oral intake eight hours prior to surgery, and the insertion of an orogastric or a nasogastric tube are helpful in minimizing the risk of gastric injury.

If a trocar-based bowel injury is appreciated, the site of perforation should be carefully evaluated. The evaluation should include consideration of a possible through-and-through bowel injury.

- Penetrating bowel injuries should be managed like any other penetrating injury within the abdomen.
- Open conversion and traditional management are most typically performed.
- Small perforations or lacerations can be repaired primarily.
- Extensive bowel injuries require resection.
- If the patient has undergone bowel preparation and the surgeon is comfortable with laparoscopic reconstruction, repair of an injured hollow viscus can be carried out by laparoscopic intracorporeal suturing or stapling techniques.
- Consultation with a general surgeon is strongly recommended.

Despite consensus to the contrary, analysis of three prospective, randomized studies to date shows that that a Veress needle access technique for trocar insertion is no more hazardous than a direct vision trocar insertion (Hasson technique) (10,12,13). As with any technique, the skill and experience of the surgeon is the key. For Veress needle insertion, adherence to the proper Veress needle insufflation protocol is essential. Specifically, the needle should irrigate easily, aspiration should not yield blood or fecal matter, the surgeon should observe a positive drop test (fluid passes through needle into the peritoneal cavity), there should be unrestricted advancement of the needle by 1 to 2 cm after entry, and the initial insufflation pressures should be low (Table 1). If these signs are not all present, the needle should be withdrawn and passed again via the same site or a different site to minimize the potential for access-based injury.

> When a trocar-induced bowel injury is suspected, the surgeon should resist the temptation to remove the trocar, because the offending trocar can be used to identify the site of bowel injury expeditiously and minimize the leakage of bowel contents into the peritoneal cavity.

Certain patients deserve special consideration as they represent an increased risk for access. Patients with very high or low body mass index can be a challenge. Similarly, patients with prior abdominal surgery should be approached with great caution. In the authors' experience, and documented in the literature, application of nonbladed (dilating) trocars minimize the risk of bowel and vascular injury (14,15).

Trocar access via any technique is generally safe. However, meticulous technique should always be applied to minimize the potential for injury. An open laparotomy set should be immediately available in the operating room during laparoscopic procedures for expeditious emergent conversion.

Before exiting the abdomen, careful and meticulous inspection of the bowel and trocar sites should be performed to identify any unrecognized bowel injury.

Open Access Method

The open or Hasson technique is a safe method of access, and is recommended in patients with previous abdominal surgery, if there is difficulty in the establishment of pneumoperitoneum with Veress needle, or for children and very thin patients.

However, just as with Veress needle access, bowel and vascular injuries have been described (7,8,16). Penfield reported an incidence of 0.2% complication rate among 10,840 open laparoscopies, including a 0.06% incidence of bowel injury (17). There are fewer reports of bowel injuries using Hasson's method of access than with the Veress needle technique. It is however useful for the laparoscopic surgeon to be proficient with both techniques.

Gastrointestinal Effects of Pneumoperitoneum

Halevy et al., in a series comparing open and laparoscopic cholecystectomy, have demonstrated that laparoscopic surgery results in significantly less disruption of normal gastrointestinal motility when compared to open surgery (18).

The mechanism(s) of decreased ileus with laparoscopic surgery remain(s) unclear. Another concern with abdominal laparoscopy has been gastroesophageal reflux. Despite the increased intra-abdominal pressures associated with insufflation, there has been no increased incidence of gastroesophageal reflux and regurgitation in patients undergoing laparoscopic procedures (19). However, the combination of elevated intra-abdominal pressures from the pneumoperitoneum, morbid obesity, and the application of the Trendelenburg position can increase the likelihood of regurgitation and aspiration of gastric contents. To avoid reflux, high-risk patients may be premedicated with 10 mg of intravenous metoclopramide. Also, administration of H_2 blockers can reduce gastric acidity and the associated morbidity if aspiration of gastric contents should occur. Finally, a cuffed endotracheal tube should prevent aspiration of stomach contents.

NON–ACCESS-RELATED BOWEL INJURIES

Bishoff et al. performed a retrospective review of bowel injuries during urologic laparoscopy in 915 cases at two institutions and reported an overall incidence of 0.8% non–access-related bowel injuries (6). The authors reported bowel perforation in two patients (0.2%) and serosal injury of the intestine or stomach in six patients (0.6%). Intraoperatively recognized bowel injuries occurred in six patients: three during staging pelvic lymph node dissection, two during pyeloplasty, and one during nephrectomy. Unrecognized bowel perforation during surgery occurred in two patients. Additionally, there were two patients referred from outside institutions who had unrecognized bowel perforation. In this series, three of the four patients with unrecognized bowel injuries had rapid progression to sepsis, and two subsequently died.

The authors observed that the postoperative signs and symptoms of laparoscopic bowel perforation were different from the classic postoperative symptoms of bowel perforation that occur with open surgery.

In the above series, all five patients with unrecognized bowel injuries presented in a characteristic manner that did not include traditional peritoneal signs. The initial presentation in each of these cases included persistent and relatively increased pain at a single trocar site without significant erythema or discharge. Each patient had leukopenia, and only one patient had fever greater than 38°C. Upon exploration, the painful trocar site was closest to the injured bowel segment. Abdominal distension and diarrhea were also noted. Two patients with colonic injuries after pelvic lymph node dissection had rapid onset of sepsis, without typical peritoneal signs, and died within four days.

<div style="float:left">

When bowel injury is recognized intraoperatively, immediate repair is indicated.

Almost all unrecognized injuries that present in the postoperative period will require open laparotomy.

In the postoperative period, if there is any concern for possible unrecognized bowel injury, a computed tomography scan of the abdomen with oral contrast should be performed expeditiously.

</div>

The authors also performed a Medline search on laparoscopic bowel injuries reported in the surgical and gynecological literature and discovered a total of 12 series with an overall incidence of 0.13% (266/205,969 cases) bowel injuries (both access and non–access-related), the majority (69%) of which were not recognized at surgery (Table 2) (6,17,20–30). Of the 266 patients with bowel injuries, eight patients died as a direct result of unrecognized intraoperative bowel injury. Small bowel injuries accounted for 58%, and colon and stomach injuries comprised 32% and 7%, respectively. Fifty percent of injuries resulted from application of electrocautery, and 32% of injuries were access related from Veress needles or trocars. Eighty percent of bowel injuries were managed by laparotomy and open repair.

The etiology of the unusual presentation of laparoscopic bowel injury compared to the open surgery is uncertain. It has been speculated that the possible lower immune and metabolic stimulus caused by laparoscopic surgery may allow more rapid progression toward sepsis before natural homeostatic responses occur (31–34). The absence of a large skin incision, which may be the site of maximum trauma, may result in less stimulation of acute phase reactants and reduced postoperative metabolic and cytokine response.

When bowel injury is recognized intraoperatively, immediate repair is indicated.

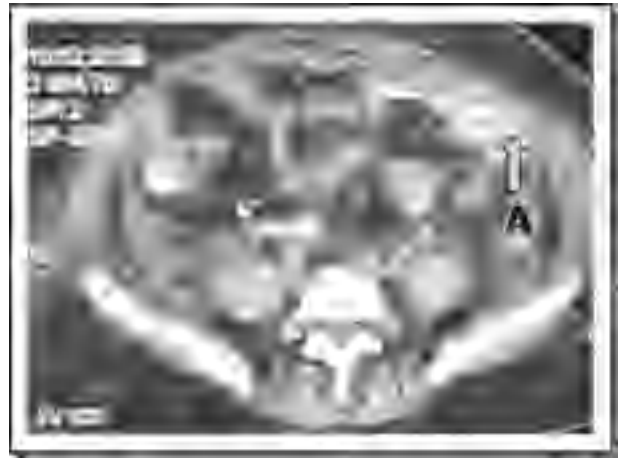
Several reports have demonstrated the safety of laparoscopic repair and avoidance of diverting colostomy. Colonic injuries in unprepared patients that require bowel resection should be considered for a diverting colostomy.

Almost all unrecognized injuries that present in the postoperative period will require open laparotomy.

On rare occasions, patients have been managed by total parenteral nutrition and percutaneous drainage or expectantly for sepsis and cardiovascular collapse. However, this is not considered a standard management strategy and should be reserved for highly selected cases.

In the postoperative period, if there is any concern for possible unrecognized bowel injury, a computed tomography scan of the abdomen with oral contrast should be performed expeditiously.

Computed tomography scan can identify bowel perforation, postoperative bleeding, urinoma, and urinary obstruction. Contrast in the peritoneal cavity and a local thickening of the bowel wall may be noted on computed tomography, and this finding should prompt immediate exploration (Fig. 1). At times, computed tomography scan with contrast may have to be done two or three times over a one- to two-week period before the diagnosis is made. A plain abdominal film may reveal an ileus. The finding

FIGURE 1 ■ Postoperative computed tomography scan of the abdomen in a patient four days after laparoscopic radical nephrectomy. Scan performed after administering oral contrast shows contrast outside the bowel lumen (*A*), suggestive of bowel perforation.


of free air is often seen up to two weeks after laparoscopy and is not absolutely indicative of bowel perforation.

If the patient does not respond quickly to antibiotics, and signs of peritonitis develop, laparotomy is mandated.

On exploration if there is suspected thermal bowel injury, the area of damage is usually more extensive than what is visually appreciated; hence, a wide excision should be performed to ensure removal of all potentially compromised tissue. The wound should be adequately drained, and the patient should have antibiotic coverage. Aggressive clinical and radiological monitoring will allow early recognition of bowel injury and will expedite early surgical exploration when warranted. A high level of suspicion and rapid clinical response are crucial in avoiding a disaster.

> If the patient does not respond quickly to antibiotics and signs of peritonitis develop, laparotomy is mandated.

ELECTROCAUTERY BOWEL INJURY

Thermal or energy-based bowel injuries represent some of the most serious complications of laparoscopic surgery (6). Monopolar electrosurgical current is attributed with the greatest number of instrument-related mishaps.

In the 1990s, the incidence of complications related to laparoscopic electrosurgery has been reported to be 2 to 5 per 1000.

The most feared electrosurgical are bowel related and result from stray monopolar electrosurgical current. However, by using only metal ports and by never using plastic collars on metal ports, this problem can be greatly reduced. In recent years, the development of "active electrode monitoring" has been very helpful in detecting any "leak" of current. This equipment will immediately turn off the flow of electrical current whenever an insulation leak is detected.

> Thermal or energy-based bowel injuries represent some of the most serious complications of laparoscopic surgery. Monopolar electrosurgical current is attributed with the greatest number of instrument-related mishaps.

Unfortunately energy-based bowel injuries are frequently not recognized during surgery, and manifest only in the postoperative period. The majority of patients present three to seven days postoperatively with abdominal pain, nausea, low-grade fever, and a moderate leukocytosis/leukopenia.

Patient's inability to void may be an early manifestation of bowel injury, or gastrointestinal bleeding can be an atypical manifestation of bowel injury. Knowledge of the biophysics of electrosurgery, and the mechanisms of electrosurgical injury are important to understanding and avoiding the potential complications of electrosurgery in laparoscopy. Electrosurgical injury can result from unrecognized energy transfer in the operational field or, less commonly, to unnoticed stray current outside the laparoscopic field. The stray current can result from insulation failure, direct coupling, or capacitive coupling. Capacitive coupling is the most worrisome of these complications because it is difficult for the surgeon to defend against this problem.

> Unfortunately energy-based bowel injuries are frequently not recognized during surgery, and manifest only in the postoperative period. The majority of patients present three to seven days postoperatively with abdominal pain, nausea, low-grade fever, and a moderate leukocytosis/leukopenia.

The most intuitive types of electrothermal injuries result from the direct application of an energy probe onto nontarget tissue as a result of unintended activation. Another form of electrosurgical injury results from defects in the insulation along the instrument. This type of insulation break may be increased when using a 5-mm insulated instrument through a 10-mm sleeve, because the 5-mm instrument is more likely to rub against the inside edge of a 10-mm trocar sleeve tip compared to a 5-mm one.

Direct coupling results from unintended contact of a noninsulated instrument like a laparoscope or metal-grasping forceps with the active electrosurgical instrument. More worrisome, however, is capacitive coupling, which occurs when electric current is transferred from an active electrode through intact insulation into adjacent conductive material such as bowel structures. Capacitive coupling can occur with a hybrid trocar sleeve, which has a plastic anchor, stopping the transmission of current from the metal trocar into the abdominal wall over a large surface and allow capacitive coupling to adjacent bowel resulting in burns. Activating the electrode in the air when not in use will create an "open" circuit, which can also result in a capacitive current effect. Use of electrosurgical accessory safety equipment, which monitors active electrode, actively shields against stray current.

Unfortunately, approximately 75% of electrothermal injuries are not recognized at the time of occurrence, and thus present in the postoperative period. The small bowel is the most frequently injured.

Symptoms of bowel perforation depending on the severity of the coagulation necrosis are usually seen three to seven days after the procedure. The reports of histopathologic findings have been reported to have significant influence on medical–legal claims. The features are an area of coagulation necrosis, absence of capillary ingrowth or fibroblastic muscle coat reconstruction and absence of white cell infiltration except in focal areas of viable borders.

Prevention of electrosurgical injuries is paramount. The best way to avoid electrosurgical injury is to avoid the application of monopolar energy sources.

We have altered our surgical technique to minimize the use of laparoscopic monopolar energy. Application of alternative energy sources such as ultrasound energy (i.e., Harmonic Scalpel[a]) or SonoSurg[b] and bipolar energy minimizes the need for monopolar energy sources and can reduce the risk of electrosurgical injuries. Electrosurgical injuries can also be prevented or minimized by regular equipment maintenance. The insulation on every piece of electrosurgical equipment should be checked prior to application. An active awareness by the surgical team of the principles of electrosurgery and the mechanisms of electrocautery injury can also be helpful in minimizing the risk of injury.

- The management of electrosurgical bowel injuries can be challenging.
- "Superficial" small thermal injuries to the bowel may be treated prophylactically with a laparoscopic-guided purse-string suture. However, as electrosurgical burns are more extensive than they appear visually, the purse-string suture should be placed well beyond the obvious demarcation of the injury.
- If there is any question as to the "superficial" nature of the bowel injury, more aggressive management strategies should be employed.
- If a deeper or perforating bowel injury is noted, a generous excision of the affected area of the bowel or, more commonly, a resection of a segment of bowel is required to prevent serious complications.

Thompson et al. reported on the conservative management of superficial thermal bowel injuries with observation in the hospital, hyperalimentation, and intravenous antibiotics (35). The authors reported that 2/33 (6%) patients with superficial appearing electrosurgical bowel injuries required laparotomy because these two cases resulted in acute perforation during the observation period. Clearly, however, intraoperative repair of damaged bowel is significantly safer and should be performed in every case of suspected electrosurgical bowel injury. Application of bipolar coagulation energy may be used to avoid visceral and vascular injuries associated with monopolar electrocautery, but thermal injury can still occur with bipolar instrumentation. The use of shielded instruments, bipolar electrosurgery, and visualization of the entire "hot" portion of the instrument will decrease the risk of inadvertent injury to adjacent tissues. A full abdominal inspection should be done at the beginning and end of each laparoscopic procedure to rule out any visceral injury. Careful application of energy sources is critical to minimize the risk of energy-based injuries; efforts should be made to avoid contact with nontarget tissues and other instrumentation, which may result in direct coupling. The insulation of each monopolar and bipolar instrument should be checked by the operative staff and the surgeon prior to application. Use of ultrasonic shears can prevent many of the complications associated with monopolar electrocautery, because ultrasound instruments do not apply current within the body

and have less energy spread from the site of application compared to monopolar and bipolar instrumentation.

MECHANICAL BOWEL INJURY

Mechanical bowel injuries may result from different types of instruments, and may be either blunt or sharp. In the authors' experience, mechanical injuries most commonly occur outside the laparoscopic field of vision. Blind introduction of instruments or retraction, or dissection of the tissues outside of the field of vision is most commonly responsible for mechanical injury.

On recognition, the majority of mechanical injuries may undergo immediate repair by intracorporeal suturing, even though the patient has not had a formal bowel preparation. Bowel resection is rarely necessary considering the localized mechanical damage to the bowel.

The abdomen is irrigated copiously with 3 to 4 L of saline at the end of the procedure. More significant injuries may require excision of bowel segment, and consultation with a general surgeon should be considered for more extensive injuries.

If not recognized intraoperatively, fever, nausea, ileus, and other signs of laparoscopic bowel injury as previously described develop in the very early postoperative period. Diagnosis is suspected if the patient is not having an expected postoperative recovery. Again, computed tomography scan with oral contrast agent is invaluable and should be performed early if there is any suspicion of bowel injury. Once recognized, immediate return to the operating room for local excision or resection of the bowel with end-to-end anastomosis and peritoneal lavage with saline irrigation is performed.

Delicate handling of the tissue and care during introduction of the instruments through the laparoscopic trocars, preferably under direct vision, should prevent mechanical bowel injury. Additionally, instruments should not be left unattended within the abdominal cavity while they are not in use.

GASTRIC OR DUODENAL INJURIES

Inadvertant injury to the stomach can occur specifically during left nephrectomy or adrenalectomy. A small gastric perforation can be closed by intracorporeal laparoscopic purse-string suturing, if the surgeon is comfortable with laparoscopic suturing technique.

An abdominal drain is placed adjacent to the repaired site and the stomach is decompressed with a nasogastric tube. Injury to the duodenum during Kocherization is a very serious complication because duodenal leak has high morbidity and a potential mortality.

Duodenal injury occurs most frequently during renal surgery on the right side or during laparoscopic retroperitoneal lymphadenectomy. Duodenal injury is managed by open conversion and repair of the duodenal injury along with placement of an abdominal drain.

It may necessitate resection of a segment of the duodenum and duodenojejunal anastomosis. Intraoperative general surgical consultation is mandatory. Total parenteral nutrition may also be necessary. Gentle handling of tissues and avoidance of the use of energy close to the bowel segment should prevent the above injuries. Duodenal injury can be avoided in most cases by an active search for the duodenum during surgical procedures that require Kocherization. As soon as the ascending colon is reflected, the surgeon should begin an active search for the duodenum. While usually quite distinct, the duodenum can be decompressed and difficult to discern. Active searching for the duodenum increases the likelihood of identification without damaging this sensitive structure.

HEPATOBILIARY, SPLENIC, OR PANCREATIC INJURY

Hepatic and splenic injury may result from Veress needle passage, initial trocar insertion, or an unmonitored auxiliary instrument.

Organomegaly noted on computed tomography imaging before laparoscopy should prompt lower abdominal or umbilical primary trocar placement. As haptic feedback is limited with laparoscopy, retraction injuries to organs, which are outside the surgeon's field of vision, are a common source of laparoscopic liver and splenic injury. Retraction injuries can be minimized by application of a mechanical self-retaining retraction system that is connected at one end to the side rails of the operating room table and

at the other end, to the shaft of the retracting instrument. The retractor can then be placed in position under direct vision and then locked in position. Unlike an assistant who may fatigue, the fixed retraction systems are indefatigable, reliable, and safe.

Minor injuries to the liver or spleen may be controlled by compression onto the bleeding site with a rolled surgical gauze, or hemostatic cellulose gauze. Surgical hemostatic agents such as fibrin glue or Floseal®c are also very useful for superficial injuries to the liver and spleen. If these measures fail, open surgical repair of a liver injury or splenectomy may be necessary.

Injury to gall bladder can occur due to perforation. Laparoscopic cholecystectomy after general surgical consultation is appropriate.

Pancreatic injury can occur during left-sided renal or adrenal surgery.

Preoperative evaluation of the computed tomography scan help the surgeon identify a long tail of pancreas, which may drape over the adrenal gland or over a portion of Gerota'a fascia. Careful dissection of the plane between the tail of pancreas and the Gerota's fascia should prevent trauma to the pancreas.

In all cases of suspected pancreatic injury, an intra-abdominal suction drain is left in the left renal bed, and postoperatively, fluid from the drain is sent for amylase levels for evidence of pancreatic injury.

If there is superficial injury to the pancreas, general surgical consultation is obtained and usually a drain in the region for few days should suffice. A major pancreatic duct injury may necessitate distal pancreatectomy by laparoscopic stapling technique or by an open conversion. If the laparoscopic technique is employed, a tissue load should be applied on the tail of the pancreas. If an open pancreatic duct is identified, this structure should be closed with a figure of eight suture to minimize the risk of leakage. In all cases of suspected pancreatic injury, a suction drain should be left in position.

PREVIOUS OPEN ABDOMINAL SURGERY AND LAPAROSCOPIC SURGERY

Previous abdominal surgery is generally considered a risk factor for bowel injury during subsequent laparoscopic access and dissection. The effect of previous abdominal surgery (open or laparoscopic) on urological laparoscopy in a single center was studied by Parsons et al. (36). Of the 700 patients 52% (366) had never undergone abdominal surgery, 15% (105) had history of abdominal surgery at the same anatomical region, and 33% (229) had abdominal surgery at a different region. The complication rates for patients who had no previous surgery, who had same-site surgery, and who had different site surgery were 4.8%, 9.4%, and 10.7%, respectively. Conversion to open surgery was 1.2%, 7.5%, and 5.7%, respectively. However, there was no statistical differences between the above three groups in terms of complication ($p = 0.11$) and conversion ($p = 0.08$) rates in patients with and without previous abdominal surgery.

Mechanical bowel preparation is recommended in patients with prior abdominal surgery due to the increased risk of bowel injury in these cases. Bowel preparation will not decrease the risk of bowel injury, but may avert a diverting colostomy if an injury should occur. Application of open direct vision (Hasson) trocar placement may help to minimize the risk of bowel injury in patients with prior abdominal surgery. Patients with prior abdominal laparoscopic surgery represent a special case. Pattaras et al. compared postoperative adhesion formation after open and laparoscopic procedures and demonstrated that de novo bowel adhesions following operative laparoscopy were minimal (37). While care is still required in patients with prior laparoscopic abdominal surgery, the risk of bowel injury is likely smaller compared to that in patients with prior open surgery.

HAND-ASSISTED LAPAROSCOPY

With the hand-assisted laparoscopic approach, a standard 6 to 8 cm incision is made at the outset of the procedure, and the pneumoperitoneum is commonly obtained via the hand-assisted device. With the hand-assisted laparoscopic approach, access-related bowel and vascular complications should be extremely rare. In contrast, wound complications such as herniation and infection are more common (38). Care should be taken to avoid inclusion of a bowel loop during closure of the hand-assisted device site,

---

because these are difficult wounds to close with the patient in a semilateral position. Prospective, randomized trials are in progress to truly compare the relative efficacy and safety of hand-assisted versus standard laparoscopic techniques.

TROCAR SITE HERNIA

Trocar site hernias are reported to occur in 0.77% to 3% of all types of laparoscopic procedures (39,40).

If the bowel function does not return early, causes such as postoperative ileus, bowel perforation, or trocar site hernia causing bowel obstruction should be suspected.

In adults, trocar sites of < 5 mm are at low risk for the development of incisional hernias. These sites are not closed in the adult, but are closed in the child. For >10 mm trocar insertion sites created by cutting bladed tipped trocars, the fascia is approximated with a single figure-of-eight absorbable suture using a Carter–Thomason cannula or other suture-assist device. Trocars should be removed under vision to identify any herniated omentum or intestine. CO_2 is largely evacuated before the removal of the trocars, and the valves of the cannula are closed to prevent sucking a bowel loop, up into the wound.

Of note, traditional bladed trocars create a fascial defect equal to the diameter of the trocar. In contrast, nonbladed dilating trocars create a defect half the diameter of the trocar. Thus, 12-mm dilating trocars should not require fascial closure because the fascial defect will only be 6-mm in size. In our experience, 12-mm dilating trocars are only closed when patients have a history of weak fascia (i.e., prior hernia), are malnourished, have been taking steroids, or have some other pathology, which can degrade the integrity of the normal fascia. With this technique, the authors have seen no hernias despite deployment of over a thousand dilating trocars. However, many surgeons, even when using nonbladed trocars, prefer to still close any midline abdominal port because it crosses no muscle. Although there are no reports in the literature, the authors are aware of a single adult case of a nonmidline trocar site herniation with a dilating trocar (41).

Trocar site herniation may manifest by localized abdominal discomfort, a palpable tender or a nontender bulge at the previous trocar site, or with signs of bowel obstruction. The diagnosis is made by computed tomography scan, which will show a loop of bowel protruding through the abdominal fascia. If suspected, exploration, either laparoscopic (via an uninvolved port site) or open, should be undertaken. Usually the bowel loop can be reduced without the need for resection.

RECTAL INJURY DURING RADICAL PROSTATECTOMY

Rectal injury during radical prostatectomy converts the case from a clean contaminated to a contaminated procedure and may increase the risk of septic complications, such as wound infection, pelvic abscess, peritonitis, rectourethral fistula, and death. The reported incidence of rectal injury during open radical prostatectomy ranges from 0% to 9%. The average incidence of rectal injuries reported in the larger series of laparoscopic radical prostatectomies is 1.7% (28/1647 procedures) (42). Guillonneau et al. reported 13 rectal injuries (1.3%) in their first 1000 laparoscopic transperitoneal radical prostatectomies (42). None of these patients had previous prostatic surgery, or had received preoperative radiotherapy or hormonal therapy. Of the 13 rectal injuries, 11 were diagnosed intraoperatively and primarily repaired. Of the 11 intraoperative rectal repairs, nine healed primarily without colostomy. Two patients who had intraoperative rectal repair by a single-layer closure developed fever and abdominal pain. Both were explored and required resuturing of small rectal defect without colostomy in one and the other required colostomy. Rectal injury was diagnosed postoperatively in two patients. Both of them presented with umbilical pain, fever, and abdominal distension after three and four days. One had a small rectal perforation, which was managed by colostomy only. The other patient had colostomy only, but developed a rectourethral fistula, which required perineal repair after three months. In the majority of the above cases (10/11), rectal injury occurred during non-nerve–sparing radical prostatectomy. Ten of 11 rectal injuries were recognized intraoperatively, the injuries occurred during the dissection of the posterior surface of the prostatic apex and in one during wide excision of the neurovascular bundle.

The management of rectal injuries during laparoscopic radical prostatectomy depends on the nature of the injury and the surgeon's experience. Minor rectal injuries identified intraoperatively may be closed laparoscopically if the surgeon is comfortable with laparoscopic reconstructive technique. Larger rectal injuries require laparotomy and bowel diversion.

The management of rectal injuries during laparoscopic radical prostatectomy depends on the nature of the injury and the surgeon's experience. Minor rectal injuries

identified intraoperatively may be closed laparoscopically if the surgeon is comfortable with laparoscopic reconstructive technique. Larger rectal injuries require laparotomy and bowel diversion.

Once rectal injury is recognized intraoperatively, the operative field is copiously irrigated with saline and povidone iodine, and the prostatectomy is completed. Thereafter, the margins of the rectal defect are clearly identified with an intrarectal metallic bougie or by digital rectal examination. The rectal wall mucosa and muscular layers are defined. The rectal wall is then closed in two layers, inner mucosa and outer seromuscular layer, with continuous sutures with a 3-0 polyglactin 17 mm half circle needle. The integrity of the repair is then checked by filling the rectum with air after it has been obstructed more proximally. Air is instilled via a rectal catheter to distend the rectal lumen, and the field is inspected. Filling the pelvis with sterile saline will help identify air bubbles. After irrigating the pelvic cavity again, vesicourethral anastomosis is performed. The posterior sutures are placed with careful attention not to incorporate the rectal wall, and the water tightness of the anastomosis is confirmed by filling the bladder with 180 mL of normal saline through the urethral catheter. Abbou and coworkers also report their experience of successful primary closure of rectal injury by laparoscopic intracorporeal suturing (43). In addition, these authors describe reinforcement of double-layered closure of rectal injury by a fat flap made from omentum for a transperitoneal approach or perirectal fat for an extraperitoneal approach.

A drain is placed posterior to the bladder close to the rectal repair and a second drain is placed anteriorly in the space of Retzius. Anal dilation is not required. Broad-spectrum antibiotics (third-generation cephalosporins and metronidazole) are given for five to seven days. Oral liquids are started the day after surgery and after passing flatus and a low-residue diet is initiated. A voiding cystourethrogram is performed after 10 to 14 days, and the urethral catheter is removed if there is no evidence of anastomotic leak or passage of flatus through the Foley catheter.

Rectal injury can occur when the Denonvilliers' fascia is not properly incised at the base of the prostate during the retrovesical dissection or more often during the apical dissection.

Early in one's experience, the use of an intrarectal bougie may facilitate detection of the plane of Denonvilliers' fascia and allow better detection of the limits of the rectal wall by movement of the rectum and tactile sensation produced by the bougie. Extreme care should be taken during prostate dissection in patients who had neoadjuvant hormonal ablation treatment, previous transurethral prostatectomy, previous rectal surgery, pelvic radiation, infection, and in those patients who have undergone multiple prostate biopsies or saturation biopsy of the prostate. In these patients, the natural planes of dissection are likely to be poor.

SURGEON EXPERIENCE

Studies have shown that the incidence of complications and the conversion rate decrease significantly after the surgeon has performed more than 40 to 50 laparoscopic procedures (4,44). Complications, as previously noted, are also related to the difficulty of the laparoscopic procedure. Laparoscopic training is now a part of all urological residency programs, and extensive training is now offered in more than 20 fellowships in the United States. Assisting in laparoscopic procedures and then independently performing procedures under the supervision of an experienced surgeon can be accomplished via a formal mentoring system. This should minimize major complications including bowel complications.

> **SUMMARY**
>
> ■ Laparoscopic bowel injury, if not promptly recognized and treated, can result in devastating consequences.
> ■ The postoperative presenting symptoms and signs are not typical of bowel perforation following open surgery.
> ■ Close postoperative clinical monitoring and serial imaging with computed tomography of the abdomen and pelvis are valuable.
> ■ A low threshold for surgical exploration could be lifesaving.

Rectal injury can occur when the Denonvilliers' fascia is not properly incised at the base of the prostate during the retrovesical dissection or more often during the apical dissection.

- A thorough knowledge of the anatomy, surgeon's experience, and constant awareness of the potential problems associated with energy-based instrumentation are crucial in preventing majority of the gastrointestinal complications of urologic laparoscopy.
- Detailed preoperative discussion with the patient about all possible complications including bowel injury is mandatory.
- Proper patient selection, surgeon's experience, meticulous attention to detail, and knowledge of potential complications that are associated with each procedure are the most important factors in minimizing complications.

LAPAROSCOPIC COMPLICATIONS: NEUROMUSCULAR

Dan B. French and Robert Marcovich

Department of Urology, University of Texas Health Science Center at San Antonio, San Antonio, Texas, U.S.A.

INTRODUCTION

Laparoscopic surgery has benefited an immeasurable number of urologic patients in the past decade. Practitioners offer a laparoscopic approach because of its well-known advantages, including decreased postoperative pain, more rapid recovery, and improved cosmesis. Nevertheless, laparoscopy shares many of the risks of open surgery, including the potential for neuromuscular complications. Although rare, a neuromuscular injury can counteract the positive aspects of laparoscopy and result in prolonged recovery and increased, perhaps chronic, postoperative pain. Because most neuromuscular injuries occur outside of the operative field, and over a relatively prolonged time period, the surgeon must be particularly vigilant to guard against their occurrence before, during, and after the case.

Neuromuscular complications are generally well defined in the contemporary open surgical literature, but much less has been written about such injuries in the laparoscopic setting. Neuromuscular injuries comprise relatively minor incisional neuralgias, peripheral nerve damage, and limb- and life-threatening compartment syndromes resulting in rhabdomyolysis.

ANATOMIC OVERVIEW (1)

Brachial Plexus

The most common peripheral nerves or neural structures at risk for surgery-related injury in the upper extremity are the brachial plexus and the ulnar and median nerves, whereas in the lower extremity, the femoral, obturator, and peroneal nerves are at risk.

The brachial plexus (Fig. 1) is derived from the ventral rami of C5 through T1 and gives rise to most nerves supplying the arm. The plexus begins in the neck and proceeds into the axilla as it passes under the clavicle and over the first rib. The plexus can be divided into three different cords, but it is more important to understand that, from these cords, the terminal branches of the plexus become the radial, median, ulnar, musculocutaneous, and axillary nerves.

Ulnar Nerve

The ulnar nerve, receiving fibers from C8 and T1, courses anterior to the triceps muscle and then dives into the medial intermuscular septum. It then proceeds posterior to the medial epicondyle (Fig. 2). At this point, the nerve lies in a superficial position and is susceptible to trauma. The nerve is also vulnerable to compression in the cubital tunnel, which is composed of a tendinous arch joining the humeral and ulnar heads. The nerve then enters the forearm and supplies the flexor carpi ulnaris and half of the flexor digitorum profundus

The most common peripheral nerves or neural structures at risk for surgery-related injury in the upper extremity are the brachial plexus and the ulnar and median nerves, whereas in the lower extremity, the femoral, obturator, and peroneal nerves are at risk.

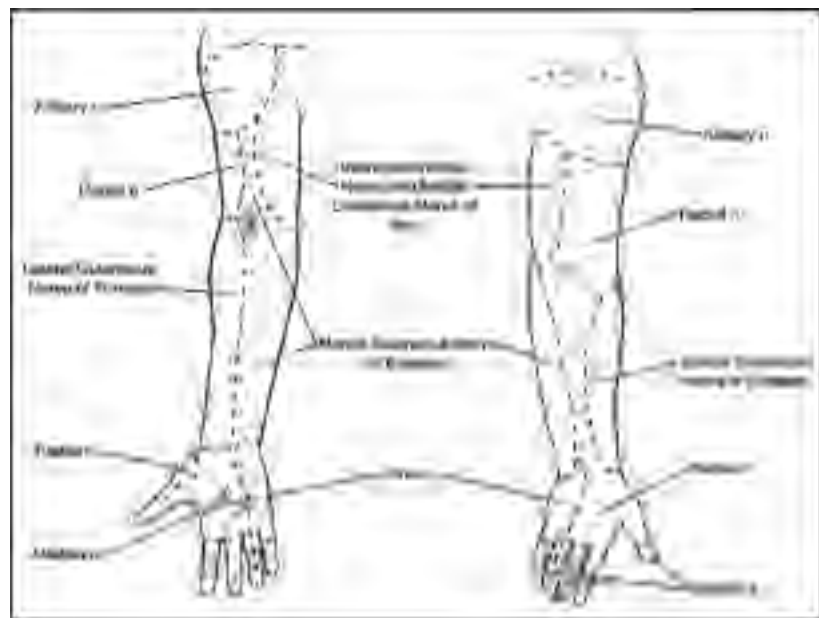
FIGURE 3 ■ Sensory innervation of the upper extremity.


muscles. Its cutaneous innervation provides sensation to the fifth digit and half of the fourth digit along with sensation to that part of the hand (Fig. 3).

Median Nerve

The median nerve receives fibers from C6 through T1. It crosses from lateral to the brachial artery to the medial side in the middle of the arm. It then descends into the cubital fossa and enters the forearm with the brachial artery. It supplies the remainder of the flexor muscles not supplied by the ulnar nerve, including flexor pollicis longus and the other half of the flexor digitorum profundus. Cutaneous innervation provides sensation to the first, second, and third digits and that part of the hand on the palmar side (Fig. 3). On the dorsal side, it only provides sensation to the distal first through third digits.

Femoral Nerve

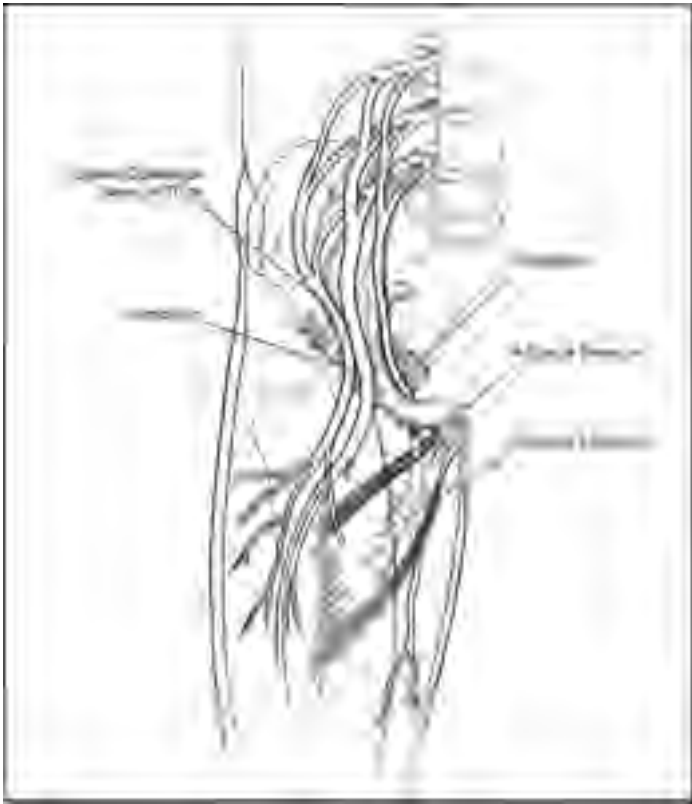
The femoral nerve is derived from the L2 to L4 roots of the lumbar plexus and, from the psoas muscle, runs deep to the inguinal ligament at its midpoint, and courses with and


FIGURE 4 ■ Anatomy and motor innervation of femoral and obturator nerves.
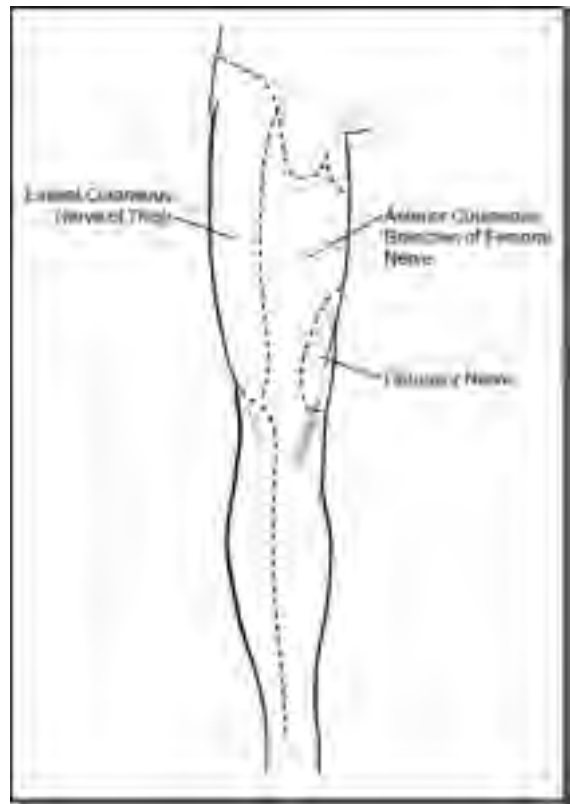

FIGURE 5 ■ Sensory innervation of the femoral and obturator nerves.

lateral to the femoral vessels in the thigh (Fig. 4). It innervates the anterior thigh muscles. Sensory innervation is to the anterior and medial thigh (Fig. 5).

Obturator Nerve

The obturator nerve also has its roots from L2 to L4 and courses from the lumbar plexus along the pelvic sidewall and into the obturator canal (Fig. 4). Lymph nodes reside in the extraperitoneal fat in close proximity to the obturator nerve along the pelvic sidewall. The obturator nerve supplies the thigh adductors including the adductors longus, brevis, and magnus. Sensory innervation is to the medial thigh (Fig. 5).

Peroneal Nerve

The common peroneal nerve (Fig. 6) is a branch of the sciatic nerve originating at the superior angle of the popliteal fossa. It leaves the fossa and winds around the head of the fibula, where it is susceptible to injury. Subsequently, it divides into its terminal branches, supplying the anterior muscles of the leg as well as the fibularis muscles. Motor functions of the peroneal nerve include dorsiflexion and plantarflexion of the foot (Fig. 7), whereas sensory innervation is to the lateral and anterior leg and dorsum of foot (Fig. 8).

RISK FACTORS FOR NEUROMUSCULAR INJURY

Patient Factors

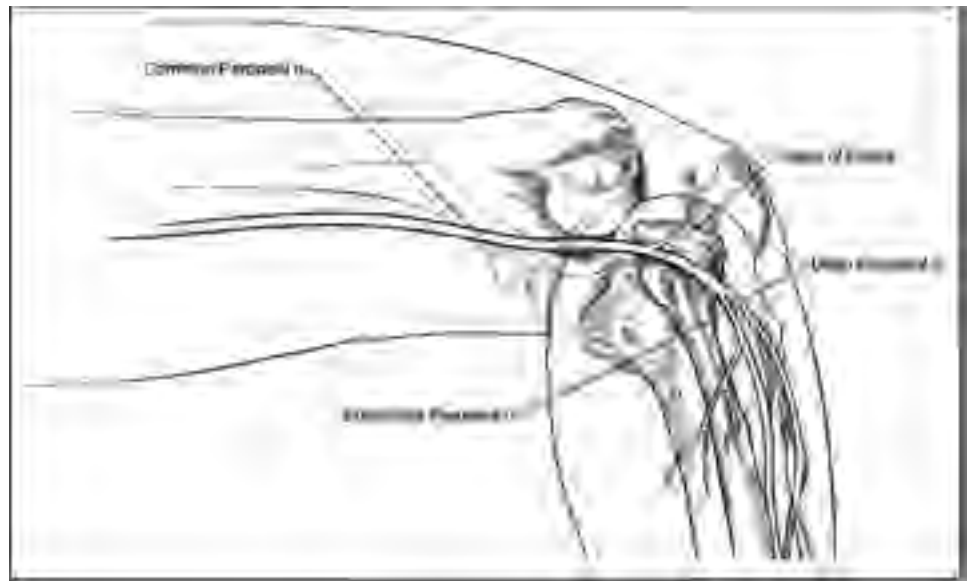
Several risk factors for peripheral nerve injury and rhabdomyolysis related to the patient have been cited, including patient age and body habitus (Table 1).

Body Habitus

It seems logical that patients with less body fat would be more susceptible to compression injuries due to decreased natural padding of bony prominences. The literature on this topic is divided and varies according to which nerve is studied. Kvist-Poulsen and Borel found that femoral neuropathy after hysterectomy was not related to body habitus,

TABLE 1 ■ Risk Factors for Neuromuscular Complications

Advanced patient age
Lean body habitus
Muscular build
Longer operative time
Extreme lithotomy or full flank position
Upper retroperitoneal procedure

FIGURE 6 ■ Common peroneal nerve in proximity to head of fibula and bifurcating into deep and superficial peroneal nerves.


but to other factors such as type of retractor used (2), which would not apply in the laparoscopic setting. In contrast, Kwaan and Rappoport described brachial plexus stretch injuries occurring more frequently in patients of lighter body weight (3). The discrepancy in these findings may be explained by the fact that positioning during hysterectomy maintains the femoral nerve in anatomic position whereas the brachial plexus is susceptible to stretch or compression in various positions, including those likely to be used for retroperitoneal laparoscopy.

Although there is a paucity of literature on this as it pertains to laparoscopy, it would appear that the surgeon should be especially vigilant for nerve injuries in thin patients.

With respect to body weight and risk of rhabdomyolysis, Wolf et al. found in a survey of neuromuscular injuries during urologic laparoscopy that patients with rhabdomyolysis were significantly heavier than other patients with complications (4). Although generally heavier, some of these patients were relatively lean with a body mass index of less than 26, suggesting that muscle mass more than obesity may be a risk factor.

> Although there is a paucity of literature on this as it pertains to laparoscopy, it would appear that the surgeon should be especially vigilant for nerve injuries in thin patients.

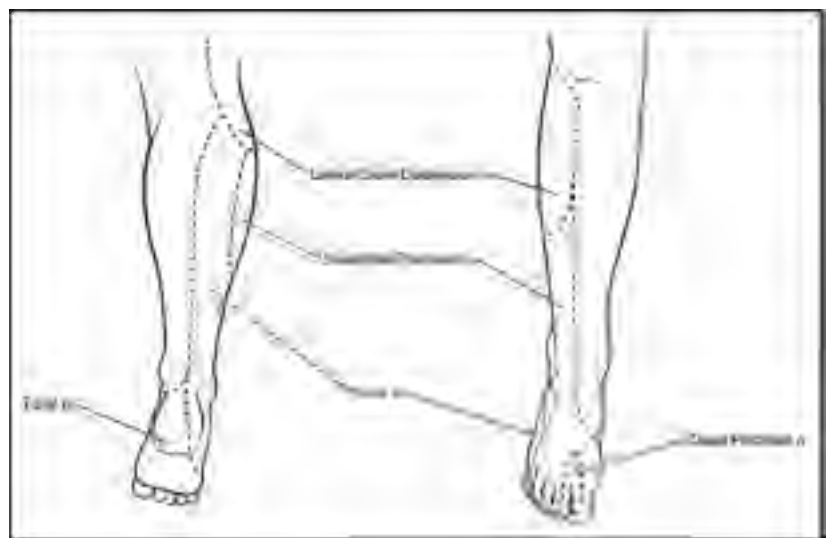
FIGURE 7 ■ Motor function of the peroneal nerves.


FIGURE 8 ■ Sensory innervation of the superficial and deep peroneal nerves.

Gender

Of the six patients who experienced rhabdomyolysis in the survey of Wolf et al., five (83%) were males (3). It is unlikely that male gender is an independent risk for rhabdomyolysis, but rather a surrogate for increased lean body mass.

Age

Advanced age may be a risk factor for the development of peripheral neuropathy postoperatively. Wolf et al. found that those patients with motor nerve palsies were the oldest group and postulated a higher prevalence of preexisting subclinical nerve deterioration in the elderly (3).

Operative Factors

Operative Time

Operative time is also a risk factor for rhabdomyolysis and peripheral nerve injury, making it a greater concern in laparoscopy, which can subject the patient to prolonged periods on the operating table. Rhabdomyolysis has been reported in as little as 4.5 hours in the full flank position (5), and similar times are reported for the lithotomy position.

In peripheral neuropathies caused by nerve compression or stretching, risk of nerve injury increases as operative time increases. Prolonged positioning in the lithotomy position is known to increase risk of lower extremity neuropathy (6).

Operative Position

> The occurrence of rhabdomyolysis during extreme lithotomy positioning is well documented.

The risk of peripheral nerve injury and rhabdomyolysis also depends on operative position. The occurrence of rhabdomyolysis during extreme lithotomy positioning is well documented. Wolf et al. found that all patients in their survey who developed clinical rhabdomyolysis were placed in the flank position. Although this condition was more common in patients in full flank position (67% of patients with rhabdomyolysis) versus modified flank (37%), table flexion did not appear to make a difference (3).

Operative positioning plays a major role in development of postoperative peripheral neuropathy. The flank position places upper extremity nerves at risk. The downside brachial plexus is at risk for compression injury in this position. The lithotomy position is associated with a host of lower extremity neuropathies, including femoral, peroneal, and sciatic neuropathies.

The flank and modified flank positions can be associated with postoperative pain in the upside shoulder secondary to stretch injury to the suprascapular nerve during circumduction or because of joint contusion (3). Wolf et al. found that patients who are thin and young with relatively free range of motion of the shoulder joint were at risk for this type of complication (3).

Upper Abdominal vs. Lower Abdominal Procedures

In their analysis of neuromuscular complications in urologic laparoscopy, Wolf et al. drew a distinction between upper retroperitoneal and lower retroperitoneal procedures (3). They found that upper retroperitoneal procedures were more than twice as likely (3.1% vs. 1.5%) to result in neuromuscular complication than lower retroperitoneal procedures. While the authors did not speculate as to the reason for this difference, it is likely that use of the flank position in upper retroperitoneal procedures may be a contributing factor.

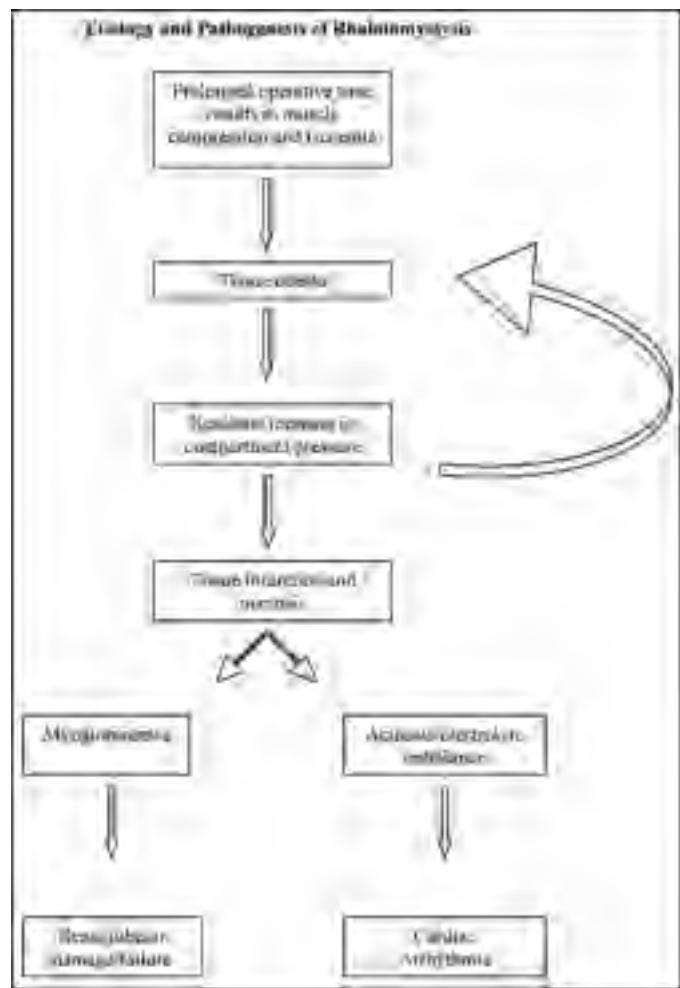
TYPES OF INJURIES

Rhabdomyolysis

> Rhabdomyolysis is the most severe neuromuscular complication of laparoscopic surgery. Thirty percent of cases result in acute renal failure.

Rhabdomyolysis is the most severe neuromuscular complication of laparoscopic surgery. Thirty percent of cases result in acute renal failure (7).

The pathogenesis of rhabdomyolysis is a cascade of events that begins with prolonged muscle compression (Fig. 9) leading to tissue ischemia. It has been estimated that ischemia develops at tissue pressures that are within 10–30 mmHg of diastolic blood pressure (8). As a result, the compressed ischemic tissue becomes edematous, precipitating a further rise in compartment pressures. This process is exacerbated when the patient is repositioned postoperatively and the ischemic compartment is reperfused. If this self-perpetuating cycle continues, tissue ischemia leads to necrosis, resulting in acidosis and release of myoglobin from damaged muscle cells. In the setting of metabolic acidosis, myoglobin and heme breakdown products cause renal tubular obstruction, contributing to acute renal failure (9).

FIGURE 9 ■ Pathogenesis of rhabdomyolysis.


Hypotension during the surgical procedure may potentiate rhabdomyolysis because the compartment pressure will more closely approach the diastolic blood pressure during such episodes. Hypotension should increase the surgeon's index of suspicion for rhabdomyolysis. Patients with peripheral vascular disease are felt to be at increased risk secondary to preexisting impairment of perfusion to the lower extremity myofascial compartments. Operative time is also another concern, as mentioned previously. With respect to positioning, extreme lithotomy and lateral decubitus using a kidney rest are the two positions associated with rhabdomyolysis for urologic procedures.

The first key to diagnosis is having a high index of suspicion when any of the aforementioned factors are present. The patient will complain of pain, often intense, at the site of tissue necrosis, and this may present even as soon as the patient is transferred to the recovery room. There is usually swelling and erythema of the affected area. The urine assumes a characteristic tea color caused by myoglobin pigment and tests positive for myoglobin. Serum creatine phosphokinase levels are markedly elevated, usually above 10,000–20,000 IU/L and sometimes over 100,000 IU/L, peaking several days postoperatively. Arterial blood gas will confirm metabolic acidosis. Imaging is usually not necessary for diagnosis, although Ali et al. described using a Tc[99m] whole body bone scan to confirm the diagnosis in a case where the urine myoglobin was negative (10). Serum potassium and creatinine levels should also be monitored, ever mindful of the possibility for acute renal failure and all its sequelae.

Once rhabdomyolysis is suspected, treatment should be initiated promptly. Hydration, urinary alkalization, and diuresis are the mainstays of treatment.

These help minimize the toxic effects of myoglobin on the renal tubules. Bildsten et al. suggested the use of sodium bicarbonate intravenously at a dose of 50–100 mEq/L to keep urine pH above 6.5 and furosemide or mannitol in conjunction

Once rhabdomyolysis is suspected, treatment should be initiated promptly. Hydration, urinary alkalization, and diuresis are the mainstays of treatment.

with intravenous hydration to maintain urine output at or above 1.5 mL/kg/hr (11). Frequent monitoring of serum electrolytes is necessary until renal function has stabilized. If renal failure progresses, hemodialysis may be necessary in the acute setting until renal function has returned.

Peripheral Neuropathies

Pathogenesis

Injuries to peripheral nerves have several etiologies. It is commonly accepted that stretch, compression, generalized ischemia, or any combination thereof contribute to postoperative sensory or motor deficits. Compression can be from direct contact with a surface from positioning or it may be indirect as the nerve is stretched over a bony prominence. All of these factors ultimately result in ischemia or mechanical damage that lead to structural and/or functional derangement of the affected nerve (12). Alvine and Schurrer have suggested that subclinical neuropathies are present in many patients who suffer a postoperative nerve injury (13). This conclusion is based on the fact that nerve conduction velocities were abnormally slow in both the affected and contralateral ulnar nerves in patients with postoperative ulnar neuropathies. Most studies note an average time to onset of symptoms of three to five days (Table 2).

Brachial Plexus Palsy

The brachial plexus is at risk of injury due to stretching from surgical positioning. The brachial plexus (C5–T1) courses from its vertebral foramina into the axilla and lies near several bony prominences that can act as a fulcrum, contributing to stretch injury. Stretch is thought to be maximal at 90° abduction and slight extension (14). When positioning the patient, it would be prudent to avoid the combination of extension and abduction. The clinical sequelae of brachial nerve injury vary according to which part of the plexus, upper versus lower, is injured. Stretch injury usually affects the upper plexus (C5–C7). Injury to this part of the plexus usually results in decreased strength and weakness of the affected arm, and is usually painless, though radicular pain may occur. There also may be a sensory deficit of the first three digits and the lateral forearm. Lower plexus injury is rarely due to surgical positioning.

When it occurs, brachial plexus palsy is usually due to Trendelenburg positioning, with the patient supported by shoulder pads. Thus, the potential for this type of injury exists in patients undergoing laparoscopic radical prostatectomy and laparoscopic radical cystectomy, or any other procedure in which the patient is in steep Trendelenburg for a prolonged period of time.

> When it occurs, brachial plexus palsy is usually due to Trendelenburg positioning, with the patient supported by shoulder pads. Thus, the potential for this type of injury exists in patients undergoing laparoscopic radical prostatectomy and laparoscopic radical cystectomy, or any other procedure in which the patient is in steep Trendelenburg for a prolonged period of time.

TABLE 2 ■ Summary of Peripheral Neuropathies

Nerve	Position	Cause of injury	Prevention of injury	Deficit
Brachial plexus (C5–T1)	Shoulder abduction + extension or use of shoulder braces in steep Trendelenburg	Stretch of the nerve roots	Avoiding 90° of abduction with extension and avoiding use of shoulder braces	Usually painless weakness of affected arm (C5–C7) or "waiter's tip" deformity (C8–T1)
Ulnar nerve	Elbow flexion and pronation	Nerve compression as it passes through cubital tunnel	Avoid extreme elbow flexion and adding pressure to elbow with tape	Numbness or pain at elbow and along fifth digit. Weakness of flexion of fourth and fifth digits
Median nerve	Complete extension of elbow	Nerve stretch	Avoid complete elbow extension by padding under forearm	Pain or tingling of thumb, index, and middle fingers. Thenar muscle weakness
Peroneal nerve (L4, 5; S1, 2)	Lithotomy	Nerve compression by stirrups as nerve passes over head of fibula	Ensure weight of leg is supported by heal in stirrup, proper padding of lateral aspect of leg	Numbness of foot dorsum, weakness of foot and toe extension
Femoral nerve (L2–4)	Any	Direct surgical trauma to nerve	Care to avoid prolonged pressure or trauma to iliopsoas muscle intraoperatively	Numbness of anterior and medial thigh and weakness of quadriceps muscles
Obturator nerve (L2–4)	Any, but usually lithotomy	Direct surgical trauma to nerve	Careful intraoperative dissection and use of electrocautery	Pain radiating through medial thigh

Wolf et al. noted that none of their cases of pelvic laparoscopy with the patient in steep Trendelenburg suffered upper extremity injuries (3), but this was prior to the era of laparoscopic prostatectomy and cystectomy. Should injury to the lower portion of the plexus occur, it usually manifests as a motor deficit, with the arm favoring an adducted and posteriorly extended position known as a "waiter's tip deformity."

Ulnar Neuropathy
Symptoms of ulnar neuropathy are that of pain about the elbow or along the fifth digit and that side of the hand. Alternatively, the patient may experience tingling, paresthesia, hypesthesia, and/or numbness in the ulnar distribution (Fig. 3). Motor deficits include weakness in flexion of the fourth and fifth digits. Alvine et al. noted that six of their 17 patients with ulnar neuropathy were positioned in the flank position, and in all of these patients, the injury occurred in the arm contralateral to the side that was in contact with the operating table (12). Nerve damage is due to compression of the ulnar nerve in the cubital tunnel that results from elbow flexion. The nerve is more susceptible to external compression when in the pronated position. Thus, when positioning a patient, avoidance of prolonged and extreme elbow flexion as well as pronation is advisable. When taping the arm as it is brought across the body, as for laparoscopic nephrectomy in the modified flank position, it is best to avoid placing the tape directly over the unpadded elbow, because it may contribute to compression of the ulnar nerve.

Median Neuropathy
According to Warner, muscular patients with large biceps who do not usually fully extend their elbows are susceptible to stretch injury of the median nerve when the elbow is fully extended under anesthesia (Fig. 10) (11). Although not specific to laparoscopy, this scenario could potentially occur during laparoscopic surgery. Symptoms include pain or tingling in the middle finger, index finger, and thumb, and weakness of the thenar muscles. Prevention of this injury includes padding of the forearm to keep the elbow slightly flexed.

Peroneal Neuropathy
The common peroneal nerve is susceptible to compression injury because it courses around the head of the fibula (Fig. 6). Poor positioning in a leg holder can easily compress this bony prominence because it has little overlying tissue for natural padding. The peroneal nerve of the downside leg can also be compressed if not carefully padded when the patient is in flank position. Symptoms of peroneal neuropathy include weakness of foot and toe extension and numbness over the dorsum of the foot (Figs. 7 and 8). Positioning the foot in the leg holder with the weight of the legs supported by the heel and avoidance of direct contact with the fibular head or generous padding of this area will help prevent injury to the peroneal nerve.

Femoral Neuropathy
Femoral nerve injury results most commonly from retractor placement during open surgery and is therefore unlikely to be encountered after laparoscopic procedures. It is thought that retractors stretch the nerve or cause ischemia as they apply pressure to the iliopsoas muscle. It is conceivable that a direct injury could occur during laparoscopy from dissection along the pelvic sidewall. Femoral neuropathy manifests as weakness of the quadriceps muscles and sensory deficits of the anterior and medial thigh (Fig. 5).

Obturator Neuropathy

Direct surgical trauma to the nerve, rather than positioning, causes obturator neuropathy.

Direct surgical trauma to the nerve, rather than positioning, causes obturator neuropathy. Wolf et al. reported this in two of 405 patients undergoing pelvic laparoscopic surgery (3). Stolzenburg noted a higher incidence of obturator nerve injury occurring in two of 70 patients undergoing laparoscopic prostatectomy (15), a series representing the authors' initial experience with that procedure. Symptoms of obturator neuropathy include pain radiating from the groin down to the medial thigh and weakness of the thigh adductor muscles.

Abdominal Wall Neuralgias
Wolf et al. defined abdominal wall neuralgias as pain, impaired sensation, or hyperesthesia radiating from a port site (3). These were the most common type of neuromuscular complication reported in their survey, with an incidence of 1%. It is interesting to note that patients experiencing abdominal wall neuralgias had relatively low-body mass index, perhaps indicating a greater statistical likelihood of a trocar injury to a cutaneous nerve in patients with relatively less surface area compared to larger patients.

FIGURE 10 ■ Stretching of the median nerve with full extension of the elbow.

Prevention and Management of Peripheral Neuropathy

The most effective way to manage a neuromuscular injury is to prevent it from happening in the first place. The overall low incidence of such complications in both the open surgical and laparoscopic literature attests to how effective the surgical community has been in preventing their occurrence. The first principle is that all members of the operating room team, including the surgeon, assistant, anesthesiologist, scrub nurse, and circulator must contribute to ensuring that the patient is correctly positioned and padded. All joints must be in an anatomically normal position, avoiding both hyperextension and hyper-flexion, as well as overabduction and overadduction. Joints, especially the shoulder, elbows, and knees should be supported with pillows or similar padding. If the operating table is to be repositioned during the case (as for laparoscopic nephrectomy in the modified flank position), it should be tested prior to draping the patient to ensure that minimal movement of the patient occurs in the new position, that joints remain appropriately supported, and that no unprotected areas come in contact with an unpadded surface. If the patient is secured to the operating table with tape, bony prominences should be protected with a towel or gel pad to avoid compression injury, especially during procedures in which the table positioning changes and potentially increases the pressure on these areas. Cushioning is particularly important for procedures expected to exceed five hours in order to minimize the risk of rhabdomyolysis. Prior to such procedures, it would be prudent to inform the patient of the possibility of neuromuscular injury and to document this in the preoperative surgical consent.

Fortunately, most peripheral neuropathies are self-limited, requiring no treatment other than observation and reassurance. Duration of symptoms is variable, but most resolve within weeks to months after the insult. Occasionally, symptoms persist past one year, and can even remain permanently. Consultation with a neurologist soon after symptoms are noted can help identify the reason for injury and possibly provide prognosis. The neurologist may perform electromyography or nerve conduction velocity studies to further elucidate the problem and can aid in recommending treatment, including physical therapy.

TABLE 3 ■ Incidence of Neuromuscular Complications in Selected Urologic Laparoscopic Series

Series (Ref.)	Year	No. of cases	Type of procedure	% Neuromuscular injury	Types of injury
Stolzenburg et al. (15)	2003	70	Lap prostatectomy	2.8	Obturator nerve palsy

SUMMARY

- Neuromuscular complications from laparoscopic surgery are uncommon (Table 3) and probably no more likely to occur than in open surgery.
- Most neuromuscular complications are not specific to laparoscopy, though certain aspects of laparoscopy such as positioning of the patient and operative time can place patients at risk.
- Neuromuscular injuries range from abdominal wall neuralgia to potentially life-threatening rhabdomyolysis. Although uncommon, these injuries are often preventable.
- Preoperative knowledge of risk factors and attention to patient positioning and operative technique can minimize their incidence.
- In the case of rhabdomyolysis, early diagnosis and prompt treatment can minimize the gravity of the sequelae.

INTRODUCTION

Laparoscopic urology has evolved from relatively simple and limited procedures to the practice of a variety of sophisticated operations. As the complexity and number of laparoscopic cases expand, an increase in the number, magnitude, and spectrum of surgical related complications is inevitable.

INCIDENCE

The records of 619 patients that underwent major urologic laparoscopic procedures at the Cleveland Clinic and had at least one chest X-ray taken in the immediate or early postoperative period were analyzed (1). Of these patients, 438 (71%) had completely normal chest X-ray.

> In a recent study from the Cleveland Clinic, medical pulmonary complications, surgical thoracic complications, and subclinical incidentally detected gas collections in the chest were identified in 12.6%, 0.5%, and 5.5% of patients, respectively.

In a recent study from the Cleveland Clinic, medical pulmonary complications, surgical thoracic complications, and subclinical incidentally detected gas collections in the chest were identified in 12.6%, 0.5%, and 5.5% of patients, respectively.

Medical complications (12.6%) included pulmonary infiltrate/atelectasis (9.7%), pleural effusion (4.8%), and pulmonary embolus (0.3%). Surgical complications included symptomatic pneumothorax in four patients (0.35%), hemothorax in one (0.08%), and chylothorax in one (0.08%). Subclinical abnormal thoracic gas collections were radiographically noted in 34 of the 619 patients (5.5%) with a chest X-ray: 19 pneumomediastinum (3.1%), 10 pneumothorax (1.6%), and 5 pneumopericardium (0.8%) (Tables 1 and 2). No patient had an open conversion to complete the initial proposed operation. Only one patient (0.08%) required an open reexploration of the thorax in the entire series. There was no patient mortality due to a thoracic complication (1).

> Retroperitoneal laparoscopy was associated with a higher incidence of abnormal thoracic gas collections (transperitoneal 3, retroperitoneal 33).

The number of transperitoneal and retroperitoneal procedures was equivalent. Retroperitoneal laparoscopy was associated with a higher incidence of abnormal thoracic gas collections (transperitoneal 3, retroperitoneal 33).

However, all these radiographic findings were incidental and asymptomatic, requiring no further intervention. On the other hand, the incidence of thoracic complications that required additional surgical intervention during transperitoneal and retroperitoneal laparoscopy was similar: one case and three cases, respectively (1).

ETIOLOGY

Pneumothorax

Pneumothorax following abdominal laparoscopic procedures can result from a variety of causes. In patients without obvious iatrogenic pleural or diaphragmatic injury, congenital

diaphragmatic defects, such as a patent pleuroperitoneal canal or attenuated areas in the diaphragm due to improper embryonic fusion, may allow peritoneal CO_2 to gain access into the pleural space (2–4). Retroperitoneally insufflated CO_2 can dissect along natural musculofascial planes into the mediastinal space. Once inside the mediastinum, CO_2 can gain entry into the pleural cavity through the pulmonary hilum dissecting along pulmonary vasculature, or through a rupture in the mediastinal pleura resulting in pneumothorax formation (2,4). An apical pneumothorax can occur due to the rupture of apical blebs from barotrauma (positive pressure during mechanical ventilation) (3). Aspiration of the pneumothorax could determine whether it occurred due to endotracheal anesthesia and positive pressure ventilation, or due to tissue propagation of carbon dioxide. Other anesthesia-related issues such as pleural injury during central line placement or elevated maximum end-tidal carbon dioxide pressure can be potentially causative (3).

> During retroperitoneoscopy, subcutaneous emphysema extending up to the neck could potentially allow CO_2 to enter the superior mediastinum and apical pleural space.

During retroperitoneoscopy, subcutaneous emphysema extending up to the neck could potentially allow CO_2 to enter the superior mediastinum and apical pleural space (2–4).

Inadvertent pleural or diaphragmatic injury is an obvious cause of pneumothorax during renal surgery, open or laparoscopic (5). In a series of 253 open flank operations, pleural injury occurred in 63 cases (25%) (6). In another series of 130 open extraperitoneal live donor nephrectomies, pleurotomy occurred in 11 cases (8.5%) (5). Pleural or diaphragmatic injuries can occur during two specific aspects of a laparoscopic procedure: port insertion or tissue dissection. Del Pizzo et al. recently documented pleural injury in 0.6% of 1765 patients undergoing laparoscopic renal surgery at four institutions (7). Pleurotomy occurred during transperitoneal laparoscopy ($N = 8$) while mobilizing the kidney ($N = 6$) or liver ($N = 2$), or during retroperitoneal port placement ($N = 2$). In the series from the Cleveland Clinic, two pleural/diaphragmatic injuries occurred during port insertion for retroperitoneoscopy. In the first case, patient's morbid obesity prevented adequate palpation and identification of the 12th rib, resulting in supracostal port placement with subsequent pleural and diaphragmatic injury. In the second case, the posterior 12 mm port transgressed the most inferior edge of the pleura, resulting in a pneumothorax.

Pneumothorax has also been reported following urological laparoscopic surgery in pediatric patients. Waterman et al. reported that out of 285 laparoscopic urologic procedures performed at their institution, pneumothorax developed in four pediatric patients (three females, one male) (8). Patient age ranged from 8 months to 11 years (mean 5.4 years). Laparoscopic surgical procedures performed included right upper pole partial nephrectomy, left upper pole partial nephroureterectomy, removal of left multicystic dysplastic kidney and bilateral Cohen reimplantation of ureters. Pneumothorax was suspected due to decreased oxygen saturations, subcutaneous emphysema, increased respiratory effort, and decreased chest lung sounds unilaterally (8). Pneumothorax was confirmed with chest X-rays. Conservative management of pneumothorax was used in three patients and a pigtail chest tube was used in one.

Pneumomediastinum

For pneumomediastinum to occur during transperitoneal laparoscopy, the abdominally insufflated CO_2 has to track through the aortic and esophageal hiatus into the mediastinum (2,4).

> During retroperitoneal laparoscopy, the lack of subdiaphragmatic peritoneum may facilitate cephalad tracking of CO_2 along the aorta and cava toward the mediastinum. Therefore, pneumomediastinum may be more likely to occur during retroperitoneoscopy.

During retroperitoneal laparoscopy, the lack of subdiaphragmatic peritoneum may facilitate cephalad tracking of CO_2 along the aorta and cava toward the mediastinum (2,4). Therefore, pneumomediastinum may be more likely to occur during retroperitoneoscopy.

In reviewing 63 chest X rays following laparoscopic renal surgery, Wolf et al. identified asymptomatic pneumomediastinum not related to iatrogenic pleural injury in eight cases (13%) (9). Incidental pneumomediastinum occurred more commonly after extraperitoneal procedures (30%) compared to transperitoneal laparoscopy (4.6%). The same finding is reported by the Cleveland Clinic study where 18 (93%) of the 19 patients with pneumomediastinum had undergone retroperitoneal laparoscopy (1).

Pneumopericardium

The exact mechanism of a pneumopericardium formation is unclear. Persistent embryological communications between the pericardial and peritoneal cavities, or rupture of accumulated mediastinal CO_2 alongside a blood vessel are possible etiologic mechanisms (10,11). Although extremely rare, pneumopericardium can result in cardiac tamponade syndrome in the presence of continuous air flow under pressure.

Due to the high solubility of CO_2, in the select clinically stable patient with pneumothorax, pneumopericardium, and pneumomediastinum expectant management including close monitoring and serial chest X-rays is advocated.

Clinically significant pneumothorax may require intraoperative or early postoperative intervention.

DIAGNOSIS AND MANAGEMENT

Due to the high solubility of CO_2, in the select clinically stable patient with pneumothorax, pneumopericardium, and pneumomediastinum expectant management including close monitoring and serial chest X-rays is advocated.

Subclinical gas collections in the chest are usually asymptomatic, and require no further intervention. These abnormal chest gas collections are incidentally detected on routine postoperative X-ray. Perhaps in the early laparoscopic experience, all patients should undergo chest X-ray routinely in the recovery room. However, with evolving experience, postoperative chest X-rays should be obtained selectively only if there is any clinical suspicion of a thoracic complication, according to the patient's clinical status.

Clinically significant pneumothorax may require intraoperative or early postoperative intervention.

Routine postoperative chest X-ray may reveal an extensive pneumothorax with lung collapse requiring a thoracostomy tube. Intraoperatively, sudden hypotension or decrease in O_2 saturation may represent alert signs of a large pneumothorax. Therefore, cooperation between the anesthesiologist and surgical teams is crucial for the precise diagnosis of this complication. Filling the operative field with irrigation fluid can identify air bubbles coming from an inadvertent pleurotomy. A red rubber catheter can be inserted directly into the pleural space and figure-of-eight stitches can be placed laparoscopically to repair the pleural injury around the red rubber catheter, which is attached to continuous water-seal suction. Alternatively, the diaphragmatic rent can be laparoscopically suture repaired with the pneumoperitoneum pressure decreased to 5 mmHg and the anesthesiologist providing positive ventilatory pressure. In the Cleveland Clinic study, two patients developed large pneumothoraces recognized only postoperatively, necessitating chest tube drainage. In both cases, although no frank pleural or diaphragmatic injury was detected intraoperatively, the authors cannot rule it out (1). Similarly, in an open series of 253 flank procedures, two patients developed postoperative pneumothorax without any intraoperative recognition of pleurotomy (6). As such, a high index of suspicion should be maintained because pleural or diaphragmatic injury may not always be recognized intraoperatively.

Rare thoracic surgical complications such as hemothorax and chylothorax have also been reported (1). Acute hemothorax occurred following a retroperitoneoscopic kidney tumor cryoablation. Because of the particular body habitus and obesity (body mass index = 36) of this patient, bony landmarks were difficult to palpate resulting in undiagnosed supracostal placement of the posterior port. Following cryoablation, in the recovery room, the patient was hypotensive, and a chest X-ray demonstrated "whiteout" of the left hemithorax. A tube thoracostomy was inserted with return of fresh blood. An emergency open thoracotomy identified an intercostal arterial bleeder which was suture ligated. Additionally, a 3 cm diaphragmatic rent created by the supracostal port was identified and suture repaired.

Following synchronous bilateral retroperitoneal laparoscopic native nephrectomy for locally symptomatic, huge, autosomal dominant polycystic kidneys, a patient returned to the emergency room complaining of sharp left pleuritic pain with mild shortness of breath. A chest computed tomography scan revealed a large left pleural effusion causing collapse of the left lower lung. Abdominal computed tomography did not reveal any retroperitoneal fluid collection. Pleurocentesis retrieved 300 cc of milky chylous fluid high in chylomicrons and triglyceride. This chylothorax was successfully treated conservatively with low fat diet and medium-chain triglyceride supplementation.

If a diaphragmatic or pleural injury is recognized intraoperatively, the anesthesiologist should be notified immediately. Usually, with careful adjustment of ventilatory parameters, the patient remains clinically stable, allowing completion of the proposed laparoscopic procedure and repair of the diaphragmatic rent.

PREVENTION

If a diaphragmatic or pleural injury is recognized intraoperatively, the anesthesiologist should be notified immediately. Usually, with careful adjustment of ventilatory parameters, the patient remains clinically stable, allowing completion of the proposed laparoscopic procedure and repair of the diaphragmatic rent.

During transperitoneal laparoscopy, care should be taken not to injure the diaphragm while mobilizing the spleen and liver.

During port placement for retroperitoneal laparoscopy in obese patients, whenever the bony landmarks are not clearly identifiable, intraoperative ultrasonography can be employed to precisely locate the 12th rib, thus avoiding inadvertent supracostal port placement (12). When creating the retroperitoneal space, the balloon dilator should be positioned anterior to the psoas muscle and fascia. This maneuver prevents

A blunt tip trocar can be used as the primary port to prevent subcutaneous emphysema.

Full relaxation of the abdominal muscles, as well as avoidance of coughing and straining during laparoscopic procedures is additional precautions to prevent abnormal thoracic gas collections during transperitoneal and retroperitoneal laparoscopy.

stripping the psoas muscle of its investing fascia, and minimizes cephalad tracking of CO_2 along the psoas muscle fibers into the thoracic cavity (4).

A Blunt tip trocar can be used as the primary port to prevent subcutaneous emphysema.

This trocar has an internal fascial retention balloon and an external adjustable foam cuff, which combine to achieve an air-tight seal, thus eliminating air leakage at the primary port site.

Full relaxation of the abdominal muscles, as well as avoidance of coughing and straining during laparoscopic procedures is additional precautions to prevent abnormal thoracic gas collections during transperitoneal and retroperitoneal laparoscopy (13).

These precautions avoid sudden elevations of abdominal pressure above 20 mmHg, which may potentially force abdominal CO_2 through the diaphragmatic hiatus into the mediastinum.

SUMMARY

- Medical pulmonary complications, surgical thoracic complications, and subclinical incidentally detected gas collections in the chest may occur after laparoscopic procedures.
- Retroperitoneoscopy is associated with a higher incidence of abnormal gas collections.
- The select clinically stable patient with pneumothorax, pneumopericardium, and pneumomediastinum occurring after laparoscopy can be treated with expectant management, including close monitoring and serial chest X-ray.
- Clinically significant pneumothorax may require intraoperative or early postoperative intervention.
- An intraoperative diaphragmatic or pleural injury in a patient who remains clinically stable can be managed with careful adjustment of ventilatory parameters. The proposed laparoscopic procedure can be completed and the diaphragmatic rent repaired.
- Full relaxation of the abdominal muscles and avoidance of coughing and straining during laparoscopic procedures are additional precautions to prevent abnormal thoracic gas collections during transperitoneal and retroperitoneal laparoscopy.

GYNECOLOGIC INJURIES INVOLVING THE URINARY SYSTEM

John E. Jelovsek and Tommaso Falcone
Department of Gynecology and Obstetrics, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

Paul K. Tulikangas
Division of Urogynecology, Department of Obstetrics and Gynecology, University of Connecticut, Hartford, Connecticut, U.S.A.

INTRODUCTION

Potential gynecologic disorders that a laparoscopic urologic surgeon may encounter include a gynecologic disorder involving the lower urinary tract, a urinary tract injury that occurred during gynecologic laparoscopic surgery and requiring repair, or an incidental gynecologic disorder identified during a urologic procedure and requiring clinical management.

GYNECOLOGIC DISORDERS THAT INVOLVE THE LOWER URINARY TRACT

Beginning early in embryonic development of the female fetus, the cloaca is divided by the urorectal septum. The urogenital sinus then develops into the bladder, urethra, and lower vagina. The ureters continue to develop from the ureteric bud and join with the developing kidney. This early primordial relationship illustrates the intimate association between the lower urinary tract and the female reproductive system. As a consequence, pathologic processes affecting one system may inevitably involve both systems. It is imperative among surgeons of the female pelvis to have a thorough knowledge of the relationship shared between the gynecologic and urologic systems.

PREOPERATIVE GYNECOLOGIC EVALUATION

Pregnancy status should be determined in all females of reproductive age undergoing surgery. Any suspicion of a pelvic mass, abdominal enlargement, or enlarged uterus should prompt the discussion of the patient's pregnancy status. This is the most common form of pelvic mass in a reproductive age female.

The pregnancy status should be determined in all females of reproductive age undergoing surgery. Any suspicion of a pelvic mass, abdominal enlargement, or enlarged uterus should prompt the discussion of the patient's pregnancy status. This is the most common form of pelvic mass in a reproductive age female.

Pelvic masses including pregnancy, enlarged uteri due to leiomyoma or sarcoma, or adnexal masses are clinically sized using the weeks of gestational age scale. This provides clinicians with a standardized range to use while communicating about clinical assessment of a pelvic mass. The 12-week sized mass is palpated at the level of the pubic symphysis while a 20-week sized mass is palpated at the level of the patient's umbilicus. These sizes are typical for normal pregnancies.

It is not uncommon to perform laparoscopy in the pregnant patient. Although the effects to the fetus during laparoscopic surgery are currently unclear, it is generally agreed upon to closely monitor insufflation pressure.

It is not uncommon to perform laparoscopy in the pregnant patient. Although the effects to the fetus during laparoscopic surgery are currently unclear, it is generally agreed upon to closely monitor insufflation pressure.

Lachman et al. reported on 518 procedures performed during pregnancy. Forty-five percent were cholecystectomy, 34% adnexal surgery, and 15% appendectomy (1). Barnard et al. found that pressures greater than 15 mmHg seemed to decrease uteroplacental blood flow (2). Despite several series reporting that laparoscopy can be successfully performed during pregnancy, it is imperative upon the physician to appropriately assess and counsel the gravid patient regarding increased risks to both her and her fetus.

Minimal gynecologic parameters to be assessed preoperatively are:

- Pregnancy status
- Menstrual cycle history
- Pap smear history
- Patient's interest in future fertility
- Pelvic examination

The most important information is a history of irregular periods or postmenopausal bleeding. This should not be ignored, and if present an evaluation and/or appropriate consultation should be initiated. Typically, an ultrasound evaluation of the endometrium and an endometrial biopsy are performed.

If the patient has not yet completed her family, a discussion of the potential impact of the surgery on her future fertility is recommended. The general principle in modern gynecologic surgery is to be as conservative as possible, especially in women of reproductive age.

UTERINE LEIOMYOMATA

Uterine leiomyomata, usually referred to as fibroids, are the most common benign tumors of reproductive age women. The annual incidence of diagnosed leiomyomata in a cohort of U.S. women aged 25 to 44 was 12.8/1000 women years (3). Estimates show that between 140,000 and 180,000 hysterectomies are performed annually with the majority being performed for uterine leiomyomata (4). The majority of uterine fibroids are asymptomatic and will not require interventions or further investigations. In the properly selected woman with symptomatic fibroids, the result from selected treatment should be an improvement in the quality of life (5). The symptoms usually include abnormal bleeding, dysmenorrhea, or noncyclic symptoms such as pelvic pressure.

Leiomyomata may be located anywhere on the uterus, uterine cervix, or even retroperitoneal space. If large enough, fibroids can result in ureteral compression laterally against the pelvic sidewall. Pelvic exam should be performed preoperatively in an attempt to identify leiomyomata of sufficient size that may contribute to possible bladder symptomatology. These involve symptoms of stress incontinence or detrusor overactivity as they compress the bladder. The variety of positions of fibroids often places the ureter at risk during hysterectomy. Lateral fibroids may impinge upon the uterine vessels, causing them to be deviated as they run along the lateral aspect of the uterus. When clamping the vessels near the uterine cervix during hysterectomy, caution should be exercised to stay as close to the uterus as possible. This is done to avoid clamping excessive parametrial tissue that oftentimes places tension on the ureter medially.

Treatments for symptomatic leiomyomata can be classified as either medical or invasive therapy. Medical therapy includes nonsteroidal anti-inflammatory drugs, oral contraceptive pills, progestational agents, or GnRH agonists. Invasive therapy typically includes uterine artery embolization, coagulation, myomectomy, or hysterectomy. A large systematic review of the literature published from 1975 through 2000 concluded that there were almost no high quality evidence-based treatment strategies (6). When such evidence-based strategies are not interpretable, individual patient and clinician opinion are relied upon.

In the case of an incidental leiomyoma discovered at laparotomy for a primary urologic disease, no intervention is required. If the patient is symptomatic, then a preoperative discussion of her options should be obtained. If the size of the leiomyoma

impedes a proper surgical approach, this also should be discussed preoperatively, and an appropriate decision by the patient should be obtained.

HYSTERECTOMY

Because hysterectomy is one of the
most commonly performed gynecologic
procedures in the United States, it is no
surprise that the majority of urologic
injuries occur with this procedure.
Most injuries to the ureter occur while
attempting to clamp the uterine
vessels near their path alongside the
uterine cervix.

Because hysterectomy is one of the most commonly performed gynecologic procedures in the United States, it is no surprise that the majority of urologic injuries occur with this procedure. Most injuries to the ureter occur while attempting to clamp the uterine vessels near their path alongside the uterine cervix.

Efforts should be made to avoid lateral deviation into the parametrium, while isolating the uterine vessels. This oftentimes kinks the ureter, resulting in obstruction. It may also lead to ureterovaginal fistula. The second common site of injury to the ureter occurs when clamping the ovarian vessels as they pass through the infundibulopelvic ligament. The close approximation of the ureter medially and inferiorly as it enters the true pelvis often results in damage at this point. This may involve inadvertent clamping or thermal injury to complete transection. The most common site of injury to the bladder during hysterectomy occurs when separating the uterus and bladder anteriorly. Injury above the trigone may occur in this area.

In 1999, Gilmour et al. reviewed reports of lower urinary tract injury from 1966 to 1998 (7). Listed in Tables 1 and 2 are the frequencies of ureteral and bladder injuries after major gynecologic surgery.

The overall frequency of ureteral injury was 1.6/1000. The overall frequency of bladder injury was 2.6/1000. In 2004, the evaluate study included two parallel randomized trials of laparoscopic versus abdominal hysterectomy and laparoscopic versus vaginal hysterectomy (8). The primary outcome was rate of complications. In the laparoscopic versus abdominal trial, laparoscopy was associated with higher complications (11.1% vs. 6.2%, $p = 0.02$; difference, 4.9%, 95% confidence interval, 0.9–9.1). The number needed to treat to harm was 20. The rate of bladder and ureteral injuries was 2.1% and 0.9%, respectively, in the laparoscopic group versus 1% and 0% in the abdominal group. In the laparoscopic versus vaginal study, there was no difference in the rate of major complications (9.8% vs. 9.5%, $p = 0.92$; difference, 0.3%, -5.2% to 5.8%), and the number needed to treat to harm was 333.

PELVIC ADHESIONS

In the reproductive age female, there is concern regarding adhesion formation and resultant infertility. Adhesions are thought to interfere with ovum pickup by the tubal fimbriae. Although the evidence of external adhesions' contribution to decreased fertility is controversial, it is generally recommended to minimize the extent of damage to the serosal surfaces of both the ovary and fallopian tube in females of reproductive age. The potential decrease in fertility as a result of pelvic adhesions should be discussed with the patient.

Pelvic adhesions may result from previous surgery, inflammatory disorders, pelvic infection, or endometriosis. The pathogenesis involves creating a deperitonealized surface. When damage occurs to this surface, the repair process is rapid and essentially in place by eight days. The first process involves primitive mesothelial cells that repair serosal defects from the underlying mesenchyme. The second healing process occurs when fibrin deposits are laid down after three days (9). This results in adhesion formation.

There is a long held belief that adhesions cause chronic pelvic pain. Good evidence exists showing that adhesiolysis does not improve chronic pain. In 2003, Swank et al. reported 100 patients with continuous or intermittent abdominal pain thought to be due to adhesions from previous surgery of at least six months' duration (10). These patients were randomized to diagnostic laparoscopy versus diagnostic laparoscopy and lysis of adhesions. The authors found there was significant pain relief and improvement in generalized quality of life in both groups up to a year from surgery. However, there was no difference between groups, concluding that laparoscopic lysis of adhesions is not more beneficial than diagnostic laparoscopy alone. This may not apply to patients with an identifiable pelvic pathology such as endometriosis in which evidence supports resection of the pathology.

TABLE 1 ■ Frequency of Ureteral Injuries After Major Gynecologic Surgery

Study	Year	Operation	No. of operations	No. of ureteral injuries	No. of ureteral injuries/1000 operations	No. of injuries recognized intraoperatively	No. of injuries recognized postoperatively

PELVIC INFLAMMATORY DISEASE

The most frequent acute infection in reproductive age, nonpregnant women is pelvic inflammatory disease. It is an enormous public health problem.

Pelvic inflammatory disease should always be considered in the differential diagnosis of acute febrile abdominal pain. Infections of the uterus, tubes, and ovaries may cause infertility and can cause life-threatening sepsis in a significant number of women.

The most frequent acute infection in reproductive age, nonpregnant women is pelvic inflammatory disease. It is an enormous public health problem. In 1998, direct costs were estimated to be around 1.9 billion (11). *Chlamydia* is the most common infectious disease reported to health departments among young, sexually active females. *Chlamydia* and *Neisseria gonorrhea* are among the major causes of cervicitis and pelvic inflammatory disease. The U.S. Centers for Disease Control and Prevention, however, recommends coverage for a mix of pathogens not just limited to these two organisms. *Chlamydia* and *Neisseria gonorrhea* are included as well as a mix of anaerobes, gram-negative facultative bacteria, and streptococci.

Diagnosis of pelvic inflammatory disease is a clinical diagnosis. It is made based upon historical and clinical exam findings including a thorough pelvic exam. Laparoscopy is not necessary for the diagnosis of pelvic inflammatory disease. However, many authors have described the diagnosis using the laparoscope. In 1969, Jacobson and Westrom described visual criteria for the laparoscopic diagnosis of salpingitis (12). These include hyperemia of the tubal surface, edema of the tubal wall, and exudate on the tubal surface or from the fimbriated ends when the tubes are patent. Adhesions from pelvic inflammatory disease are usually described as thin and filmy, and involve the fimbriated ends of the fallopian tubes. Patients with active pelvic inflammatory disease may show an erythematous uterus and fallopian tubes. A yellowish-green exudate is sometimes seen around the tubes and ovaries or in the posterior cul-de-sac.

Obstruction to the end of the fallopian tube may result in a hydrosalpinx or pyosalpinx. It is not uncommon to encounter hydrosalpinx inadvertently in an asymptomatic patient while performing laparoscopic surgery for other pathology. Data on management of hydrosalpinx are mixed. The presence of hydrosalpinx reduces the pregnancy rate in patients undergoing in vitro fertilization. Removal of the fallopian tube has been shown to improve fertility rates from in vitro fertilization. However, it is not recommended that an incidentally discovered hydrosalpinx should

be removed without prior discussion with the patient. Consultation regarding the patient's future fertility desires is imperative before attempting to remove an existing hydrosalpinx.

Most patients with pelvic inflammatory disease are treated on an outpatient basis. The Pelvic Inflammatory Disease Evaluation and Clinical Health Study reported on 35 months of follow-up in patients who were diagnosed with mild to moderate pelvic inflammatory disease (13). A single intramuscular dose of cefoxitin (2 g) with probenecid and oral doxycycline for 14 days was as effective as a 48-hour administration of cefoxitin every six hours and the doxycycline course. At 35 months there was no difference in pregnancy rates, recurrence of pelvic inflammatory disease, chronic pelvic pain, or ectopic pregnancy.

The most severe cases of pelvic inflammatory disease will progress to form tuboovarian abscess. These pockets of inflammation are associated with tissue induration and may involve the uterus, ovaries, tubes, and in many cases the bowel. There have been cases of tuboovarian abscess as a cause of ureteral obstruction (14). This can occur unilaterally or bilaterally. Usually, treatment of the tuboovarian abscess will relieve the induration of the periureteral tissues, resulting in resolution of the hydronephrosis. Removal of the offending organ containing the abscess should be considered. In patients who desire future fertility laparoscopic or computed tomography–guided drainage can be performed.

ADNEXAL MASSES

A common finding in both reproductive and nonreproductive age females is an adnexal cyst. These are sometimes found incidentally during urologic procedures. These may arise from the ovary, fallopian tube, or paratubal areas. In the reproductive age female, benign cysts usually include pelvic inflammatory disease, ectopic pregnancy, paratubal cysts, or Hydatid cysts of Morgagni. These cysts are remnants of the mesonephric or paramesonephric systems. They are usually less than 1cm and simple. Physiologic cysts include corpus luteal cysts, follicular cysts, or theca lutein cysts.

The most common ovarian tumor in children and younger women is the mature cystic teratoma or dermoid cyst. These cysts contain the three embryologic germ cell layers: endoderm, mesoderm, and ectoderm. Consequently, they often contain hair, teeth, and sebaceous fluid within the cyst cavity. These cysts are notorious for causing ovarian torsion in children or during pregnancy. Caution should be exercised if rupture of this cyst occurs.

If ovarian cyst rupture occurs during laparoscopy, it is often helpful to place the patient in the reverse Trendelenburg position, to prevent the cyst contents from spreading throughout the pelvis. Using warm irrigation fluid, copiously irrigate the pelvic cavity to prevent the peritonitis that may result from the cyst contents.

In general, the suspicion for malignancy does increase in the postmenopausal patient. Not all adnexal masses in postmenopausal women are malignant, however. The rate of asymptomatic simple ovarian cysts in postmenopausal women ranges from 3.3% to 6.6% (15,16). In 116 women who had pelvic ultrasound screening by Conway et al., ovarian cysts resolved spontaneously in 27 women (23%) and persisted in 69 (59%); 20 women (17%) were lost to follow-up. These women were reevaluated every three to six months for five years. Eighteen had surgery, two-thirds undergoing laparoscopic unilateral or bilateral salpingo-oophorectomy (15).

Pelvic ultrasound is the single most important clinical test in predicting if an adnexal mass is benign or malignant. Typical benign characteristics include a thin cyst wall, with no internal projections/papillary excrescences, thin septa, or low echogenicity. Conway et al. reported that cysts removed from the 18 women noted above were benign cystic adenomas. These findings are consistent with a similar study by Hall and McCarthy (17) supporting that benign cystadenomas appear to be the most common histological finding in persistent simple postmenopausal cysts.

When the surgeon encounters a benign adnexal mass, one may proceed with ovarian cystectomy or oophorectomy if clinically indicated and the patient has given consent. Aspiration of ovarian cysts should not be performed to aid in a diagnosis. In 1994, a meta-analysis showed that aspiration of ovarian cysts had a negative predictive value of 58% to 98% in the diagnosis of malignancy (18). Aspiration does not prevent ovarian cysts from recurrence. When doubt arises as to malignancy status, an intraoperative consult by a gynecologist or gynecologic oncologist is recommended.

Benign epithelial neoplasms such as serous cystadenoma, mucinous cystadenoma, cystadenofibroma, Brenner tumor, and tumors of low malignant potential begin to increase in incidence as the patient ages. The overwhelming majority of malignant ovarian cancer is epithelial in origin. During 1997 to 2001, the U.S. National Cancer Institute reported the age-adjusted incidence of ovarian cancer for all races to be 13.9 cases per 100,000 (95% confidence interval, 13.7–14.2). Half of all cases occur in women over the age of 65 (19). The most important risk factor is having a first-degree relative with a history of the disease. Most patients with epithelial ovarian cancer present with advanced disease including a pelvic mass associated with ascites and an increased CA-125 level. In surgery, multiple small nodules with metastases on intraperitoneal organs are often seen. The most commonly involved extrapelvic organs include the bowel, liver, omentum, and diaphragm. If one suspects malignancy it is suggested to obtain a tissue sample for pathology and abort the procedure or consult with a gynecologic oncologist.

OVARIAN REMNANT

Ovarian remnant syndrome is a condition of continued pelvic pain, ovarian follicle formation, and premenopausal levels of pituitary hormones. It is a complication of oophorectomy, where pieces of ovarian cortex are left behind. This tissue is responsive to pituitary hormones and can retain the ability to produce estradiol (20). It is often suspected in a patient with continued pelvic pain and a persistent adnexal mass after a bilateral oophorectomy. An increased risk of ovarian remnant is associated with performing oophorectomy, when the ovaries are adherent to the pelvic sidewall, rectosigmoid, and/or the cul-de-sac. This may occur in cases of endometriosis, pelvic adhesions, or pelvic inflammatory disease (21). The risk may also increase risk with misapplication or improper use of pretied surgical loops, staplers, or bipolar electrodessication (22). This results in the remaining ovarian tissue being scarred along the pelvic sidewall frequently involving the peritoneum adjacent to the ureter. In 1962, Kaufmann, a urologist, made the discovery of ovarian remnants during the investigation of patients with ureteral obstruction (23). The dissection can be tedious, often requiring removal of the remaining ovarian tissue by first entering the retroperitoneal space at the pelvic brim to identify and isolate the infundibulopelvic ligament containing the ovarian vessels and adjacent ureter as it enters the pelvis (24,25).

CERVICAL CANCER

The World Health Organization reports cervical cancer as the second largest cause of female cancer mortality worldwide with 288,000 deaths yearly. Roughly 510,000 cases of cervical cancer are reported each year with approximately 80% of these from developing countries. Human papilloma virus is a cause of cervical cancer with prevalence of approximately 630 million infections in the world.

Invasive cervical cancer is a well-known cause of both ureteral obstruction and invasion into the bladder. Although cervical cancer is clinically staged, the presence of hydronephrosis on imaging due to tumor fulfils one of two criteria for the diagnosis of Stage IIIB cervical cancer in the International Federation of Gynecology and Obstetrics staging system. The proximity of the distal third of the ureter to the upper vagina and lower uterine cervix make this area susceptible to the direct invasive nature of advanced cervical cancer. The predominant route of spread is from the cervix into the vaginal mucosa, into the uterine myometrium, into the paracervical lymphatics, and then into the pelvic nodes. This is followed by extension into the adjacent structures, wall of the pelvis, bladder, or rectum with possible resulting vesicovaginal or rectovaginal fistula. Most patients will ultimately die from bilateral ureteral obstruction and subsequent sepsis.

Treatment of cervical cancer with radiation or surgery has a high incidence of urologic complications. In 2001, Fujikawa reported on 271 patients who were treated with external beam therapy and intracavitary brachytherapy for cervical cancer. Eight percent had urologic complications requiring surgical intervention, while 13% had complications of the rectum or intestine (26). Spontaneous rupture of the bladder has also been reported by the same group.

Radical hysterectomy is used for early stage treatment of cervical cancer. This involves resection of the parametrial tissues including the uterosacral ligaments, portions of the cardinal ligaments, and upper third of the vagina. Radical hysterectomy has

been associated with changes in bladder compliance and bladder capacity (27). This often results from direct injury to the sensory and motor nerve supply to the bladder. It is not uncommon for individuals to have voiding dysfunction for over a month after surgery often requiring intermittent self-catheterization or continuous bladder drainage.

ENDOMETRIOSIS

Endometriosis is the presence of functioning endometrial tissue outside of the endometrium and myometrium. The clinical syndrome involves cyclic pelvic pain that begins just before menses and lasts throughout the days of menstrual flow, noncyclic chronic pelvic pain, and dyspareunia. It is associated with inflammation, immune system abnormalities (28), and neoangiogenesis often causing infertility, scarring of the fallopian tubes, dysmenorrhea, dyschezia, and dyspareunia. The prevalence of pelvic endometriosis is estimated to be around 10% (29) of reproductive age women and prevalent in 2% of postmenopausal women (30). Sources of estrogen in the postmenopausal patient primarily arise from the cytochrome p450 enzyme aromatase. Aromatase is primarily expressed in ovarian granulosa cells, placental syncytiotrophoblast, adipose tissue, skin fibroblasts, and the brain (31). Cases of endometriosis have been reported in the gastrointestinal tract, urinary tract, pulmonary, musculoskeletal, peripheral, and central nervous system.

In advanced cases of endometriosis, the pelvic exam reveals irregular and tender nodularity in the posterior fornix of the vagina in the area of the insertion of the uterosacral ligaments on the poster-apical portion of the vagina. An adnexal mass may also be palpated. Pelvic ultrasound may reveal echogenic cystic structures present in the adnexa containing debris consistent with blood present within the cyst walls.

Endometriotic implants vary in size and appearance. They range from the classically described "powder burn" appearance to reddish-blue nodules and ovarian cysts. The repetitive process of hemolysis and encapsulation of debris causes extensive scarring of the affected surface. These surfaces usually include the ovary and posterior cul-de-sac with involvement of the distal uterosacral ligaments. Extensive involvement will include the rectum, tubes and ovaries, and the bladder. The overall positive predictive value for laparoscopic visualization of endometriosis is 43% to 45% (32,33). This is similar to appropriate history taking and physical exam. It is preferable to have a pathologic diagnosis if one suspects an implant may be endometriosis.

First line therapy of endometriosis usually involves hormonal management. Medications include Danazol, an isoxazol derivative of 17 α-ethinyl testosterone, and progestational agents such as medroxyprogesterone acetate, norethindrone, or norgestrel. Gonadotropin releasing hormone agonists are also used. These agents down-regulate the pituitary gland causing a decline in gonadotropin levels, resulting in a castrating effect. Medical therapy seems to be useful in treatment of mild to moderate disease.

Surgical resection is a commonly used treatment for moderate to severe cases of endometriosis or those cases of failed medical management. It is recommended for cases of cyst formation, invasion or obstruction to the bowel, ureters, or bladder. Most patients with endometriosis will not have involvement of the lower urinary tract. However, in cases of extensive endometriosis, the ureters are frequently involved. The scarring results in fibrosis of the surrounding periureteral tissue, often leading to obstruction. It is often necessary to enter the retroperitoneal space releasing the ureter laterally, away from the affected implants along the pelvic peritoneum. The goal is to remove all diseased tissue and restore pelvic anatomy (34). However, in advanced cases of endometriosis, intentional and nonintentional ureterotomy are relatively common.

Data regarding surgical treatment for endometriosis causing recurrent pelvic pain are mixed. In 1994, Sutton et al. reported on a randomized, double-blind study of endometriosis ablation plus uterosacral nerve ablation versus sham surgery (35). Three months after laparoscopy, 56% of the surgically treated women continued to experience pain relief, whereas 48% of the sham operation women also experienced pain relief. Thus, for at least three months there is a persistent placebo effect of surgery. After six months, 22% of the sham operation women experienced pain relief, whereas 62.5% of the surgically treated women experienced pain relief (35). This study illustrates that even in the best of hands and when studied in a controlled and prospective manner, laparoscopic surgery in which lesions are ablated results in a nearly 40% failure rate six months after surgery.

Ureter repair in patients with endometriosis is difficult because of the extensive fibrosis. To access the endometriosis around the ureter, extensive dissection is performed with potential compromise of the blood supply. Repair of the ureter in these situations could lead to stenosis at the repair site. Experimental studies in the porcine model have shown that repair of the ureter after extensive dissection that is typical of endometriosis surgery has a higher rate of stenosis (36).

FISTULA

The most common form of vesicovaginal fistula in North America is injury to the bladder during hysterectomy.

In developing countries, the main cause is childbirth. Invasive cervical cancer or radiation therapy for this disease is also a contributor to the formation of vesicovaginal fistulas. Most fistulas resulting from hysterectomy occur during removal of the uterine cervix. The vaginal portion is usually located at the area where the vaginal cuff was sutured together, identified by the linear vaginal scar.

URINARY TRACT INJURY DURING GYNECOLOGIC PROCEDURES

Most urologic injuries that occur during gynecologic procedures are to the lower urinary tract. Laparoscopic hysterectomy is the most common surgery associated with lower urinary tract injury.

A large review in Finland found rates of urinary tract injury in laparoscopic hysterectomy of 22.8/1000. Urinary tract injury rates for trans abdominal hysterectomy and trans vaginal hysterectomy were 1.7/1000 and 0.4/1000, respectively (37). Unfortunately, the incidence of injury to the lower urinary tract has increased with the advent of new laparoscopic techniques (38). Hopefully, this number will decrease as surgeons gain more experience with advanced laparoscopic surgery.

The complexity of the laparoscopic procedure also increases the risk of injury to the lower urinary tract. The incidence of injury to the lower urinary tract after diagnostic laparoscopy is relatively low, less than 0.6/1000, whereas the risk of injury during operative laparoscopy was 3.0/1000. The majority of these injuries occurred during laparoscopic hysterectomy (39).

INJURY TO THE URETHRA

Injury can occur during suburethral sling procedures, often done in conjunction with laparoscopic hysterectomies and surgeries for pelvic organ prolapse. Typically, these injuries are managed either with prolonged catheter drainage or with surgical reanastomosis. Injury to the urethra is unusual during laparoscopic gynecologic surgery.

INJURY TO THE BLADDER

Cystotomy is the most common urinary tract injury (Table 2).

Dissection of the bladder off the lower uterine segment, cervix, and upper vagina is necessary for a total hysterectomy. Less dissection is needed for a supracervical hysterectomy and not surprisingly results in a lower rate of cystotomy (37). Cystotomy is also a common injury during the dissection for laparoscopic retropubic colposuspension (40).

When bladder injuries are not recognized intraoperatively they often lead to significant morbidity, including postoperative urinomas, bowel obstructions, infections, and fistula (41). Observation of gas in the Foley bag or bubbles at the time of cystoscopy is a common intraoperative sign of bladder injury during laparoscopy.

When an intraoperative injury is suspected, consultation with urologist and evaluation of the lower urinary tract are recommended. Typically this involves intravenous injection of Indigo carmine (5 cc) and cystoscopy. The bladder and both ureters should be evaluated in all cases.

Energy sources such as monopolar and bipolar electrocautery, CO_2 laser, and the ultrasonic scalpel can all be associated with injuries to the bladder or ureter. These energy sources were evaluated in an animal model to determine the accuracy of clinical

Small injuries to the dome of the bladder can often be managed with prolonged bladder drainage. When surgical repair is required, this can often be accomplished with laparoscopic suture techniques. If injury occurs at the time of hysterectomy, transvaginal repair is also an option.

assessment of the injuries and the extent of lateral spread. Laparoscopic assessment is as accurate as gross assessment of the injured tissue (42). Monopolar cautery has the greatest risk of lateral spread (43).

Small injuries to the dome of the bladder can often be managed with prolonged bladder drainage. When surgical repair is required, this can often be accomplished with laparoscopic suture techniques. If injury occurs at the time of hysterectomy, transvaginal repair is also an option.

The route chosen for repair should reflect the surgeon's ability and experience. A closed pelvic drain should be considered if the repair is not watertight.

INJURIES TO THE URETER

Older studies document ureteral injury rates of as high as 30% during major pelvic surgery (44). More recent studies, however, report ureteral injury rates of less than 2% (Table 1). Many ureteric injuries may be asymptomatic, ultimately resulting in loss of renal function (44). Current guidelines recommend identification and tracing the course of the ureter during all gynecologic surgeries (45).

Intraoperative consultation for a ureteric injury should involve assessment of both ureters and the bladder for potential injury.

Injury to the ureter—clinical scenarios and management:

- If there is concern regarding a possible ureteric injury but none can be visualized laparoscopically, evaluation with cystoscopy with confirmation of ureteral patency is adequate.
- If during this evaluation patency of a ureter cannot be confirmed, a ureteral stent should be placed.
- If the pelvic ureter is obstructed, it should be repaired. However, prior to pursuing surgical repair of the ureter, the patient medical record should be reviewed for possible causes of prior urinary tract injury.
- If there is any question regarding renal function or another upper urinary tract injury, an intraoperative urogram should be performed to confirm bilateral renal function.
- When the ureter has been obviously transected, laparoscopic ureteroureterostomy or reimplantation is an option (46,47).

Typically, injuries near the bladder are reimplanted, and injuries higher in the pelvis are reanastomosed. Laparoscopic reanastomosis has been documented in a number of gynecologic procedures. A retrograde ureteral stent is placed, and four interrupted sutures are placed circumferentially around the ureter. We have found it helpful to place a single interrupted suture to align the ends of the ureter to facilitate stent placement (47). When a tension-free ureteroureterostomy is not possible, reimplantation in the bladder should be considered. This is often done with a bladder flap. Fibrin glue and laser welding have been used successfully to repair ureterotomy in an animal model (48).

Another clinical scenario that occurs is injury to the ureter with an energy source but no ureterostomy. In this setting, bilateral ureteral patency should be confirmed. Passage of a ureteral stent in these cases has been reported with both successful and unsuccessful outcomes (49,50). Consideration should be given to surgical repair in these settings.

MANIPULATORS

By and large, one of the most difficult aspects of any laparoscopic surgeon when dealing with the female pelvis is uterine manipulation.

By and large, one of the most difficult aspects of any laparoscopic surgeon when dealing with the female pelvis is uterine manipulation.

The level of difficulty has been raised in many laparoscopic cases predominately due to inappropriate manipulation. This not only interferes with the procedure at hand but also limits the surgeon's inspection for other pathologies in the pelvis. A lubricated sponge stick can be placed into the posterior fornix of the vagina. There are several problems with this approach. It does not allow for the uterine fundus to be manipulated either out of the pelvis or into the pelvis away from the bladder.

Several uterine manipulators have been specifically designed just for these purposes. They are useful in procedures where the assistant holding traction may stand between the patient's legs allowing the surgeon to use both hands for the procedure. The Hulka tenaculum is a commonly used device for uterine manipulation. During the pelvic examination under anesthesia, the position (e.g., anteversion or retroversion) of the uterus is assessed. A single tooth tenaculum is used to grasp the anterior lip of the cervix. Gentle traction is pulled toward the examiner to straighten out the angle often present between the cervical canal and the anteverted or retroverted uterine fundus. The Hulka is then placed with the

curve of the tenaculum pointing in the direction of the uterine fundus. If the uterus is retroverted, flipping the tenaculum into the ante-verted position is performed once placed into the uterine cavity. When the uterus is placed in the anteverted position, the tooth is clamped on the anterior lip of the cervix, and the single tooth tenaculum is removed.

The Rumi manipulator is another useful device. This is placed in a similar fashion to the Hulka. Once placed, it may be locked into either an anteverted or retroverted position. Several other benefits of this device include the ability to inject dye into the uterus to assess tubal patency and the ability to accommodate the Koh device (51). This Koh device is useful during laparoscopic hysterectomy. The system consists of a pneumo-occluder and a cup, combined with a uterine manipulator usually the Rumi manipulator. The cup, which is both visible and palpable, is placed over the cervix to delineate vaginal fornices, thus ensuring safe desiccation and avoiding ureteral dissection during colpotomy (51).

SUMMARY

- Laparoscopic hysterectomy is the most common surgery associated with lower urinary tract injury.
- Cystotomy is the most common urinary tract injury. Small injuries to the dome of the bladder can often be managed with prolonged bladder drainage. When surgical repair is required, this can often be accomplished with laparoscopic suture techniques. If injury occurs at the time of hysterectomy, transvaginal repair is also an option.
- If there is concern regarding a possible ureteric injury but none can be visualized laparoscopically, ureteral patency should be confirmed. Otherwise, a ureteral stent should be placed. An obstructed pelvic ureter should be repaired.
- If there is any question regarding renal function or another upper urinary tract injury, an intraoperative urogram should be performed to confirm bilateral renal function.
- When the ureter has been obviously transected, laparoscopic ureteroureterostomy or reimplantation is an option.
- Injury to the urethra is unusual during laparoscopic gynecologic surgery. However, injury can occur during suburethral sling procedures, often done in conjunction with laparoscopic hysterectomies and surgeries for pelvic organ prolapse. Typically these injuries are managed either with prolonged catheter drainage or with surgical reanastomosis.
- If ovarian cyst rupture occurs during laparoscopy, it is often helpful to place the patient in the reverse Trendelenburg position to prevent the cyst contents from spreading throughout the pelvis. Using warm irrigation fluid, copiously irrigate the pelvic cavity to prevent the peritonitis that may result from the cyst contents.

LAPAROSCOPY: SELECT ASPECTS

IMMUNOLOGIC ASPECTS OF LAPAROSCOPY

Prokar Dasgupta and Ben Challacombe

Laparoscopic Urology and Robotics, Guy's Hospital and Guy's King's and Thomas's School of Medicine, London, U.K.

INTRODUCTION

Since the first laparoscopic procedures involving diagnostic laparoscopy for gynecological pathology, surgeons have observed less postoperative pain, shorter recovery times, and better cosmesis with laparoscopy compared to conventional open surgery.

Open surgery is associated with a period of immunosuppression in the immediate postoperative period (1). Due to its minimally invasive nature, laparoscopic surgery is believed to lessen surgical trauma and so causes less disturbance of immune function. This may contribute to the rapid recovery noted after many laparoscopic operations. As a result, laparoscopic surgery has been investigated for a potential reduction in stress and immune responses.

A large number of animal—mainly rodent—and human studies have investigated the immune response to laparoscopic surgery by the measurement of a number of recognized immunological markers. As preservation of both systemic and intraperitoneal immunity is important in surgery in general and particularly in oncological procedures, an understanding of the impact of laparoscopy on immune function is highly relevant. A number of prospective and a few randomized controlled trials comparing laparoscopy to open surgery have been reported.

The immunologic benefits of laparoscopic surgery are most obvious in relatively atraumatic procedures such as cholecystectomy and antireflux surgery. For more complex procedures such as resection of colorectal cancer the benefits are less obvious and the evidence controversial.

Although laparoscopy for colorectal cancer may be associated with higher survival and lower recurrence rates (2), it has been related to high incidence of port site metastasis. This is comparable to the incidence of wound metastasis observed after open surgery (2). Long-term results from randomized trials are eagerly awaited.

As laparoscopy becomes established in the field of urology, the study of immunological dysfunction after procedures such as laparoscopic nephrectomy will become more important. At this time, data from randomized trials are sorely lacking. Perhaps, the laparoscopic equivalent of colorectal surgery is laparoscopic radical cystectomy for bladder cancer. Despite being a challenging technique with potential complications, laparoscopic radical cystectomy has a number of advantages compared to open radical cystectomy. Fluid loss from the bowel during surgery is lesser than open radical cystectomy and there is some evidence that in general the patient's immune system is better preserved with laparoscopy. In our experience of laparoscopic radical cystectomy with laparoscopic-assisted ileal conduit postoperative morbidity, blood

> The immunologic benefits of laparoscopic surgery are most obvious in relatively atraumatic procedures such as cholecystectomy and antireflux surgery. For more complex procedures such as resection of colorectal cancer the benefits are less obvious and the evidence controversial.

transfusion and the use of high dependency/intensive care unit was lesser than that of a comparable contemporary group of patients undergoing open radical cystectomy. Postoperative ileus was shorter and patients were able to start enteral feeding much earlier. Mean hospital stay was short and full recovery very rapid. Early data also indicate that laparoscopic radical cystectomy is oncologically equivalent to open radical cystectomy. Surgical margins are usually negative and at follow-up of up to two years 3% of patients develop metastatic disease (3). Laparoscopic radical cystectomy would be an ideal procedure to study the immunological effects of urological laparoscopy as the difference in technique and recovery, compared to open radical cystectomy, are quite marked.

It is a sobering thought that surgical problems related to acquired immuno deficiency syndrome are becoming more common as the incidence of human immuno virus seropositivity increases. Patients with acquired immuno deficiency syndrome are living longer due to improved medical therapy. Laparoscopy is being applied more frequently for diagnostic and therapeutic purposes and these immunocompromised patients may benefit from decreased perioperative immune depression (4).

BASIC PRINCIPLES OF IMMUNOLOGY

We are all exposed to a large variety of infectious agents that would cause pathological damage if left unchecked. In majority of normal individuals, these infections are of limited duration and leave little damage because of the human defense mechanisms in the form of the immune system.

The human immune system has two major functional divisions—the innate and adaptive systems. Both act in concert, with innate immunity forming the first line of defense. Breaching of innate defenses leads to activation of the adaptive system. The two key features of the adaptive system are specificity and memory.

The function of the adaptive immune system is to recognize an antigen and mount an immune response to eliminate it. Generally speaking, there are two major types of immune responses—those against intracellular pathogens and those against extracellular microorganisms. The intracellular antigens, presented at the surface of the cells of the body are recognized by T lymphocytes and this was previously termed cell-mediated immunity. The extracellular antigens are recognized by antibodies produced by B lymphocytes, a process previously termed humoral immunity.

Another important distinction between the two arms of the immune system is that antibodies generally recognize intact antigens while T cells recognize antigen fragments presented to them with molecules encoded by the major histocompatibility complex. The human major histocompatibility complex is known as the human leucocyte antigen locus and is located on chromosome 6. There are four main blocks of genes on this locus—I, II, III, and IV.

There are two major types of T cell. CD8+ cells or cytotoxic T cells (Tc) recognize antigen fragments associated with major histocompatibility complex class I molecules while the CD4+ or helper T cells (Th) recognize antigen associated with major histocompatibility complex class II molecules presented on cells known as antigen presenting cells (Fig. 1). CD4+ Th cells are classified into Th1 and Th2 cells. Th1 cells increase cellular immunity while Th2 cells induce specific antibody production from B cells. If the antigen presenting cells are macrophages, the CD4+ cells release a variety of cytokines, which activate the macrophages to destroy the antigen. On the other hand, if the antigen presenting cell are B cells, the CD4+ cells help them to make antibodies (5). The term CD stands for "clusters of differentiation," a nomenclature initially proposed in Paris in 1982 and subsequently updated at a workshop in Boston in 1993. There are around 151 CD clusters and subclusters but these are continually evolving particularly as a result of the human genome project. The complete sequence of the human genome now allows for medical researchers to consider studying the human as a "system," and information gained from comparing normal and aberrant processes in other species can be applied to the comprehensive study of human disease mechanisms. These concepts provide great opportunities for di-oxy ribose nucleic acid or genetic-based diagnostic and therapeutic applications (6). An example of a long contiguous stretch of human sequence analyzed so far is the T-cell

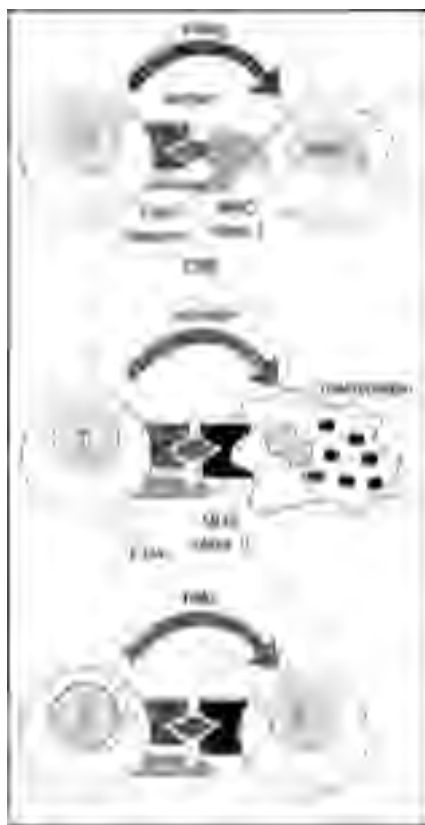

FIGURE 2 ■ Professor Elie Metchnikoff—Nobel Laureate who described phagocytosis as an immune defense mechanism.

receptor (7). There are 45 functional antigen recognition genes in the human beta T-cell receptor and it is possible to create arrays that interrogate the expression patterns of each of these genes during T-cell development. The expression of these genes can be studied to determine which kinds of T cells are triggered in response to surgical injury.

In addition, polymorphonuclear leukocytes or neutrophils and macrophages primarily phagocytose antigens for intracellular destruction in their lysosomes. The word phagocytosis or the ability to engulf microorganisms was coined by the Russian Nobel laureate, Elie Metchnikoff in 1883 (Fig. 2). Metchnikoff thought polymorphonuclears to be "microphages" as opposed to the larger "macrophages." We owe our understanding of this arm of the immune system to Metchnikoff's vision.

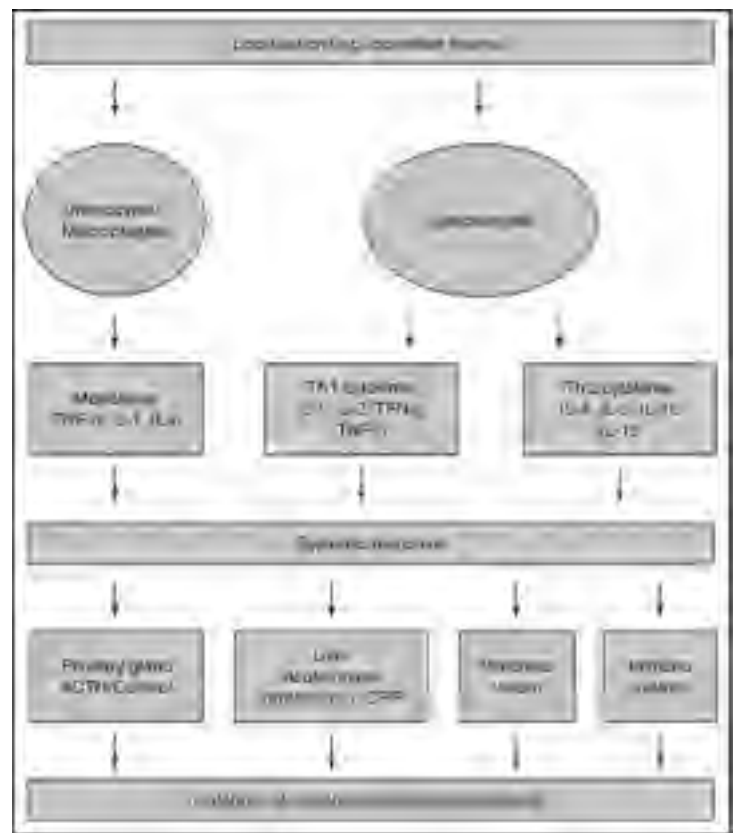
The overall immune response to surgical trauma is summarized in Figure 3.

LAPAROSCOPY AND SYSTEMIC IMMUNITY

Laparoscopic surgery causes less tissue trauma than open surgery and is likely to be associated with better preservation of systemic immune function and contribute to quicker recovery (1,8,9).

In general, immunological function is depressed after open surgery, with adverse altera- tions in cytokine levels and changes in the function of cellular components of the systemic immune response (10–12). On the contrary, the body's response to laparoscopy is one of lesser immune activation as opposed to immunosuppression (13).

The usual physiological reaction to injury is an early rise in serum stress hormone levels along with a decrease in cellular immune response. These manifests as a reduction in lymphocyte and macrophage interaction, decreased activity of natural killer

FIGURE 3 ■ Immune responses to surgical trauma. *Abbreviations*: TNF, tumor necrosis factor; IL, interleukin, CRP, C reactive protein. *Source*: From Ref. 86.


cells, decreased lymphocyte and neutrophil chemotaxis, and a reduction in delayed-type hypersensitivity (14).

Effects on Acute-Phase Response and Cytokines

The acute-phase response and cytokines are important components of immunological function. Decreased production of cytokines reflecting a reduced inflammatory reaction after laparoscopy might be considered beneficial during the postoperative period.

C-reactive protein is the most widely studied acute-phase response protein following surgery. C-reactive protein levels usually rise 4 to 12 hours after surgery, peak at 24 to 72 hours and thereafter remain raised for about two weeks (12). Other acute-phase response proteins, such as fibrinogen and transferrin do not usually alter in a similar way in response to surgical trauma (15,16).

Postoperative C-reactive protein levels are significantly lower during the first two days after laparoscopic than after open surgery (17–19).

In a prospective randomized study of laparoscopic versus small-incision open cholecystectomy, Squirrell et al. (20) demonstrated significantly lower C-reactive protein levels following laparoscopic cholecystectomy. However, they found no differences in serum cortisol levels between the two groups and concluded that the neuro-endocrine component of the metabolic response, i.e., cortisol, was not influenced by the type of surgical access (20). These findings were contradicted by McMahon et al. (16), who found no differences in the levels of C-reactive protein or other acute-phase response proteins such as albumin and transferrin between laparoscopic and minilaparotomy cholecystectomy. Because open cholecystectomy in this study was performed through a much smaller incision than would normally be used for open surgical procedures, these results indicate that the trauma of abdominal access influences immunological function. Other studies of laparoscopic versus small-incision cholecystectomy also support this hypothesis (15).

The cytokines interleukin-1 (IL-1), tumor necrosis factor, and IL-6 are important molecules in acute-phase response (21,22). IL-1 and tumor necrosis factor receptors are believed to regulate cytokine activity and their serum levels indirectly reflect serum cytokine levels.

> Postoperative C-reactive protein levels are significantly lower during the first two days after laparoscopic than after open surgery.

While no difference in soluble tumor necrosis factor receptor levels has been noted after laparoscopic and conventional surgery, serum IL-1 receptor levels are significantly lower after laparoscopy, indicating a lesser degree of inflammatory response to injury (23).

IL-6 expression is believed to be directly proportional to the extent of surgical trauma (24) and a significant difference has been found in plasma levels after open and laparoscopic cholecystectomy (17–19,25). In a randomized controlled trial of laparoscopic versus conventional colorectal resection, Schwenk et al. (26) demonstrated a postoperative increase in IL-6 in both groups, with a more marked response after open surgery. Leung et al. (27) randomized patients to either laparoscopically assisted or open resection of rectosigmoid carcinoma and found no increase in tumor necrosis factor-α levels in either group. Serum levels of both IL-1β and IL-6 peaked two hours after operation, with a significantly smaller response after laparoscopic surgery. Others have found no consistency in IL-6 levels following different surgical approaches (28). Johnson et al. (29) demonstrated significantly higher serum IL-6 levels after laparoscopically assisted colectomy in dogs, compared with the conventional open approach, and Stage et al. (30) reported similar results in a prospective randomized clinical trial.

Hill et al. (31) failed to find any differences in the postoperative IL-6 level following laparoscopic and conventional inguinal hernia repair, which could be because the surgical insult caused by open hernia repair is not sufficient to generate increased levels of these markers. In a similar study, no difference in plasma cortisol, growth hormone, prolactin, and serum IL-6 levels was found following laparoscopic and open surgery for inguinal hernia, but a rise in C-reactive protein concentration and suppression of endotoxin-induced tumor necrosis factor-α production was recorded in both groups with greater changes after open hernia repair (32).

Kuntz et al. compared laparoscopically assisted and open colonic resection in a rat model and measured the serum levels of cortisone, neopterin, and IL-1β just before, during, and after operation, and on the first and seventh postoperative days. They detected significant differences between the study groups for all three variables on the first postoperative day. After a week the levels of cortisone and neopterin had returned to normal (33).

Comparing laparoscopically assisted surgery for Crohn's disease with open surgery, Kishi et al. (34) found C-reactive protein levels and leukocyte counts to be lower following laparoscopic surgery. Hildebrandt et al. also compared open and laparoscopically assisted resection for Crohn's disease and found increased levels of C-reactive protein, IL-6, IL-10 but without any demonstrable difference between the two groups. However, they reported significantly lower plasma granulocyte elastase levels after laparoscopic surgery compared with the open operation (35). It needs to be kept in mind that inflammatory bowel conditions such as Crohn's disease and ulcerative colitis can themselves cause alterations in cytokine levels and any changes following surgery whether laparoscopic or open need to be interpreted with a degree of caution (1).

In summary, the outcomes of both animal and clinical studies clearly demonstrate lesser activation of cytokines IL-1, IL-6, and C-reactive protein following laparoscopic surgery compared with equivalent open procedures. However, differences in the activation of other cytokines such as tumor necrosis factor, IL-8, and changes in the levels of acute-phase response proteins like fibrinogen, albumin, and transferrin are less obvious.

The majority of the clinical studies have shown an immunological advantage of laparoscopic over open cholecystectomy. The same cannot be said for laparoscopic colectomy and inguinal hernia repair, where results supporting advantages of the laparoscopic approach have been inconsistent.

Effect on Polymorphonuclear Leukocytes

Surgical stress affects polymorphonuclear function in the postoperative period. The phagocytic and chemotactic activity of neutrophils is reduced after surgery (36). Several studies have demonstrated a significant increase in overall peripheral leukocyte numbers following open, but not laparoscopic, procedures (19,37). Sietses et al. did not observe any difference in polymorphonuclear count between patients undergoing laparoscopic and open Nissen fundoplication. However, they found a significant reduction in the phagocytic activity of polymorphonuclears after open surgery, which was not noted following laparoscopic fundoplication (38). They also found significantly greater surface expression of CD11b, a receptor important in polymorphonuclear migration, in patients undergoing open surgery compared with those having laparoscopy (38).

Differences in stimulated free oxygen radical production have also been noted between open and laparoscopic techniques (38), suggesting a higher state of polymorphonuclear activation after open procedures. Likewise, the concentration of elastase, an indicator of polymorphonuclear activation, increases after both open and laparoscopic surgery, but returns to preoperative levels within three days after laparoscopic but not open surgery. The postoperative production of hypochloric acid, a potent neutrophil antimicrobial antioxidant, has been shown to fall significantly after open but not laparoscopic surgery (39).

Nies et al. (40) randomized patients with acute cholecystitis to undergo either laparoscopic or open cholecystectomy and found significantly greater intraoperative and postoperative histamine levels in patients after the former procedure. Histamine levels reached their highest levels during establishment of pneumoperitoneum and laparoscopic access.

> Significantly less activation and preserved polymorphonuclear function correlate with the clinical observation of fewer postoperative septic complications following laparoscopic surgery.

Significantly less activation and preserved polymorphonuclear function correlate with the clinical observation of fewer postoperative septic complications following laparoscopic surgery. This suggests that a laparoscopic approach might be beneficial in the surgical management of intra-abdominal sepsis or peritonitis, although this remains a matter of debate as higher intra-abdominal pressure during laparoscopy may worsen clinical sepsis (1).

Effect on Delayed-Type Hypersensitivity and T Lymphocytes

Delayed-type hypersensitivity responses can indirectly reflect changes in T-lymphocyte populations in patients undergoing surgical procedures. Although it seems that delayed-type hypersensitivity is better preserved after laparoscopic than open surgery, it is still not clear which components of the cascade are responsible for this preservation of cellular immunological response (1,13).

Gutt et al. assessed cell-mediated immune function by measuring the size of skin pustules induced by intradermal injection of *Staphylococcus aureus* in rats undergoing laparoscopically assisted and open cecal resection. Animals having laparoscopic procedures had smaller and more rapidly healing pustules than their open surgical counterparts (41). Similarly, Allendorf et al. investigated cell-mediated immune function following laparoscopically assisted and open bowel resections in rats using delayed-type hypersensitivity responses to keyhole limpet hemocyanin and phytohemagglutinin antigens. The delayed-type hypersensitivity responses at two days to both of these antigens were significantly greater after laparoscopically assisted resection than after open surgery, but these differences were no longer evident on the third postoperative day (42). The same group also measured the effect of incision length and exposure method for cecal resection on postoperative immune function as assessed by delayed-type hypersensitivity response. Rats underwent laparotomy (7 cm incision), minilaparotomy (3.5 cm), or laparoscopy (via four ports). Cell-mediated immune responses following laparoscopic surgery were 20% greater than those were after open surgery with a long incision, indicating better preservation of systemic immunity (10).

Gitzelmann et al. compared the cell-mediated immune response following CO_2 pneumoperitoneum, extraperitoneal incision, and laparotomy in an animal model and demonstrated that delayed-type hypersensitivity responses and the ability to reject an immunogenic tumor were better preserved after CO_2 pneumoperitoneum than after extraperitoneal incision or laparotomy (43).

Peripheral lymphocytes are the effectors of cellular immunity and decreased T-cell function has been reported by several investigators following surgical stress (1,44). In an experimental study, Lee et al. (45) found a significantly lower lymphocyte proliferation rate after laparotomy than after CO_2 insufflation. No difference was found between insufflation and the anesthesia-only control group at any point in time. In an interesting study, they also demonstrated that the lower lymphocyte proliferation rate following open surgery was independent of the atmospheric environment, as they found no significant difference between laparotomy performed in room air or in a sealed CO_2 chamber (46).

Cristaldi et al. (47) found a reduction in natural killer cell numbers following both open and laparoscopic cholecystectomy, but the reduction was less after the latter. In a contradictory study, decreased natural killer cell cytotoxicity was noted following both laparoscopic and open procedures, with no advantage for the laparoscopic approach (48). Cristaldi et al. also reported a lower total lymphocyte count after conventional surgery compared with the equivalent laparoscopic approach. They demonstrated persistent depression of CD4+ cells following open but

not after laparoscopic surgery (47). Vallina and Velasco (49) found the ratio of CD4+:CD8+ to be decreased to 13% below preoperative levels on the first day after laparoscopic cholecystectomy. This ratio normalized a week after surgery.

Lennard et al. (50) classified operations as major or minor and assessed the effect of open surgery on lymphocyte subpopulations. Based on this classification, open cholecystectomy was categorized as major surgery. Using the same classification, Evrard et al. compared changes in lymphocyte subpopulations following laparoscopic and open cholecystectomy. They reported that alterations in lymphocytes after laparoscopic cholecystectomy were equivalent to those seen in Lennard's minor surgery group classification (51).

Studies reported to date clearly indicate that T-cell function and cell-mediated immunity are better preserved after laparoscopic than after open surgery. Most clinical studies have compared laparoscopic to open cholecystectomy, and caution must be exercised when extrapolating these results to other operations where trauma of access may be significantly greater.

Most clinical studies have compared laparoscopic to open cholecystectomy, and caution must be exercised when extrapolating these results to other operations where trauma of access may be significantly greater.

Effect on Monocyte-Macrophage Function

The monocyte-macrophages are responsible for phagocytosis and the principal source of tumor necrosis factor and IL-1 following T-cell stimulation. Gutt et al. investigated the phagocytic activity of rat macrophages by means of an intravascular carbon clearance test during conventional and laparoscopic fundoplication using pneumoperitoneum and gasless laparoscopy. Although the fastest carbon elimination half-life was found in rats undergoing gasless laparoscopy, carbon clearance after conventional laparoscopy was significantly greater than that associated with open surgery (52).

The monocyte-macrophage system also plays an important role as antigen presenting cells in association with human leucocyte antigen expression. A significant reduction in human leucocyte antigen-DR expression has been reported after open operation, but not after laparoscopic surgery. However, Brune et al. (53) found that this decrease in monocyte human leucocyte antigen-DR expression might not alter the antigen-presenting capacity of monocytes in either surgical group. Klava et al. assessed the potential role of IFN-γ by determining the capacity of monocytes to respond to this cytokine following open and laparoscopic surgical procedures. They observed that laparoscopic surgery is associated with a similar level of suppression of monocyte human leucocyte antigen-DR expression as seen after open surgery (54). This expression is refractory to further stimulation by IFN-γ. This is consistent with other reports (53) that have demonstrated similar suppression but with earlier return to normal levels after laparoscopic than open surgery.

Monocyte-mediated cytotoxicity correlates closely with Kupffer cell-mediated cytotoxicity and both of these cells play a key role in limiting tumor growth in the liver. Vittimberga et al. (55) observed no difference in cytokine response following laparoscopy and open surgery, but intracellular Kupffer cell signalling was slightly different between laparoscopy and laparotomy. On the other hand, Sietses et al. (56) investigated three different laparoscopic procedures and demonstrated that laparoscopic surgery preserves monocyte-mediated cytotoxicity in contrast to the conventional approach.

LAPAROSCOPY AND INTRAPERITONEAL IMMUNE FUNCTION

The advantages of less systemic immunosuppression following laparoscopic surgery may not necessarily be mirrored at the level of the peritoneal membrane. The choice of insufflation gas and intraperitoneal pressure are also known to modulate the local immune environment (57). The peritoneum plays a major role in the immunological response to abdominal surgery (58) and cytokine levels in the peritoneal fluid are known to steadily increase after laparotomy.

Peritoneal macrophages play an integral role in the inflammatory response to intra-abdominal infection and cancer (59). The scavenging action of these macrophages is partly mediated by the production of inflammatory cytokines, such as tumor necrosis factor-α. The use of CO_2 as the insufflating agent has been associated in some experimental studies with impaired production of tumor necrosis factor-α by peritoneal macrophages (59,60) and this may impair their scavenging ability.

Peritoneal macrophages harvested from rats that had undergone laparoscopy with CO_2 a day earlier produced significantly less tumor necrosis factor-α in vivo than macrophages from rats that had undergone gasless laparoscopy or laparotomy (61). This response persisted when macrophages were collected three days after operation

(62). In vitro experiments performed by West et al. (63) yielded similar results. Macrophage tumor necrosis factor and IL-1 responses to bacterial endotoxin were lower for cells incubated in CO_2 than in either air or helium. IL-1 inhibition occurred within 15 minutes of CO_2 exposure and IL-1 mribose nucleic acid was similarly reduced. Tumor necrosis factor levels were inhibited only after prolonged incubation and persisted after removal of CO_2. Tumor necrosis factor mribose nucleic acid levels remained unaffected. Hajri et al. (64) assessed systemic and peritoneal immune function in rats and found that the levels of tumor necrosis factor-α, IL-6, and inducible nitric oxide synthase gene transcription were significantly enhanced in peripheral white blood cells and depressed in peritoneal cells. These results indicate an impairment of peritoneal macrophage immune activity following CO_2 pneumoperitoneum.

The exposure of macrophages to CO_2 also causes impaired responsiveness to lipopolysaccharide-stimulated cytokine release, which can attenuate the cancer cell lysis activity of macrophages (60). In a human monocyte line, Jackson and Evans (59) demonstrated that exposure to a high concentration of CO_2 reduces macrophage cytokine secretion and phagocyte activity, and substantially reduces cytotoxic activity against colonic cancer cells. Exposure of cancer cells to this gas also causes significant intracellular acidification and might be associated with a higher tumor growth rate compared with that of cells exposed to helium. These findings have been contradicted by Evrard et al. (51), who found no change in the lymphocyte viability and no increase in lymphocyte lysis after CO_2 pneumoperitoneum during laparoscopic procedures. They suggested that this might be because of increased peritoneal bicarbonate production, leading to buffering of the effect of CO_2. They also showed that peritoneal lymphocytes were not destroyed by one hour of CO_2 pneumoperitoneum during laparoscopic cholecystectomy, whereas circulating lymphocyte subpopulations and cytokine levels were moderately suppressed. More efficient peritoneal bacterial clearance by macrophages has also been noted after laparoscopic surgery.

A Dutch group has shown in piglets that levels of IL-1, IL-6, tumor necrosis factor-α, macrophages, and polymorphonuclears were reduced by a laparoscopic approach and by exposure to CO_2 rather than air (65). Mice subjected to pneumoperitoneum, when compared to laparotomy and simple anesthesia groups, have significantly lower percentages of natural killer cells in peritoneal exudate (66). These natural killer cells were also shown to have less impaired cytotoxicity in the pneumoperitoneum group.

Puttick et al. (67) compared the immunological and physiological effects of conventional CO_2 insufflation at room temperature with CO_2 pneumoperitoneum at body temperature in patients undergoing laparoscopic cholecystectomy. They observed greater levels of cytokines (tumor necrosis factor, IL-1, IL-6) in the peritoneal fluid following pneumoperitoneum at room temperature.

The immune response at the peritoneal interface depends not just on the trauma of access but also on the type, pressure, and temperature of the insufflating gas.

The above studies indicate that the systemic immunological benefits observed after laparoscopic surgery may not apply at the peritoneal level and that CO_2 pneumoperitoneum attenuates the immune response of peritoneal macrophage (13). This is a paradoxical finding but has important implications when considering laparoscopy in the presence of intra-abdominal inflammation or sepsis.

The effects of surgery on the systemic immune response are summarized in Table 1 and major randomized controlled trials summarized in Table 2.

TABLE 2 ■ Summary of Randomized Control Trials of Laparoscopy Compared to Open Surgery

Author (Ref.)	Condition	Type	Results
Dunker et al. (68)	Lap-assisted vs. open bowel resection	Human	No immunological difference
Wu et al. (69)	Lap vs. open bowel resection for cancer	Human	Serum cytokines lower after lap although no peritoneal differences
Lee et al. (70)	Lap-assisted vs. open cecectomy	Rats	Peritoneal macrophage and blood monocyte function better in lap
Solomon et al. (71)	Lap vs. open rectopexy for prolapse	Human	1L-6, serum cortisol, and CRP responses favored laparoscopy
Ordemann et al. (72)	Lap vs. open bowel resection for cancer	Human	CMI and cytokine response better preserved after laparoscopy
Tang et al. (73)	Lap vs. open colorectal cancer resection	Human	Lap-assisted colectomy does not confer immunological advantages
Leung et al. (27)	Lap vs. open rectosigmoid cancer resection	Human	Systemic cytokine response less after lap-assisted resection
Schwenk et al. (26)	Lap vs. open colorectal resections	Human	IL-6, CRP lower after laparoscopy
Mutter et al. (74)	Tumor manipulation in pancreatic cancer	Rats	Manipulation causes less tumor growth after laparoscopy
Squirrell et al. (20)	Lap vs. small incision cholecystectomy	Human	Similar neuroendocrine response in the two groups
Kuntz et al. (33)	Lap vs. open colonic resection	Rats	Lesser stress and immune response to laparoscopy
Allendorf et al. (75)	Tumor growth after laparoscopy	Mice	Tumors grow larger after laparotomy than laparoscopy

Abbreviations: IL, interleukin; CRP, C reactive protein; CMI, cell mediated immunity.

TUMOR GROWTH, METASTASIS, AND IMMUNE FUNCTION

For laparoscopic oncological surgery to stand the test of time, short- and long-term results must demonstrate equivalent margin status and cancer control when compared to open surgery. For laparoscopic nephrectomy, emerging data indicate that this is indeed the case as cancer-specific survival for similar stage disease is equivalent at five years. However reports of abdominal wall and port site metastasis has led to speculation that pneumoperitoneum may have a detrimental effect on tumor growth. Nine cases of port site metastasis after urological laparoscopy have been reported in clinical and experimental studies (76). Five have been after nephrectomy, one after bladder mass biopsy of a TCC, and three after pelvic lymph node dissection (two TCC bladders and one prostate cancer). Contributing factors such as high grade and stage of tumor, violation of tumor boundaries, no use of entrapment sack, torn entrapment bag, specimen morcellation, and ascites have been noted (76). Although it is likely that the etiology of port site metastases is multifactorial, some studies have suggested that local peritoneal immune suppression may play a pivotal role in the development of tumor metastases following laparoscopic surgery (77,78). It has been suggested that CO_2 might facilitate the implantation and growth of tumor cells (62).

Several investigators have demonstrated that the incidence of port site metastases can be reduced in experimental models by excluding CO_2 from the laparoscopic environment by using either gasless laparoscopy or helium insufflation (77,80,81). This suggests that carbon dioxide, in particular, may exert an adverse metabolic effect on tumor cells that facilitates their implantation and growth. Jacobi et al. investigated the impact of different laparoscopic environments on tumor growth in a rat model. They found that CO_2 significantly promoted tumor growth, associated with a significant increase in plasma levels of IL-10 and a decrease in tumor necrosis factor-α in the postoperative period, compared with helium insufflation (82).

Cell-mediated immunity is also believed to influence postoperative tumor growth. Allendorf et al. observed significantly less growth of extra-abdominal tumor following laparoscopy compared with open surgery in immunocompetent mice (83). Comparable growth of pancreatic tumor cells after laparoscopy and laparotomy was noticed when no manipulation of the tumor was performed. Manipulation however led to significantly increased tumor growth in the laparotomy rather than the laparoscopic group.

In addition to altered peritoneal and systemic immunity, the etiological process behind port site metastasis is thought to involve the aerosolization of tumor cells due to insufflation and desufflation. Preventative measures should include adequate equipment, technical preparation and meticulous technique, avoiding gas leakage, trocar fixation to prevent dislodgment, bag retrieval (impermeable bag if morcellation is performed), avoidance of laparoscopy in ascites, and minimal handling of the tumor. At present, it seems likely that the incidence of incisional tumor recurrence is similar after both open and laparoscopic approaches (76).

In addition to altered peritoneal and systemic immunity, the etiological process behind port site metastasis is thought to involve the aerosolization of tumor cells due to insufflation and desufflation. Preventative measures should include adequate equipment, technical preparation and meticulous technique, avoiding gas leakage, trocar fixation to prevent dislodgment, bag retrieval (impermeable bag if morcellation is performed), avoidance of laparoscopy in ascites, and minimal handling of the tumor. At present, it seems likely that the incidence of incisional tumor recurrence is similar after both open and laparoscopic approaches.

LAPAROSCOPIC BOWEL INJURY

Laparoscopic bowel injuries are a rare but potentially fatal complication, especially if initial recognition is delayed. Presentation is often atypical when compared with open surgery. Aldana and colleagues looked at laparoscopic bowel injury in a rabbit model using serum monocyte, neutrophil, and lymphocyte apoptosis as indicators of the immune response. They observed that open surgery resulted in a significant increase in programmed cell death compared with controls in the immediate postoperative period following bowel injury. In comparison, laparoscopic bowel injury resulted in a delayed response that only approached open surgery levels after two weeks. They concluded that this difference in degree of cellular death could be secondary to a smaller degree of stimulation of the immune response in laparoscopic surgery. When the period of laparoscopy was extended from one to five hours, the percentage of apoptosis was similar to that seen after open surgery and no animal undergoing a five-hour procedure survived to two weeks after bowel injury (84).

> It is well recognized that patients with laparoscopic bowel injury following urological procedures do not present with the typical acute surgical abdomen.

It is well recognized that patients with laparoscopic bowel injury following urological procedures do not present with the typical acute surgical abdomen.

Bishoff et al. reported bowel perforation in 0.2% and bowel abrasion in 0.6% of cases. The latter were recognized and repaired at the time of injury but the patients with perforation presented postoperatively with single port site pain, abdominal distention, diarrhea, leukopenia, followed by cardiopulmonary collapse secondary to sepsis within 96 hours of surgery. These can be fatal injuries and it is important to recognize the initial unusual signs and reduction in leukocyte count (85). The overall incidence of bowel injury is 1.3/1000, most of which are unrecognized intraoperatively and need laparotomy to repair the injuries.

IMMUNOLOGIC ASPECTS OF LAPAROSCOPIC UROLOGY

Fornara et al. (86) reported a prospective, controlled, nonrandomized animal and patient study to determine the systemic response to laparoscopic and open surgical procedures. In the animal study, 26 female pigs aged six months underwent either a laparoscopic bilateral varix ligation followed by bilateral nephrectomy (group I), introduction of trocars (group II), or establishment of an open surgical approach (group III). In the patient study, 145 patients underwent various laparoscopic procedures (unilateral nephrectomy = 17, bilateral laparoscopic nephrectomy = 7, renal cyst marsupialization = 29, varix ligation = 17), open surgical procedures (nephrectomy = 42, inguinal orchidectomy = 8), or extracorporeal shockwave lithotripsy = 25). A weakness of this study is the fact that the patient groups are not evenly matched. IL-6, IL-10, and C-reactive protein were measured before, during, and after the operative procedure. In animals and patients, laparoscopy resulted in significantly lower serum levels of C-reactive protein during and in the postoperative period. Animals in group I showed a five-fold elevation, in group II a three-fold elevation, and in group III a nine-fold elevation of C-reactive protein. In patients, C-reactive protein was twice as high after open unilateral nephrectomy than after laparoscopic unilateral or bilateral nephrectomy. Elevation of IL-6 was less pronounced during laparoscopy, extracorporeal shockwave lithotripsy, and minor procedures like laparoscopic varix ligation or inguinal orchidectomy when compared to an open unilateral nephrectomy. IL-10 was not significantly different among the patient groups (Figs. 4 and 5). The authors concluded that the acute-phase response to operative trauma correlated more to the approach than to the extent of the procedure. Larger operations like nephrectomy trigger a marked systemic acute-phase reaction, which can be reduced by laparoscopic access. In minor operative procedures like varix ligation or exploration of cryptorchidism, laparoscopy offers technical advantages rather than minimal invasiveness as the immune response in these situations is much less.

The above findings were contradicted in a prospective study by Landman et al. (87). They compared the systemic immune and stress response of patients who underwent laparoscopic total nephrectomy and open nephrectomy for renal cell carcinoma (10,14). Unlike Fornara et al., this study concentrated on nephrectomy only for renal cancer rather than a comparison with other procedures. The open nephrectomy group comprised open radical (four), open total (two), and open partial (four) nephrectomies. Peripheral venous blood was collected preoperatively, intraoperatively, and at 24 hours, two weeks, four weeks, and three months postoperatively. Patients who had postoperative infection or illness in the three-month period following surgery were excluded

from study. Blood from these patients was analyzed for stress markers (adrenalin, noradrenalin, and cortisol), inflammatory response markers (C-reactive protein, white blood count, and leukocyte count), lymphocytic response markers (CD3, CD4, and CD8), cytokines (IL2 and IL4, INFα and tumor necrosis factorα), human leucocyte antigen-DR expression, and the proliferative response to mitogen stimulation using concanavalin A, phytohemagglutinin 10, and pokeweed mitogen. Unlike in other studies IL6 levels were not measured. Tumor histopathology and Fuhrman grade were similar between the two groups although mean tumor size was nonsignificantly smaller for the laparoscopic total nephrectomy group compared to the open nephrectomy group [4.5 ± 1.6 and 5.6 ± 2.4 cm, respectively ($p = 0.21$)]. Inflammatory and stress response markers were statistically similar for the groups at the measured time points. A significant difference between the groups was noted for the percentage and ratio of CD4+ and CD8+ lymphocytes, which is an indicator of immune activation of helper T cells. The ratios of CD4+:CD8+ were 2.7:1 for laparoscopic total nephrectomy and 1.8:1 for open nephrectomy. However, this difference was present preoperatively and sustained at all time points, thus being unlikely to represent a surgery-specific response. The cytokine response, HLA-DR, lymphocytic stimulation index for concanavalin A, phytohemagglutinin 10, and pokeweed mitogen were statistically similar for LRN and open nephrectomy at all time points. Age group analysis did show differences between the cohorts with respect to CD4+ and CD8+ lymphocytes in the 60 to 80-year olds. Additionally, in this age group intraoperative human leucocyte antigen-DR expression and tumor necrosis factorα production were higher in those undergoing open nephrectomy. In the 40 to 60-year-old group, the authors found higher 24-hour cortisol for open nephrectomy, percent CD4+ lymphocytes for laparoscopic total nephrectomy, and higher three-month proliferative capacity for laparoscopic total nephrectomy, as assessed by the phytohemagglutinin 10 index. These changes are shown in Figures 6–11. This study concluded that immunological and stress responses after laparoscopic total nephrectomy and open nephrectomy for renal cell carcinoma were similar and the few changes observed were likely to reflect preoperative changes or the effects of anesthesia. Perhaps longer anesthetic times for laparoscopic total nephrectomy masked any potential differences. It would have been useful if blood samples had been taken every 30 minutes during surgery while the patients were anesthetized to substantiate this

hypothesis. Preoperative immune dysfunction in renal cell carcinoma is known to be complex (88,89) and the findings of this study thus come as a surprise and do not explain the quicker short- and long-term recovery in patients undergoing laparoscopic total nephrectomy. It is feasible that for less extensive procedures, such as laparoscopic cholecystectomy, the laparoscopic approach is immunologically superior. In contrast, ablative laparoscopic renal surgery is quite extensive and may not have a definite immunological benefit, as assessed by current techniques to measure the immune response. Another possible explanation for the discrepancy may be the biology of renal cell carcinoma. It is feasible that the malignant disease process results in a significant alteration in immune function, such that differences between laparoscopic total nephrectomy and open nephrectomy are not detectable. Similar findings have been reported in randomized trails of surgery in colonic malignancy. Tang et al. (73) observed no difference in the immune response in laparoscopic-assisted versus open sigmoidectomy for colorectal cancer and Leung et al. (27) noted differences in the stress response but no differences in the immune response.

FUTURE DIRECTIONS

The majority of evidence appears to indicate that the preservation of immune function after an operative procedure confers advantages to the patient in terms of recovery and oncological outcome. It consequently seems likely that the deliberate stimulation of the immune system perioperatively may be a way to avoid the detrimental effects of surgery and upregulation of this nature may also result in improved cancer control. The early postoperative period may be an ideal time for induction of immune-based anticancer therapy, as tumor burden is at its lowest. Perioperative tumor vaccines may also be effective means of establishing specific immune responses against the tumor before resection (90). These concepts are being actively tested in experimental settings although they are yet to enter the clinical mainstream. It is likely that future basic science and clinical trials will identify specific areas of immune modulation in this challenging area.

Traditional methods of studying and manipulating the immune response have numerous shortcomings. They study individual components of the immune system rather than a collective "systems" response (6). The human genome project has made the "systems" approach to disease a reality. Simultaneous publication of draft versions of the genome in February 2001 in Nature and Science were important milestones and introduced major changes in medicine (91,92). Powerful tools for accurately deciphering biological information are now available. Emphasis is steadily shifting from structural genomics to functional genomics and proteomics. As a result, 21st century molecular biology in urology looks rather different and new and more effective preventive and therapeutic strategies are emerging (93,94). We urologists are getting familiar with acronyms like (expressed sequence tag—a short piece of di-oxy ribose nucleic acid sequence corresponding to a fragment of cdi-oxy ribose nucleic acid), (serial analysis of gene expression—a method that produces very short sequence tags used for gene identification), and SNP (single nucleotide polymorhisms—variations in single nucleotides between people, which may determine susceptibility and resistance to disease among different individuals), which were previously thought to be of little relevance.

High throughput tools are already providing us valuable information about important urological cancers. Like cancer, immune dysfunction is a "systems disease" and it is now obvious that the traditional method of searching for isolated genetic alterations is no longer useful. Microarray technology (95,96) allows a number of genes and genomic alterations to be studied at the same time. Some of these utilize high-speed robots such as Q-Bot. Bioinformatics is vital to make sense of this large amounts of genetic data. Such technology will allow us to better define and

compare the immunological changes after laparoscopy and open surgery. An example would be to study genetic changes associated with the T-cell receptor (Fig. 12). It would be possible to create oligonucleotide arrays that interrogate the expression patterns of each of these genes during T-cell development and their alterations after laparoscopic procedures. Commercially available signalling pathway gene arrays contain genes important to signal transduction that mediate the immune response and inflammation. These genes encode adhesion molecules, receptors, ligands, adaptors, kinases, regulators, transcription factors, and downstream effector proteins for each of these pathways. Signal transduction plays essential roles in immune cell activation, proliferation, differentiation, and apoptosis. Immune arrays that could prove useful in the field of laparoscopy are dendritic, antigen presenting cell arrays, and toll-like receptor signalling pathway arrays. These are available on chips of the size of a fingernail.

Combinatorial chemistry is an important tool where the idea is to synthesize a string of information using a combination of basic letters. For example, a combination of various molecules would lead to the creation of different three-dimensional shapes. Combinatorial chemistry can be used to facilitate the design and synthesis of new immunological targets in a rapid fashion.

Finally the most important tool for deciphering biological information is based on computational sciences. These are designed to collect, store, analyze, and ultimately distribute various types of biological information. A good example of this is the dissemination of collective information regarding the human genome project through GenBank and the Internet. This approach can only succeed through collaboration between computer scientists, applied mathematicians, biologists, and physicians (6,98).

Over the next few years, the systems' approach to immunology will become popular and this will certainly have an impact on the expanding field of minimally invasive urology.

SUMMARY

- Most clinical and experimental studies support the view that laparoscopic surgery is associated with better preservation of postoperative systemic immune function than conventional surgery. Extrapolation of such data, however, requires further elucidation.
- Major surgery results in a period of cell-mediated immunosuppression, which can affect the patient's recovery.
- Open surgery is associated with higher levels of C-reactive protein and IL-6 than laparoscopy.
- Delayed-type hypersensitivity studies indicate that open methods lead to significantly more immunosuppression than laparoscopy. This difference becomes less obvious after prolonged major laparoscopic procedures and it is possible that longer anesthetic times may have an impact on the immune response.
- There is evidence of a short-lived greater shift towards Th2 function mainly through suppression of the Th1 lymphocytes after open surgery than after laparoscopy (90).
- Laparoscopy also leads to lesser decreases in HLA-DR expression and monocyte-mediated cytotoxicity than its open counterpart.
- Intraperitoneal immunity behaves independently of systemic immune function. The systemic benefits of laparoscopic surgery may not necessarily extend to the peritoneal interface.
- Further investigation on local peritoneal immunity is needed. The degree to which CO_2 pneumoperitoneum suppresses macrophage function is uncertain, as available data are conflicting.
- It is also impossible to draw firm conclusions with regards to bacterial clearance studies. At present, laparoscopic surgery appears to be equivalent to open surgery as regards oncological outcomes although long-term data are awaited.
- High throughput tools such as microarray technology may improve the way immunological responses to laparoscopic surgery are studied.

LAPAROSCOPIC SURGERY IN THE HIGH RISK PATIENT

Assaad El-Hakim and Benjamin R. Lee

*Department of Urology, Long Island Jewish Medical Center,
New Hyde Park, New York, U.S.A.*

PREVIOUS ABDOMINAL SURGERY

The patient with previous abdominal surgery is at higher risk for visceral and vascular injuries during Veress needle and initial trocar insertion (1).

In the setting of previous surgery, an extraperitoneal/retroperitoneal approach can be undertaken. Urologic organs are well suited for this approach despite the more confined working space. Kidney, adrenal, ureteral, and prostate surgeries have all been described and successfully performed with the extraperitoneal approach. Alternatively, pneumoperitoneum can be created with a Veress needle that is inserted at least 3 cm away from previous abdominal incisions.

If pneumoperitoneum is obtained with Veress needle, insertion of the primary port is preferably performed with an optical trocar (Optiview[a] or Visiport[b]). Abdominal adhesions are more pronounced after bowel surgery and complex reconstructive procedures, particularly in the event of anastomotic leaks.

Prior abdominal or pelvic radiation is a major risk factor for adhesion formation due to chronic ischemia, and excessive care should be taken throughout these cases to prevent bowel injuries.

A previous abdominal surgery is not an absolute contraindication for laparoscopic procedures.

Open Access Technique

Advantages of open access technique in patients with previous laparotomies:

- The incidence of visceral and vascular injuries is significantly reduced.
- The risk of extraperitoneal insufflation is eliminated.
- Trocar site incisional hernia formation is decreased because the fascia is closed as part of the technique.
- In experienced hands, the open technique is cost effective and does not significantly increase the operative time.

Several open laparoscopic techniques have been described. The most commonly used is the Hasson technique (2). This is a safe method to enter the abdomen under direct open vision, and is especially suited for patients with abdominal adhesions from previous surgeries. A small (1–2 cm) skin incision is made away from previous scars. Blunt dissection is carried out until the anterior abdominal fascia is identified. The fascia is incised and the muscle fibers are spread. The underlying peritoneum is elevated

Sidebar notes:

In the setting of previous surgery, an extraperitoneal/retroperitoneal approach can be undertaken.

Alternatively, pneumoperitoneum can be created with a Veress needle that is inserted at least 3 cm away from previous abdominal incisions.

A previous abdominal surgery is not an absolute contraindication for laparoscopic procedures.

---

[a]Ethicon, Somerville, NJ.
[b]U.S. Surgical Corp., Norwalk, CT.

with hemostatic clamps and incised. Two heavy, absorbable sutures are placed on either side of the fascial incision to secure the trocar in place and to prevent gas leakage. A 10–12 mm port with blunt trocar is inserted and CO_2 insufflation is performed through the port valve. The other ports are inserted under direct laparoscopic visualization away from adhesions. The preplaced fascial sutures are tied together at the end of surgery to close the defect.

Another open technique involves a small incision over the everted umbilicus at a point where the peritoneum is closest to the skin. This technique can be used in pediatric patients and in patients with previous surgery provided there is no midline incisions, portal hypertension, recanalized umbilical vein, umbilical pathologies such as a urachal cyst, sinus, or umbilical hernia. The umbilicus is everted with toothed grasping forceps and is incised in the sagital plane. Two small retractors are inserted to expose the umbilical pillar or canal that runs from the undersurface of the skin down to the linea alba. Blunt dissection through this plane permits direct entry into the peritoneum. Once the peritoneal cavity is opened, a laparoscopic port with blunt internal trocar is then inserted under vision and insufflation started.

Lal et al. described a similar open technique without umbilical eversion whereby the umbilical cicatrix tube is used as a landmark to follow down to the linea alba where the peritoneum is adherent to the undersurface of the fascia. A supra- or subumbilical sagital incision is used, provided no midline scar is present. This technique was performed in 525 consecutive cases with no complications or port site hernias (3). Another modification of the umbilical access named the mini-open technique or the umbilical stalk technique uses a 5 mm transumbilical incision and placement of a 5 mm blunt cannula without the trocar. The original authors employed this technique for four years in 600 patients without a midline laparotomy incision incorporating the umbilicus, and have accessed the abdomen safely for laparoscopy without any complications (4).

Alternative Sites for Introducing the Veress Needle

For a previously operated abdomen with a midline incision, the Veress needle should be placed in the upper left quadrant of the abdomen just lateral to the rectus sheath. Transrectus insertion of the Veress needle is discouraged because of risk of injury to the inferior epigastric vessels.

The Veress needle at the upper quadrant region needs to be passed more deeply into the abdomen in order to enter the peritoneal cavity because all layers of the abdominal wall are present here and the risk of preperitoneal insufflation is higher. Always insert the needle at a right angle from the skin surface. Another site of insufflation should be chosen in the presence of splenomegaly. The right upper quadrant is not the most optimal site because of the size of the liver and the presence of the falciform ligament. There are some reports of liver injury in cases of hepatomegaly.

In a patient with an upper abdominal scar, the Veress needle should be placed in the right lower quadrant. The left lower quadrant should generally be avoided in older patients since there are usually adhesions between the sigmoid colon and the abdominal wall secondary to subclinical episodes of diverticulitis. For patient with a previously operated abdomen in multiple quadrants, an open technique is optimal.

Optical Trocars

This is one of the techniques used to insert the initial trocar in patients with previous laparotomies. After pneumoperitoneum is obtained with the Veress needle, a 1 cm long incision is performed away from previous scars. Towel forceps are used to elevate the abdomen, and an optical trocar is introduced with the 0 degree telescope. The optical trocar is advanced slowly through the different planes of the abdominal wall using a full 180 degree rotational movement. The blunt blade at the tip of the trocar spreads the tissue under direct visual control. Entry into the peritoneal cavity is readily documented. This decreases the risk of injury to intra-abdominal organs. Thomas et al. used the optical access trocar as the initial trocar in 1283 urological laparoscopic procedures. The optical trocar was inserted at the umbilicus in 7.4% of patients, in the right upper quadrant in 34.7%, and in the left upper quadrant in 58.5%. There were four injuries (0.31%) associated with the optical access trocar, including one bowel injury, one mesenteric with retroperitoneal hematoma, and two epigastric vessel injuries (5).

> For a previously operated abdomen with a midline incision, the Veress needle should be placed in the upper left quadrant of the abdomen just lateral to the rectus sheath. Transrectus insertion of the Veress needle is discouraged because of risk of injury to the inferior epigastric vessels.

Previous abdominal surgery does not appear to adversely affect the performance of subsequent urological laparoscopy.

Of 700 patients presenting to a single center for urological laparoscopy, 48% had a history of abdominal surgery. Overall, patients with no history of surgery compared to those with such a history tended to be older, predominantly female, and at significantly higher operative risk. Patients with a history of surgery who underwent nephrectomy or pyeloplasty were also more likely to have received blood transfusion perioperatively, which was probably related to their increased age and higher degree of medical comorbidity. There were no significant differences in operative blood loss, rate of conversion to open procedure, or rate of operative complications (6).

COAGULATION DISORDERS

The urologist may encounter disorders of hemostasis and coagulation either in the preoperative evaluation of the patients for elective surgery or in the perioperative care of patients with acute bleeding disorders. Diagnosis of the specific disorder involved requires an evaluation of the patient's history, physical examination, and appropriate laboratory tests.

An accurate history and physical examination of a patient scheduled to undergo elective operation offer the most valuable source of information regarding the risk of bleeding during surgery. A patient with a history of bleeding, easy bruisability (either spontaneous or traumatic), frequent or unusual mucosal bleeding, exceptionally high menstrual flow in females, prior history of significant or life-threatening hemorrhage associated with invasive procedures, or a family history of such problems may be at risk. A history of repeated severe epistaxis or abnormal laboratory tests may also be significant. The intake of medications should always be elicited. Especially important are drugs such as aspirin and nonsteroidal anti-inflammatory drugs, and because these preparations are widely available "over the counter," it is important to inquire specifically about them. Patients may not consider the intake of aspirin or nonsteroidal anti-inflammatory drugs as being important enough to mention when interviewed unless a specific question is asked. The most common cause of bleeding "disorders" is prescription drugs such as aspirin and warfarin. In addition, a history of liver dysfunction, renal dysfunction, or major metabolic or endocrine disorder is useful in directing preoperative screening. Hypercoagulability states and disorders include a history of deep venous thrombosis, pulmonary embolus, valvular disease, embolic or thrombotic cerebrovascular event, and atrial fibrillation.

Physical examination also provides valuable information. Evidence of excessive bruising, joint deformities, petechiae or ecchymosis, hepatosplenomegaly, excessive mobility of joints, or increased elasticity of the skin are symptoms of disorders associated with excessive perioperative bleeding. Evidence of amyloidosis (such as thickening of the skin or tongue), multiple myeloma, or other hematologic malignancies is also revealing.

It is beyond the scope of this chapter to detail all screening tests for bleeding and coagulation disorders. A hematologist should be involved in the perioperative management of these patients. The extent of laboratory testing needed for patients with a normal history and physical examination has been debated. Routine preoperative laboratory screening is useful for patients undergoing major procedures, especially involving body cavities or operations with significant dissection and the creation of raw surfaces, or patients with an abnormal history or physical examination. Routine preoperative testing is indicated for all patients undergoing urologic laparoscopy since it fulfills criteria of significant surgery. Patients with infection, sepsis syndrome (or the systemic inflammatory response syndrome), malnutrition, organ failure, and other major systemic disorders also warrant preoperative screening before surgical intervention.

In general, commonly recommended tests include prothrombin time, partial thromboplastin time, complete blood cell count with platelet count, and in some patients, bleeding time.

In general, the commonly recommended tests include the prothrombin time, the partial thromboplastin time, a complete blood cell count with platelet count, and in some patients, a bleeding time.

The prothrombin time measures the function of factor VII as well as the *common pathway* factors (factor X, prothrombin/thrombin, fibrinogen, and fibrin). The partial thromboplastin time measures the *intrinsic* pathway and reflects the activity of all clotting factors except for platelet factor III, VII, and XII. For this reason, the test is complementary to the prothrombin time and may indicate deficiencies of other clotting factors or the presence of a circulating anticoagulant.

All of the major coagulation factors are synthesized in the liver except for factor VIII, which is made in vascular endothelium and reticuloendothelial cells. The prothrombin time measures the activity of several of these factors, including factors I, II, V, VII, and X. Synthesis of prothrombin and factors VII, IX, and X depends on an adequate supply of vitamin K, which activates certain hepatic polypeptides by stimulating the synthesis of the calcium-binding residue, gamma-carboxyglutamic acid. An abnormal prothrombin time is commonly caused by vitamin K deficiency, liver disease, or both, and may rarely be seen with inherited abnormalities. Vitamin K, a fat-soluble vitamin that is found in many foods, is also produced by intestinal bacteria. Deficiency is most commonly seen in malnutrition and malabsorption syndromes, including failure to absorb dietary fat due to biliary obstruction or other causes of cholestasis. It may also be seen with antibiotic suppression of intestinal bacteria, especially when the patient is receiving inadequate oral or parenteral vitamin K replacement. Any acute or chronic liver disease may cause an abnormal prothrombin time by impairing the synthesis of essential clotting factors. Because the plasma half-life of these factors is typically less than one day, the prothrombin time responds rapidly to changes in hepatic synthetic function (7).

The platelet count identifies numbers of platelets, whereas the bleeding time estimates qualitative platelet function. None of the commonly recommended screening tests measures fibrinolytic function. Additional screening tests that may be used for specific patients include a fibrinogen level, the thrombin time, and screens for factor XIII levels. The thrombin time detects abnormalities of globulin, fibrinogen, excess fibrinolysis, and heparin-like substances. In patients suspected of having platelet dysfunction, additional assessments include platelet function tests (aggregation with epinephrine, adenosine diphosphate, collagen, and ristocetin). If a deficiency or specific factor is suspected, as in patients with a family history of hemophilia, then specific factor assays should be obtained (8).

Venous thromboprophylaxis should be considered for every patient undergoing laparoscopic urological surgery, especially certain populations with high-risk factors.

Patients who are elderly, obese, have a malignancy, or previous history of thrombosis are at increased risk of experiencing deep venous thrombosis and pulmonary embolus after surgery. Surgical factors are related to the extent of the operation and the type of anesthesia. Graduated compressive devices help to prevent thrombus formation and are suitable for low-risk patients. But those in the higher risk categories need to be anticoagulated as well. Subcutaneous unfractionated heparin and low molecular weight heparins have been found to be safe and effective in clinical practice.

Patients on aspirin or antiplatelet medication should stop these drugs 5–7 days preoperatively in order to normalize the bleeding time. In an emergency situation, desmopressin or platelet transfusion should be administered to avoid excessive risk of bleeding.

Patients on warfarin who are not at increased risk of thromboembolic events (such as previous history of venous thrombosis without recent recurrences) can stop the medication five days preoperatively, and resume the same dose on the first postoperative day if adequate hemostasis was obtained. Patients who are at moderate to high risk (atrial fibrillation), in whom warfarin cannot be stopped without replacement therapy, are started on subcutaneous low molecular weight heparin. These agents are stopped 12–24 hours before surgery and then resumed 12–24 hours postoperatively. If the prothrombin time did not normalize the day of surgery, vitamin K and/or fresh frozen plasma should be administered. Patients at very high risk should be converted on to intravenous heparin and monitored in hospital. Intravenous heparin is stopped six hours preoperatively to ensure normal partial thromboplastin time at the time of surgery, and heparin is resumed postoperatively as soon as the patient's condition permits. Warfarin is resumed when the patient is back on regular diet, and heparin is discontinued when coagulation tests have been within therapeutic levels for 48 hours. This period of overlap is called bridging and protects the patient from the initial transient prothrombotic effect of warfarin. There is always a fine balance between bleeding and hypercoagulability in these patients that needs to be judiciously determined in collaboration with the medical team.

Platelets

Platelet transfusions are indicated for patients suffering from or at significant risk of bleeding owing to thrombocytopenia and/or platelet dysfunction. Basic guidelines for platelet transfusion are outlined in Table 1. In general, platelets should not be transfused prophylactically in the absence of microvascular bleeding, a low platelet count in

TABLE 1 ■ Suggested Transfusion Guidelines for Platelets

Recent (within 24 hours) platelet count 10,000/mm^3 (for prophylaxis)
Recent (within 24 hours) platelet count 50,000/mm^3 with demonstrated microvascular bleeding ("oozing") or a planned
  surgical/invasive procedure
Demonstrated microvascular bleeding and a precipitous fall in platelet count; patients in the operating room who have had complicated procedures or
  have required more than 10 U of blood and have microvascular bleeding, giving platelets assumes adequate surgical hemostasis has been achieved
Documented platelet dysfunction (e.g., prolonged bleeding time >15 minutes, abnormal platelet function tests) with petechiae, purpura, microvascular
  bleeding ("oozing"), or surgical/invasive procedure
Unwarranted indications:
Empirical use with massive transfusion when patient is not having clinically evident microvascular bleeding ("oozing")
Prophylaxis in thrombotic thrombocytopenic purpura/hemolytic uremic syndrome or idiopathic thrombocytopenic purpura; extrinsic platelet dysfunction
  (e.g., renal failure, von Willebrand's disease)

a patient undergoing a surgical procedure, or a platelet count that has recently fallen below 10,000/mm^3. Previous guidelines recommended platelet transfusion for platelet counts of 20,000/mm^3 for prophylaxis in stable patients without oozing or in those not undergoing surgical or invasive procedures. More recent data, however, suggest that a threshold of 10,000/mm^3 causes no added bleeding while significantly reducing use of the resource (8). Patients receiving massive transfusion should not automatically receive prophylactic platelets in the absence of microvascular bleeding (9). In such patients, hypothermia effects depressed platelet function, and platelet transfusion is generally ineffective (10). Restoration of a normal temperature returns platelet function to normal and ameliorates microvascular bleeding. Ideally, platelets should be transfused after the temperature has been corrected.

Fresh Frozen Plasma

Fresh frozen plasma is used to replace labile clotting factors in patients with coagulopathy and documented deficiency of clotting factors. This condition may derive from liver dysfunction, congenital absence of clotting factor, or transfusion of factor-deficient blood products. A unit of fresh frozen plasma contains near-normal levels of all clotting factors. A unit of fresh frozen plasma increases clotting factor levels by about 3%. Adequate clotting is usually achieved with factor levels above 30%, although higher levels are advisable in patients undergoing operative or invasive procedures. The prothrombin time and the activated partial thromboplastin time can be used to assess patients for fresh frozen plasma transfusion and to follow the efficacy of administered fresh frozen plasma.

Guidelines for administration of fresh frozen plasma are listed in Table 2. Documentation of factor deficiency or abnormal prothrombin time or activated partial thromboplastin time in a patient with clinical bleeding minimizes unnecessary use of fresh frozen plasma. Fresh frozen plasma should not be used routinely by preset

TABLE 2 ■ Suggested Transfusion Guidelines for Fresh Frozen Plasma

Treatment of multiple or specific coagulation factor deficiencies with abnormal prothrombin time and/or
  activated partial thromboplastin time
Abnormal specific factor deficiency in the presence of one of the following:
    Congenital deficiency of antithrombin III; factors II, V, VII, IX, X, and XI; protein C or S; plasminogen
      or antiplasmin
    Acquired deficiency related to warfarin therapy, vitamin K deficiency, liver disease, massive
      transfusion, or disseminated intravascular coagulation
    Also indicated as prophylaxis for the above if a surgical/invasive procedure is planned
Unwarranted indications
Empirical use during massive transfusion if patient does not exhibit clinical coagulopathy
Volume replacement
Nutritional supplement

formula after red blood cell transfusion. With the availability of equally effective but safer (albumin, hetastarch) and less expensive (crystalloids) solutions, fresh frozen plasma should not be used as a volume expander (11).

A new plasma product, solvent detergent plasma, has recently been approved by the U.S. Food and Drug Administration and is available from the American Red Cross. This product is essentially fresh frozen plasma that has been treated to inactivate enveloped viruses, particularly human immunodeficiency virus, hepatitis B, and hepatitis C. As a result, solvent detergent plasma should have a virtually zero risk of transmitting these infections. It is more expensive than fresh frozen plasma, and supplies are currently limited. solvent detergent plasma is prepared from pools of 2500 U of fresh frozen plasma. The treatment with solvent detergent inactivates lipid-enveloped viruses, but does not inactivate non-lipid-enveloped virus such as hepatitis A and parvovirus (such transmission has been documented). It does not have any effect on prions, if indeed these can be transmitted by plasma transfusions (12). The benefits of using such a product would be offset by the use of many products that have not undergone viral inactivation. It appears reasonable to consider solvent detergent plasma for patients receiving plasma exclusively (or nearly so): coagulation factor deficiency, warfarin reversal, microangiopathic hemolytic anemia (thrombotic thrombocytopenic purpura, hemolytic uremic syndrome). solvent detergent plasma would be contraindicated in the following: pregnancy, except at the time of delivery; neonates; chronic hemolytic anemia; sickle cell disease; patients undergoing chemotherapy or radiation; and patients receiving large amounts of other untreated blood components.

Cryoprecipitate

Cryoprecipitate is useful in treating factor deficiency (hemophilia A), von Willebrand's disease, and hypofibrinogenemia and may help treat uremic bleeding (13). Cryoprecipitate is usually administered as a transfusion of 10 single units.

CARDIOPULMONARY DISORDERS

Patients with severe cardiopulmonary diseases have higher surgical risks regardless of the approach. Due to their low cardiopulmonary reserve, these patients may develop important complications during and after laparoscopic surgery.

Pneumoperitoneum is less well tolerated in these patients. CO_2 is quickly absorbed during laparoscopy (14). This gas is highly soluble in water and easily diffuses in body tissues. Because of its high diffusion coefficient relative to oxygen and other respiratory gases, it readily moves out of the peritoneal cavity owing to a high diffusion gradient caused by the difference in concentration of CO_2 between the intraperitoneal space and the surrounding components (e.g., blood). However, the characteristic of rapid absorption, which lessens the chance of a CO_2 gas embolus, may also lead to potential problems (e.g., hypercapnia, hypercarbia, associated cardiac arrhythmias). In particular, patients with chronic obstructive pulmonary disease may not be able to compensate for the absorbed CO_2 by increased ventilation; this may result in dangerously elevated levels of CO_2 in these patients. CO_2 also stimulates the sympathetic nervous system, which results in an increase in heart rate, cardiac contractility, and vascular resistance. Lastly, CO_2 is also stored in various body compartments (e.g., viscera, bones, muscles). After prolonged laparoscopic procedures, it may take hours before the patient has eliminated the extra CO_2 that has accumulated in these storage areas; again, this is more often the case in patients with pulmonary compromise (15,16).

The cardiovascular effects of pneumoperitoneum are diverse and are exaggerated in patients with cardiovascular disorders.

First, the effects of the pneumoperitoneum on venous return depend on atrial pressures, which, in turn, are a reflection of the hydration state of the subject. If atrial pressures are low (normal or hypovolemic state), then, during a pneumoperitoneum of up to 20 mmHg, venous return is reduced owing to increased compression of the vena cava from the pneumoperitoneum. If atrial pressures are high (hypervolemic state), the vena cava resists elevated intra-abdominal pressure, and venous return is actually enhanced. These principles apply only to an intra-abdominal pressure of up to 20 mmHg. Therefore, all patients, and in particular those with

TABLE 3 ■ Differential Diagnosis of Ascites

Hypoalbuminemia
Hepatic congestion
Peritoneal infections
Neoplasms
Lymphatic obstruction
Meigs' syndrome, struma ovarii
Chronic pancreatitis or pseudocyst
Bile ascites
Urine ascites
Chylous ascites

The respiratory effects of pneumoperitoneum are also exaggerated in the patient with pulmonary disorders. Owing to increased intra-abdominal pressure, diaphragmatic motion is limited. Pulmonary dead space remains unchanged, but functional reserve capacity decreases.

Presence of ascites is considered a contraindication to laparoscopic surgery because of the increased risk of port site metastasis.

pulmonary disease, must be closely monitored for several hours after lengthy laparoscopic procedures. It is important for the anesthetist not to rely on central venous pressure readings for any clinical decision making. If information regarding vascular volume and central venous pressure is needed, a Swan-Ganz catheter should be placed.

Tachycardia and ventricular extrasystoles may be seen as results of hypercapnia (17). Peritoneal irritation may lead to vagal stimulation and subsequently to bradyarrhythmias. Also, dysrhythmias can serve as clinical warning signs for the occurrence of pneumothorax, hypoxia, and gas embolism (14).

The respiratory effects of pneumoperitoneum are also exaggerated in the patient with pulmonary disorders. Owing to increased intra-abdominal pressure, diaphragmatic motion is limited. Pulmonary dead space remains unchanged, but functional reserve capacity decreases (14).

The average peak airway pressure needed to keep up a constant tidal volume increases parallel to the increasing intra-abdominal pressure. Although usually not of great clinical importance in a healthy patient population, it is advisable to use positive end-expiratory pressure techniques when patients with lung disease undergo general anesthesia for a laparoscopic procedure (14).

The Trendelenburg position (used in lower urinary tract surgery) has an adverse effect on respiration as well. It elevates the diaphragm and decreases vital capacity. It can also lead to a dislocation of the endotracheal tube, which, in turn, may cause right mainstem bronchus intubation. Although of little clinical significance in healthy patients, the Trendelenburg position may cause pulmonary edema in patients with increased left-sided heart pressures.

Mechanical abdominal wall lift has been proposed as an alternative method of exposure in laparoscopic surgery to obviate or minimize the adverse physiologic effects of pneumoperitoneum in patients with high cardiopulmonary risk factors. Other theoretical advantages of this technology include minimization of the risk of CO_2 embolism in trauma patients and tumor dissemination in patients undergoing laparoscopic surgery for cancer. Abdominal wall lift systems do appear to reduce the adverse cardiovascular and respiratory effects, but they do so at the expense of surgical exposure, which is less optimal than that provided by the positive-pressure pneumoperitoneum. This reduced exposure increases the technical manipulation and exposure during the operation and, hence, the operating times. This problem is overcome by combination of abdominal wall lift with low-pressure (3–4 mmHg) pneumoperitoneum. This combination provides good surgical exposure without adverse cardiovascular consequences (18).

ASCITES

Presence of ascites is considered a contraindication to laparoscopic surgery because of the increased risk of port site metastasis.

Neoplasic ascites is usually secondary to primary hepatic neoplasms, metastases to liver or peritoneum, lymphomas, leukemias, or myeloid metaplasia. The differential diagnosis of ascites is shown in Table 3 (19).

The diagnosis of ascites is obtained by paracentesis and fluid analysis. Peritoneal effusion, like pleural effusion, can be subdivided as exudative or transudative based on its characteristics. The serum-ascites albumin gradient (serum albumin level/ascitic fluid albumin level) correlates directly with portal pressure and can also be used to classify ascites. Patients with gradients $\geq 1.1\,g/dL$ have portal hypertension, and those with gradients $<1.1\,g/dL$ do not; the accuracy of this method is in excess of 95% (20). A blood-ascitic fluid albumin gradient $<1.1\,g/dL$ is suggestive of malignant ascites. The characteristics of malignant ascitic fluid include a bloody appearance, high total protein levels ($>2.0\,g/dL$), high LDH levels (>200 IU), low glucose ($<60\,mg/dL$), and high red blood cell contents. An ascitic fluid polymorphonuclear leukocyte count $>500/\mu L$ is suggestive of spontaneous bacterial peritonitis (19).

Tsivian and Sidi recently reviewed published experimental and clinical studies on port site metastases after urological laparoscopy. Nine cases of port site metastases have been described before 2003 (21). Etiological factors included the presence of ascites,

natural malignant disease behavior, host immune status, local wound factors, and insufficient technical experience of the surgeons and operating team. The authors suggested several preventive steps including avoiding laparoscopic surgery in patients with ascites.

The presence of ascites (irrespective of type) has been previously recognized as a significant and independent risk factor for early port site recurrences in the general surgery and gynecology literature (22,23).

> The presence of ascites (irrespective of type) has been previously recognized as a significant and independent risk factor for early port site recurrences in the general surgery and gynecology literature.

OBESITY

Obesity poses a major challenge to the laparoscopic surgeon, both from the surgical (technical) and the medical aspect. Obesity has been recognized as an independent cardiovascular risk factor, and is associated with serious medical comorbidity including the metabolic syndrome, which is characterized by impaired glucose tolerance, dyslipidemia, and hypertension. Other medical conditions caused or aggravated by obesity include sleep apnea, daytime sleepiness, asthma, and gastroesophageal reflux. Physical disability, body image, and depressive illness can also be present. All these issues need to be factored in the treatment of such patients.

For adults, overweight has been defined by a body mass index (the weight in kilograms divided by the square of the height in meters) of 25 or higher, obesity by an index of 30 or higher, and extreme or "morbid" obesity by an index of 40 or higher.

> A body mass index of 40 or higher represents at least 100 lb of overweight status for men and 80 lb for women. In the United States, the age-adjusted prevalence of overweight in adults increased from 55.9% to 64.5% between the period 1988 and 1994 and the period 1999 and 2000.

A body mass index of 40 or higher represents at least 100 lb of overweight status for men and 80 lb for women. In the United States, the age-adjusted prevalence of overweight in adults increased from 55.9% to 64.5% between the period 1988 and 1994 and the period 1999 and 2000. The prevalence of obesity increased from 22.9% to 30.5%; the prevalence of extreme obesity increased from 2.9% to 4.7% (24).

The epidemic of obesity in the United States has spawned a second epidemic of bariatric surgery. The number of gastrointestinal surgeries performed annually for severe obesity increased from about 16,000 in the early 1990s to about 103,000 in 2003. This increase has been fueled by the increase in the number of people who are extremely obese; the failure of diets, exercise, and medical therapy; and the advent of laparoscopic procedures (25). Minimally invasive techniques have been used in bariatric surgery since 1993. Laparoscopic bariatric procedures have proven to be safe and conserve known benefits of laparoscopic surgery, including but not limited to a shorter recovery with an earlier return to normal activity (26,27).

> Experience gained form laparoscopic bariatric surgery paved the way for laparoscopic surgery for almost all abdominal and retroperitoneal pathologies. Obesity was once considered a relative contraindication for urologic laparoscopic surgery; however, nowadays obese patients are probably better served with minimally invasive approaches that harbor fewer complications and offer faster recovery.

Experience gained form laparoscopic bariatric surgery paved the way for laparoscopic surgery for almost all abdominal and retroperitoneal pathologies. Obesity was once considered a relative contraindication for urologic laparoscopic surgery; however, nowadays obese patients are probably better served with minimally invasive approaches that harbor fewer complications and offer faster recovery.

The acute major complications of open or laparoscopic surgery in the obese patient include pulmonary embolism, respiratory failure, cardiovascular events, wound infection, and bleeding. The most common late complication is incisional hernia. The level of risk is related to the specific procedure and the patient's age, degree of obesity, and other medical conditions. There is no comprehensive registry of such complications. Thus, it is difficult to obtain accurate data about the specific rates of serious complications and death that can be anticipated and that may occur even with excellent care.

Owing to the smaller access incision, wound infections and incisional hernias after laparoscopic surgery are expected to be less common than after open surgery. The extent of incisional hernia is related to the size of the initial incision. Incisional hernias after open surgery tend to be larger and require a more extensive repair with mesh, whereas incisional hernias that develop after laparoscopic surgery tend to be small and can be repaired with primary closure. Another easily recognized benefit of laparoscopic surgery in the obese patient is the reduced risk for retained instruments and laparotomy pads. Morbidly obese patients undergoing open surgery are at high risk for retained foreign objects. Another possible benefit of laparoscopy is the reduction in bowel obstruction because of the theoretical reduction in adhesion formation and the early return to normal bowel function.

In a comprehensive review of complications of laparoscopic bypass surgery in over 3400 patients as compared to open surgery, Podnos et al. reported that laparoscopic surgery in this morbidly obese population was associated with a decrease in wound

infection, incisional hernia, and mortality. However, there were no significant differences in the frequency of pulmonary embolism or pneumonia (28).

There are fewer reports in the urologic literature on laparoscopic surgery in the obese patient. However, contemporary series of laparoscopic nephrectomy, donor nephrectomy, adrenalectomy, and prostatectomy have been published and demonstrated safety and success of these complex procedures in obese patients.

Fugita et al. reviewed the Johns Hopkins series of intraperitoneal laparoscopic radical nephrectomy in the obese patient population. A body mass index greater than 30 was used to define obesity. Technical modifications included slightly greater insufflation pressures and a lateral shift in trocar sites. Of 101 patients, 32 were obese and 69 were not. The authors did not find significant differences in any of the analyzed parameters between the obese and nonobese patients, including operative time, time to ambulation, length of hospital stay, conversion rate to an open procedure, and complication rate. One conversion to an open procedure was required in both the obese and the nonobese laparoscopic groups (29). These authors concluded that obesity should not be considered a contraindication to laparoscopic nephrectomy. Similarly, Doublet et al. reported that retroperitoneal laparoscopic simple nephrectomy in obese patients was not associated with higher morbidity or longer hospitalization than in nonobese patients. In this series, eight patients had a body mass index 30 or greater and were compared to 40 nonobese patients. Of note, 22 patients were renal transplant recipients and underwent nephrectomy of native kidney (30). Fazeli-Matin et al. compared retrospectively the outcome of laparoscopic versus open renal and adrenal surgery in the obese patient (body mass index 30 or greater) at the Cleveland Clinic. The majority of laparoscopic procedures were performed using a retroperitoneoscopic approach. To insure adequate case matching, open group patients with factors precluding laparoscopic surgery were excluded from the study. There were 21 obese patients in each group and baseline parameters were comparable between groups. Surgical time between the laparoscopic and open groups was comparable; however, the laparoscopic group had decreased blood loss, quicker resumption of oral intake and ambulation, decreased narcotic analgesic requirements, shorter hospital stay, and quicker convalescence. The complication rate was similar (31).

The applicability of laparoscopic donor nephrectomy has also been reported in the obese donor. In a small series of 40 patients at the Georgetown Transplant Institute, the outcome of obese patients (body mass index >31) did not differ from nonobese donors (32). In a larger report, Jacobs et al. assessed 431 laparoscopic living donor nephrectomies. The markedly obese group consisted of 41 patients with a body mass index greater than 35. Forty-one controls with a body mass index less than 30 were matched to the obese donors. Donor operations in the markedly obese were significantly longer by an average of 40 minutes. Obese donors were more likely to require open conversion. More and larger laparoscopic ports were used in the markedly obese. The postoperative recovery of the gastrointestinal tract, hospitalization time, analgesic requirements, and total complications were equal in the two groups, although the obese donors' complications tended to be cardiopulmonary problems. But most importantly, the recipient graft function was equivalent between the two groups (33).

Markedly obese patients have an increased risk of complications from surgery, regardless of the approach.

The current literature suggests that laparoscopic renal and adrenal surgery is technically feasible in the obese patient and results in decreased blood loss, quicker return of bowel function, less analgesic requirement, shorter convalescence, and reduced hospital stay as compared to open surgery. Upper tract laparoscopic surgery in this subset of patients does not seem to negatively impact the long-term functional and oncologic outcomes.

Less is known about lower tract laparoscopic surgery in obese patients. In a multi-institutional review of the incidence and factors contributing to conversion from laparoscopic radical prostatectomy to open prostatectomy among eight U.S. surgeons, obesity was found to be a major player. Of 670 operations, 13 (1.9%) were converted to open. Comorbidities associated with conversion were prior pelvic surgery and obesity (body mass index greater than 30). Six of the 13 conversions occurred in the surgeons' first five cases. Despite open conversion, the functional outcomes did not appear to be adversely affected (34). In another review of 100 consecutive cases of transperitoneal laparoscopic radical prostatectomy, prostate weight, androgen deprivation, and prior abdominal surgery did not significantly affect the operative time. However, obesity and the level of surgeon's experience increased the operative time by an average of 38 minutes (35).

> Markedly obese patients have an increased risk of complications from surgery, regardless of the approach.

In general, obese patients should initially be considered as relative contraindication to laparoscopic surgery until the learning curve has been overcome. In experienced hands, obese patients do benefit from the minimal invasiveness of laparoscopy. Regardless of approaches, obese patients remain at higher risks of medical and surgical complications due to associated comorbidities and technical difficulty. Appropriate patient selection, optimization of medical condition, and informed consent are paramount in this process.

Surgical planning and medical optimization of the patient condition are emphasized in the obese. The patient should be cleared for surgery by the medical team. Deep venous thrombosis prophylaxis is achieved with subcutaneous heparin or low molecular weight heparin, compressive lower extremity stockings or pneumatic sleeves, and early ambulation. Prophylactic antibiotics (first- or second-generation cephalosporins) are also administered perioperatively. Minor intraoperative modifications can facilitate the procedure in obese patients and these include proper trocar site selection, which is usually more lateral in upper tract surgery. We do not recommend routine use of higher insufflation pressure because it compromises ventilation; however, occasional increased pressure may achieve a larger working space.

In general, obese patients should initially be considered as relative contraindication to laparoscopic surgery until the learning curve has been overcome. In experienced hands, obese patients do benefit from the minimal invasiveness of laparoscopy. Regardless of approaches, obese patients remain at higher risks of medical and surgical complications due to associated comorbidities and technical difficulty. Appropriate patient selection, optimization of medical condition, and informed consent are paramount in this process.

ADVANCED AGE

Elderly patients are considered at high surgical risk because of the increased American Society of Anesthesiologists score generally due to associated comorbidities. In addition, normal physiologic changes of aging such as decreased cardiopulmonary reserve may predispose patients to increased complications from prolonged pneumo-peritoneum.

The minimally invasive nature of laparoscopic surgery in general offers several advantages over open surgery in the elderly patient population.

The minimally invasive nature of laparoscopic surgery in general offers several advantages over open surgery in the elderly patient population.

Dhoste et al. described the cardiovascular and pulmonary changes induced by pneumoperitoneum in 16 patients aged >75 years and American Society of Anesthesiologists III. Cardiovascular monitoring included a radial artery catheter and a pulmonary artery catheter. Peritoneal insufflation resulted in improvement of cardiovascular function with increases in cardiac index, heart rate, mean arterial pressure, and SvO_2, which was the result of a sympathetic stimulation. No change in preload, right ventricular end diastolic volume index and systemic vascular resistance was recorded. There was an increase in $PaCO_2$ 15 minutes after CO_2 insufflation and a further elevation after 60 minutes. There was no change in the intrapulmonary shunt pressure. This study demonstrated that pneumoperitoneum is well tolerated in older patients (36).

There are several reports documenting safety and efficacy of laparoscopic surgery in the elderly patient especially in the general surgery literature. In a study of 5884 consecutive patients who underwent an attempted laparoscopic cholecystectomy, 395 patients (6.7%) were older than 65 years. The results of laparoscopic cholecystectomy in patients aged 65–69 years were comparable with those reported in younger patients. Patients older than 70 years had a two-fold increase in complicated biliary tract disease and conversion rates because of the nature of the disease, but had a low mortality rate (2%) despite an increase in American Society of Anesthesiologists classification (37). Senagore et al. compared short-term outcomes in age-matched cohorts of patients undergoing laparoscopic versus open segmental colectomy in patients younger versus older than 70 years of age. The length of hospital stay was significantly shorter with laparoscopic surgery in both age cohorts. The direct hospital costs were significantly lower only with laparoscopic colectomy in the older cohorts. Using the physiologic and operative severity score for the enumeration of morbidity and mortality, it was noted that laparoscopy patients in both age groups experienced a rate of morbidity that was significantly lower than expected (38). Another study compared 65 patients (aged 70 and above) who underwent laparoscopic colorectal resection with 89 who had open surgery. Laparoscopic colorectal resection was found to be safe in elderly patients and was associated with more favorable short-term outcomes in terms of earlier return of bowel function, earlier resumption of diet, and shorter hospital stay. Laparoscopy was also associated with less cardiopulmonary morbidity (39).

Hsu et al. retrospectively reviewed the outcome of laparoscopic donor nephrectomy in six patients aged 65 years or older. The median donor age was 69.5 years, and the median American Society of Anesthesiologists score was II. The median operative time was 240 minutes, with a median blood loss of 300 mL. No intraoperative complications or open conversions occurred. Postoperatively, the median time to resumption

of oral intake was one day, and the median hospital stay was three days, and the median convalescence was two weeks. The one-year renal allograft survival was 100% (40). Fornara et al. reported findings for laparoscopic nephrectomy in 11 patients in comparison with open nephrectomy in 42 patients older than 65 years. Patients in the laparoscopy group demonstrated a significant decrease in blood loss and number of blood transfusions. In addition, benefits were shown for the analgesic consumption, hospital stay, and convalescence parameters for the laparoscopy group. Although the complication rates were comparable in both groups, an increase was observed in both groups for patients aged between 75 and 84 years (41).

SUMMARY

- In the carefully selected and prepared patient, previous abdominal surgery, coagulation disorders that have been reversed, obesity, and patients suffering from controlled cardiopulmonary disorders are still candidates for laparoscopy. Even with these risk factors, patients can still benefit from known advantages of laparoscopy over open surgery.
- Patients with severe cardiopulmonary diseases have higher surgical risks regardless of the approach. Due to their low cardiopulmonary reserve, these patients may develop important complications during and after laparoscopic surgery.
- The presence of ascites is considered a contraindication to laparoscopic surgery because of the increased risk of port site metastasis.
- Laparoscopic surgery is a safe option in the elderly population. Age alone should not be considered an absolute contraindication for laparoscopy.

CHAPTER 87

LAPAROSCOPIC SURGERY DURING PREGNANCY

Michael D. Rollins and Raymond R. Price

Intermountain Healthcare/Salt Lake Clinic, Salt Lake City, Utah, U.S.A.

INTRODUCTION

Surgical intervention in the gravid patient presents a dilemma in which the surgeon must weigh the risks and benefits not only to the mother but also to the fetus. Approximately one in 500 to one in 635 women will require nonobstetrical abdominal surgery during pregnancy (1,2). Acute appendicitis, cholecystitis, and intestinal obstruction are the three most common nonobstetrical emergencies requiring surgery during pregnancy (1). Other conditions requiring surgical intervention during pregnancy include symptomatic cholelithiasis, adrenal tumors, hematological disorders that involve the spleen, ovarian cysts, adnexal mass or torsion, heterotopic pregnancy, and abdominal pain of unknown etiology.

Complications following intra-abdominal surgery during pregnancy have been attributed to disease severity and delay in diagnosis rather than to the operative procedure itself (3,4). Common reasons for this delay include the patient and physician attributing signs and symptoms of disease to pregnancy, anatomic alterations of the gravid abdomen masking classic findings of diseases, and nonoperative management of patients due to concern of endangering the fetus with diagnostic and therapeutic procedures.

Laparoscopy has improved dramatically since its advent, resulting in changes to the operative management of several disease processes. Although pregnancy was once considered an absolute contraindication to laparoscopic surgery, it is now being performed with increasing frequency. Significant experience has accrued with laparoscopy during pregnancy to rule out ectopic pregnancy and to evaluate adnexal masses in the gynecologic literature with most patients having normal intrauterine pregnancies.

Regardless of the trimester in which laparoscopy was performed, there have not been increases in fetal loss or adverse long-term outcomes (5–7).

These experiences prompted general surgeons to begin offering laparoscopic appendectomy and cholecystectomy to pregnant patients in 1991 (8–10). Multiple retrospective studies have found no significant differences in birth weight, gestational duration, intrauterine growth restriction, infant death, or fetal malformation when comparing open to laparoscopic procedures during pregnancy (11–13). Laparoscopy for nonobstetrical abdominal conditions during pregnancy is rapidly becoming the

983

preferred approach, as maternal and fetal outcomes are generally excellent following surgery.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

Uterus

Many anatomical and physiologic changes occur during pregnancy altering the presentation of pathologic conditions (Table 1). The fundus of the uterus is generally located at the umbilicus at 20 weeks gestation and just inferior to the xiphoid process at 36 weeks (Fig. 1). This leads to displacement of the intra-abdominal organs, thus altering the location of abdominal pain and tenderness found with certain conditions such as acute appendicitis (14). In addition, while lying in the supine position, the uterus may compress the inferior vena cava and aorta causing a decrease in venous return to the heart and a decrease in placental perfusion, respectively.

It is important to place the gravid patient in the dependent position to shift the uterus off of the inferior vena cava and the aorta in order to avoid maternal hypotension and decreased placental perfusion during surgery.

The changing fundal height must be remembered and evaluated before accessing the abdominal cavity for laparoscopic procedures (Fig. 2). By altering the location of initial abdominal access according to fundal height and using maneuvers to elevate the abdominal wall during insertion, either the Hasson technique or Verres needle may be performed safely (12,13,15).

Initial placement of the Verres needle or trocar into the left subcostal region may be necessary as the uterus enlarges in the second and third trimesters (16,17). Ancillary trocars are then inserted under direct visualization, modifying their typical location according to the size of the uterus (18).

Hemodynamics

Many profound physiologic changes occur in the cardiovascular system during pregnancy. Blood volume expands by 30% to 40%. The expanded blood volume during pregnancy and the direct ionotropic effects of estrogen lead to an increased heart rate and stroke volume (19). Heart rate begins to increase at the fifth week of gestation and continues to rise until the 32nd week, at which time it is approximately 15% above non-pregnant values. Cardiac output increases by 30% to 50% at the end of the second

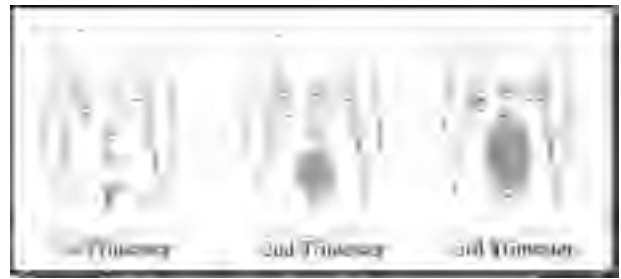
FIGURE 2 ■ Trocar placement for laparoscopic appendectomy changes by size of gravid uterus. Numbers indicate the order of insertion.


trimester with most of the increased cardiac output directed to the uterus and placenta. Maternal position largely affects cardiac output later in pregnancy. When lying in the supine position, the enlarged uterus compresses the inferior vena cava leading to a decrease in venous return and thereby a decrease in cardiac output (20). Compared to the lateral recumbent position, patients lying supine may experience a 10% to 30% decrease in cardiac output (21,22).

In nonpregnant patients, a 25% decrease in cardiac index is seen with induction of anesthesia with a further decrease to 50% normal after CO_2 insufflation and an increase in mean arterial pressure and systemic vascular resistance (23). A recent study from the Brigham and Women's Hospital demonstrated these same hemodynamic changes in pregnant patients undergoing laparoscopic surgery (24). There was no exaggerated cardiovascular response to CO_2 pneumoperitoneum during pregnancy as some have speculated might occur.

Respiratory
Alterations in the chest wall configuration and the diaphragm during pregnancy cause a restrictive pulmonary physiology. Minute ventilation increases throughout pregnancy to become almost 50% above normal at term (25). Pregnant patients are vulnerable to arterial oxygen desaturation secondary to the decreased residual lung volume and functional residual capacity caused by upward displacement of the diaphragm (26).

The upward displacement of the diaphragm is increased by CO_2 pneumoperitoneum. This has led to the recommendation that intra-abdominal pressures should be minimized during laparoscopic surgery with pressures less than 12 mmHg (27).

However, other authors have stressed the importance of adequate visualization of the intra-abdominal cavity and have used pressures up to 15 mmHg without increasing the incidence of adverse effects to either the mother or the fetus (12,13).

Coagulation
Pregnancy is considered a hypercoagulable state increasing the risk of thromboembolic phenomena due to increased venous stasis, vessel wall injury, and changes in the coagulation cascade. The effects of estrogen cause increased synthesis of clotting factors, particularly factors VII, VIII, X, and XII (28). Intra-abdominal vascular stasis secondary to inferior vena cava compression from the uterus also increases the risk of deep venous thrombosis during pregnancy with an incidence of approximately 0.1% to 0.2% (29).

CO_2 pneumoperitoneum causes a further increase in venous stasis, which is already present during pregnancy. Jorgensen et al. (30) demonstrated that abdominal insufflation up to 12 mmHg caused a statistically significant decrease in femoral blood flow velocity and an increase in femoral vein diameter, which could not be completely reversed with either intermittent pneumatic compression devices or intermittent electric calf stimulators.

Although pregnancy increases the synthesis of clotting factors, platelets normally decrease during pregnancy, possibly secondary to increased destruction (31,32). Approximately 8% of gravid patients will develop gestational thrombocytopenia with platelet counts between 70,000 and 150,000/mm^3. These patients do not appear to experience increased complications and their platelet counts generally normalize by 1–2 weeks postpartum (33).

> The upward displacement of the diaphragm is increased by CO_2 pneumoperitoneum. This has led to the recommendation that intra-abdominal pressures should be minimized during laparoscopic surgery with pressures less than 12 mmHg.

Biochemical

Normal variations in laboratory values occur during pregnancy (Table 1). The gravid patient experiences a physiologic anemia secondary to an increase in plasma volume, which exceeds the increase in red blood cell mass. This physiologic anemia of pregnancy reaches its nadir at 30–34 weeks' gestation. The pregnant state also causes a mild dilutional hypoalbuminemia with albumin levels at term being 25% lower than nonpregnant values (20). Alkaline phosphatase is elevated secondary to the effects of estrogen although other liver function tests remain normal. Alkaline phosphatase normally rises during the third trimester reaching values of 2–4 times greater than seen in nonpregnant patients. Leukocytosis is a normal result of pregnancy. During the first and second trimesters, white blood cell counts normally range from 6000 to 16,000 cells/mm^3 (34). Furthermore, marked changes in adrenocortical function are associated with pregnancy, resulting in increased levels of aldosterone, cortisol, and free cortisol (20).

SPECIAL CONSIDERATIONS

Anesthesia

As many as 2% of pregnant women in the United States undergo anesthesia for surgical procedures unrelated to delivery (35,36). Anesthetic management strategies focus predominantly on the alterations in maternal physiology from anesthesia. Although teratogenic effects of anesthesia may be of concern to patients and physicians, no anesthetic agents have been found to definitively cause fetal malformations (37).

Gravid patients normally experience a compensatory respiratory alkalosis with a $PaCO_2$ ranging from 28 to 32 mmHg and a resultant pH of approximately 7.44 (38). Fetal $PaCO_2$ is directly related to maternal $PaCO_2$. With a rise in maternal $PaCO_2$, fetal heart rate increases reflecting fetal distress (39).

Pregnant sheep models have been used to demonstrate that not only periods of severe hypercarbia ($PaCO_2$>60 mmHg) but also severe hypocapnia ($PaCO_2$<29 mmHg) reduce uterine blood flow leading to fetal distress (40). These changes have not been documented during laparoscopic surgery with appropriate anesthetic monitoring and maintenance of normal maternal pH.

Maintenance of uteroplacental blood flow is central to fetal well-being with fetal asphyxia resulting from a decrease in uteroplacental blood flow. The pharmacologic agent of choice for maintaining maternal blood pressure is ephedrine. Other vasopressors such as alpha-agonists, dopamine, and epinephrine induce uterine artery vasoconstriction resulting in decreased uterine blood flow and should be avoided (38).

Other anesthetic considerations in the gravid patient are alterations in free drug concentrations as a result of expanded blood volume, low albumin, and increased alpha 1-glycoprotein. There is an increased risk of aspiration secondary to distortion of the gastric and pyloric anatomy from the gravid uterus and the hormonally induced decrease in lower esophageal sphincter tone (38).

Radiologic Issues

Fetal safety during diagnostic imaging is a primary goal for clinicians and patients. Significant radiation exposure may lead to chromosomal mutations, neurologic abnormalities, mental retardation, and an increased the risk of childhood leukemia. For acute indications, the benefits of the mother usually outweigh the small fetal risk. Radiation dosage is the most important risk factor, but fetal age at exposure is also important (41,42). Radiological exposure is measured using units of either rad or centiGrey (1 rad = 1 cGy). Fetal mortality is the greatest when exposure occurs within the first week of conception prior to oocyte implantation (41–43). The recommended radiation dose from approximately the first week of conception through week 25 is less than 5–10 rad (44). The most sensitive time period for central nervous system teratogenesis is between 10 and 17 weeks' gestation and nonurgent X-rays should be avoided during this time. In later pregnancy, the concern shifts from teratogenesis to increasing the risk of childhood hematologic cancer. The background incidence of childhood cancer and leukemia is approximately 0.2% to 0.3%. Radiation may increase that incidence by 0.06% per 1 cGy delivered to the fetus (44). Exposure of the fetus to 0.5 rad increases the risk of spontaneous abortion, major malformations, mental retardation, and childhood malignancy to one additional case in 6000 above baseline risk (41). Recommendations are that fetal risk is considered negligible at 5 rad or less and that the risk of malformation is

Pregnant sheep models have been used to demonstrate that not only periods of severe hypercarbia ($PaCO_2$ >60 mmHg) but also severe hypocapnia ($PaCO_2$ <29 mmHg) reduce uterine blood flow leading to fetal distress. These changes have not been documented during laparoscopic surgery with appropriate anesthetic monitoring and maintenance of normal maternal pH.

significantly increased at doses above 15 rad (29). The accepted cumulative dose of ionizing radiation during pregnancy is 5 rad with no single diagnostic study exceeding this maximum (Table 2) (41).

■ The American College of Radiology has stated that pregnant patients may undergo magnetic resonance imaging at any stage of pregnancy provided that the radiologist has a discussion with the patient regarding the risks of the study, the study cannot be delayed until delivery, and no other imaging modalities can provide the necessary information (47).
■ The American College of Radiology has stated that pregnant patients may undergo magnetic resonance imaging at any stage of pregnancy provided that the radiologist has a discussion with the patient regarding the risks of the study, the study cannot be delayed until delivery, and no other imaging modalities can provide the necessary information (47).

Timing of Surgery

Operative intervention may be performed in any trimester if warranted by the patient's condition. Traditional recommendations, which were based on experiences with open surgical procedures during pregnancy, were to delay surgery until the second trimester if possible. A spontaneous abortion rate of 12% has been reported following open cholecystectomy in the first trimester, while 40% of patients undergoing open cholecystectomy in the third trimester experience preterm labor (48). Although surgery during the second trimester has generally been regarded as the safest due to a low rate of preterm delivery and a theoretically low rate of teratogenesis (49), one series reported a 5.6% risk of spontaneous abortion following open cholecystectomy (48). This experience has not been reproduced in the laparoscopic literature.

Recent large case series and one large retrospective review have demonstrated that pregnant patients may undergo laparoscopic surgery safely in any trimester without increased risk to the mother or fetus (11–13,50,51).

Additionally, delaying surgical intervention in patients with symptomatic gallstone disease during pregnancy may lead to further complications of gallstone disease such as acute cholecystitis and gallstone pancreatitis (50,52–54), which can lead to higher spontaneous abortion rates and preterm labor.

It has been suggested that the gestational age limit for successful completion of laparoscopic surgery during pregnancy is 26–28 weeks (55). This has been refuted by several studies in which laparoscopic cholecystectomy and appendectomy have been successfully performed late in the third trimester (12,13,16).

> Recent large case series and one large retrospective review have demonstrated that pregnant patients may undergo laparoscopic surgery safely in any trimester without increased risk to the mother or fetus.

Abdominal Insufflation/Exposure

CO_2 is the primary gas used to create a pneumoperitoneum for laparoscopy in nonpregnant and pregnant patients. Gaseous carbon dioxide exchange occurs with intraperitoneal insufflation. There has been much concern in the past over the effects of CO_2 pneumoperitoneum on the fetus. While studies have demonstrated that fetal acidosis does occur in animal models during CO_2 pneumoperitoneum, there have been no long-term adverse effects noted (56–58). Furthermore, there is no evidence to support detrimental effects resulting from CO_2 pneumoperitoneum in humans (55). In the pregnant ewe model, observation has been made that CO_2 pneumoperitoneum

results in a $PaCO_2$ to $ETCO_2$ gradient of 16–25 mmHg leading to fetal hypercapnia, hypertension, acidosis, and tachycardia (56,59). Although several studies have demonstrated that the fetus is slightly more acidotic than the mother and that $EtCO_2$ values lag behind corrections in $PaCO_2$, others have observed no change in fetal $PaCO_2$ when maternal sheep $PaCO_2$ was maintained within 37 ± 3.3 mmHg following CO_2 insufflation as well as a good correlation between $PaCO_2$ and $EtCO_2$ (56,58,60–62).

CO_2 insufflation has been used almost exclusively for abdominal exposure in the reported cases of successful laparoscopy during pregnancy. Pneumoperitoneum created with CO_2 appears to be safe when abdominal pressures are kept below 15 mmHg and physiologic end tidal CO_2 levels are maintained (30–40 mmHg) (12,13).

While there is no conclusive evidence in humans that CO_2 pneumoperitoneum is detrimental to the fetus, the concern has led to a search for alternative means of intra-abdominal exposure during laparoscopy. Gasless laparoscopy has been described using a mechanical abdominal wall lifting device and has been used for the management of ovarian cysts during early pregnancy with good success (63).

> CO_2 insufflation has been used almost exclusively for abdominal exposure in the reported cases of successful laparoscopy during pregnancy. Pneumoperitoneum created with CO_2 appears to be safe when abdominal pressures are kept below 15 mmHg and physiologic end tidal CO_2 levels are maintained (30–40 mmHg).

> Imperative to fetal well-being during laparoscopy is tight control of maternal hemodynamic and respiratory function in order to maintain a normal maternal pH.

Maternal and Fetal Monitoring

Imperative to fetal well-being during laparoscopy is tight control of maternal hemodynamic and respiratory function in order to maintain a normal maternal pH.

Controversy exists over the use of maternal $PaCO_2$ versus $EtCO_2$ for monitoring maternal acid/base status as a result of conflicting animal data regarding the effects on the fetus as mentioned above. Some have argued that the pregnant ewe model may not be appropriate for the study of the effects of the pneumoperitoneum on maternal acidosis and have demonstrated that capnography adequately reflects maternal acid/base status in humans (64). Furthermore, several large studies have observed that $EtCO_2$ mea-surements may be used to monitor pregnant women undergoing laparoscopy safely and effectively without adverse fetal outcomes (12,13,55).

The fetus must also be monitored for signs of distress. One sign that may be easily detected is an increased fetal heart rate. While intraoperative fetal monitoring was once thought to be the most accurate method to detect fetal distress during laparoscopy, the literature to date in which intraoperative fetal monitoring was employed has not reported any abnormalities of fetal heart rate either during the procedure or postoperatively (50,65). This has led to the recommendation of preoperative and postoperative monitoring of the fetal heart rate, with no increased fetal morbidity having been reported (12,13).

ADVANTAGES OF LAPAROSCOPIC SURGERY

The most important benefit of laparoscopy is probably the prevention of undue delay in diagnosis (17). Advantages of laparoscopy in the pregnant patient:

- Decreased fetal depression due to lessened postoperative narcotic requirements (9,10,66,67)
- Lower risk of wound complications (8,9,68)
- Diminished postoperative maternal hypoventilation (9,10)
- Shorter hospital stays
- Decreased risks of thromboembolic events due to early mobilization
- Better intra-abdominal visualization reducing the need for uterine manipulation and thereby reducing the risk of uterine irritability (17)
- Decreased uterine irritability results in lower rates of spontaneous abortion and preterm delivery (69)

SAFETY OF LAPAROSCOPY

Laparoscopic surgery during pregnancy for the management of both obstetrical and nonobstetrical disease is being performed with increasing frequency.

> Numerous clinical reports have demonstrated that pregnant patients may undergo laparoscopic surgery safely in any trimester without an increase in maternal or fetal morbidity or mortality compared with open surgery.

Numerous clinical reports have demonstrated that pregnant patients may undergo laparoscopic surgery safely in any trimester without an increase in maternal or fetal morbidity or mortality compared with open surgery.

A review of the Swedish Health Registry from 1973 to 1993, which included pregnant women who had undergone nonobstetric operations between weeks 4 and 20 of pregnancy, compared 2233 laparoscopic procedures to 2491 open procedures and found

no significant differences in birth weight, gestational duration, intrauterine growth restriction, infant death, or fetal malformation (11).

A nationwide, multicenter, retrospective survey was carried out in Israel, that included all of the operations performed on pregnant women from 1990 to 2000. One hundred and ninety-two laparoscopies (first trimester 141, second trimester 46, third trimester 5) and 197 laparotomies (first trimester 63, second trimester 110, third trimester 24) were performed. Surgical procedures were performed for adnexal disease, appendicitis, cholecystitis, heterotopic pregnancy, Crohn's colitis (hemicolectomy), and bowel obstruction. No statistically significant differences were observed between laparoscopy and laparotomy in the prevalence of abortion, preterm labor, preterm delivery, intrauterine growth restriction, or fetal anomalies. Furthermore, immediate postoperative complications were lower in the laparoscopy group, including fever, pulmonary embolus, and premature contractions (70).

Short-term outcomes following laparoscopic surgery during pregnancy have been almost uniformly good. However, there is a paucity of data evaluating the long-term effects on the resultant children. To this end, a recent study was conducted that followed, from one to eight years, the children of 11 patients who underwent laparoscopy in their 16–28th weeks of pregnancy. Laparoscopic procedures included appendectomy, cholecystectomy, and lysis of adhesions. No delay in growth or development was experienced by the children (71).

NONGYNECOLOGIC LAPAROSCOPIC PROCEDURES

Cholecystectomy

Hormonal changes that occur during pregnancy predispose patients to gallstone formation. Progesterone inhibits cholecystokinin resulting in decreased gallbladder emptying and increased gallbladder residual volume. Both estrogen and progesterone lead to biliary cholesterol hypersaturation, which increases the risk of forming gallstones (72). During obstetrical ultrasound, 2% to 4% of women are found to have asymptomatic gallstones, while symptomatic disease presents in only 5–10 of 10,000 pregnancies (1). Symptoms of biliary disease are essentially the same in the pregnant patient as in the nonpregnant patient. Most liver function tests are unaffected by pregnancy and remain useful in the diagnosis of biliary disease in the gravid patient with abdominal pain. However, alkaline phosphatase, which is normally elevated during pregnancy, is less helpful in making the diagnosis of biliary disease (72). As in nonpregnant patients, ultrasound evaluation is the diagnostic imaging technique of choice for cholelithiasis (73).

Laparoscopic cholecystectomy continues to be the most common laparoscopic general surgical procedure performed during pregnancy (49). Some recommend that the initial management of symptomatic cholelithiasis should be nonoperative during pregnancy (74). However, this management strategy has been associated with a high recurrence of symptoms leading to hospitalization (50). In addition, nonoperative management of symptomatic cholelithiasis increases the risk of gallstone pancreatitis up to 13%, which leads to fetal loss in 10% to 60% of cases (75–77). Nonoperative management has also been associated with higher incidences of spontaneous abortions, preterm labor, and preterm delivery compared to those undergoing cholecystectomy (69). Arguments for early laparoscopic cholecystectomy include the high incidence of recurrence of symptoms in patients presenting with biliary colic, the potential complication of acute cholecystitis, and the severe complication of gallstone pancreatitis. One series reported a 57% symptom recurrence rate in patients with biliary colic managed nonoperatively as well as a 23% complication rate of acute cholecystitis and gallstone pancreatitis (50). The risk of relapse in pregnant patients with symptomatic gallstones is 92% if the patient presents in the first trimester, 64% when presenting in the second trimester, and 44% in those presenting in the third trimester (78). In a review by Graham et al. (65), there was a decreased risk of spontaneous abortion during the first trimester and decreased risk of preterm labor in the third trimester in women undergoing laparos-copic cholecystectomy for symptomatic cholelithiasis.

While the nonoperative management of symptomatic cholelithiasis increases the risk of gallstone pancreatitis, symptomatic choledocholithiasis remains relatively uncommon during pregnancy (79,80). For pregnant patients with complicated gallstone disease, endoscopic retrograde cholangiopancreatography with sphincterotomy and subsequent laparoscopic cholecystectomy offers a safe and effective therapeutic option (81,82).

Appendectomy

The diagnosis of acute appendicitis during pregnancy remains a difficult one. Both anatomic and physiologic changes that occur during pregnancy often mask the classic signs and symptoms. Although the single most reliable symptom of appendicitis in pregnant patients is right lower quadrant pain (83), this may be highly variable. Throughout pregnancy, the appendix migrates upward in the right lower and upper quadrants. This migration may shift the point of maximal tenderness superiorly and laterally, which in the case of a retrocecal appendix may cause back or flank pain leading to a misdiagnosis of urinary tract infection, nephrolithiasis, or pyelonephritis (72,84). In the majority of patients fever is not present and leukocytosis, which is normal during pregnancy, may confuse the clinical picture (34,72).

Appendicitis is the most common acute general surgical condition during pregnancy, with an incidence of appendectomy during pregnancy of one in 1500 to one in 3000 (1,2,85). When uncomplicated, appendicitis results in a 1.5% fetal loss rate. Perforation, which occurs in 10% of cases, increases the fetal loss rate to 35% and may lead to preterm labor and premature delivery in as many as 40% of patients (1,69).

Because of the difficulty in clinically diagnosing acute appendicitis, the negative appendectomy rate is much higher in the pregnant than nonpregnant patient, with misdiagnosis rates as high as 22% to 55% (15,86). The higher incidence of negative appendectomy in the gravid patient is likely due both to the anatomic and physiologic changes that occur during pregnancy as well as attempts to prevent perforation, since perforation results in high maternal and fetal morbidity and mortality. Up to one-quarter of pregnant women with appendicitis develop appendiceal perforation, and appendiceal rupture has been reported to occur twice as often in the third trimester (69%) as in the first and second trimesters (87–89). A 66% incidence of perforation has been reported in patients when surgery was delayed by more than 24 hours and a 0% incidence when patients were taken to surgery within 24 hours of presentation (90).

Many authors rely heavily on clinical judgment for the diagnosis of acute appendicitis in the gravid patient. However, some studies suggest that the use of helical computed tomography that exposes the fetus to 300 mrad and ultrasonography are highly accurate for diagnosing acute appendicitis during pregnancy and may help reduce the negative appendectomy rate (91,92). In a case series of 42 women with suspected appendicitis during pregnancy, graded compression ultrasonography was 100% sensitive, 96% specific, and 98% accurate in diagnosing acute appendicitis (92).

Adrenalectomy

Laparoscopic adrenalectomy is being performed with increasing frequency in nonpregnant patients and is considered by some as the preferred approach (93).

Laparoscopic adrenalectomy for pheochromocytoma has been demonstrated to provide as much hemodynamic stability as open adrenalectomy during tumor manipulation with the added benefits of laparoscopic procedures (94). Nine cases of laparoscopic adrenalectomy during pregnancy have been reported in the literature for primary hyperaldosteronism, Cushing's syndrome, and pheochromocytoma (95–101). The retroperitoneal approach was used in one patient (97), whereas a transperitoneal approach was performed in the other eight.

Pheochromocytomas are responsible for 0.05% to 0.1% of all causes of hypertension and are rare during pregnancy with less than 200 cases reported in the literature (102,103). Although the most common symptoms in nonpregnant patients are hypertension, headaches, sweating, and palpitations, hypertension and headaches seem to predominate during pregnancy. While these tumors are rarely the cause of hypertension during pregnancy, if unrecognized or untreated they pose serious risks to both the mother and fetus. Maternal mortality rates have been reported in 17% to 48% and fetal demise in 26% to 54% of untreated cases (104–106). With early detection and treatment these mortality rates may be dramatically improved, with reported lows of 0% to 15% (105–107). Unfortunately, antenatal diagnosis is made in only 53% of cases (106).

Pheochromocytoma should be considered in the differential diagnosis of any pregnant patient developing hypertension prior to the 20th week of gestation. The diagnosis of pheochromocytoma can be made by measuring urinary chatecholamines as with nonpregnant patients because these levels are unaffected by the pregnant state. Pre-eclampsia is high on the differential of hypertension during pregnancy but may be distinguished from pheochromocytoma by the presence of proteinuria, oliguria, and thrombocytopenia in the third trimester (108). Ultrasound and magnetic resonance imaging are the preferred localization studies.

> Laparoscopic adrenalectomy is being performed with increasing frequency in nonpregnant patients and is considered by some as the preferred approach.

Successful treatment of pheochromocytomas requires a multidisciplinary approach including the obstetrician, endocrinologist, anesthesiologist, and surgeon. Once the diagnosis is established, pharmacologic therapy should be started immediately. Alpha-adrenergic blockade with phenoxybenzamine is used to control hypertension and, if necessary, selective beta-blockade with metoprolol or atenolol is used to control tachycardia during pregnancy (103). Control of hypertension is vital in these patients because severe hypertension can result in uteroplacental insufficiency, early separation of the placenta, and fetal death. Phenoxybenzamine decreases the systemic peripheral vascular resistance and will allow for intravascular volume replacement before surgery. If diagnosed in the third trimester, removal of the tumor is delayed until after delivery if blood pressure can be controlled medically (100,109). To date, there have been four case reports of laparoscopic adrenalectomy for pheochromocytoma in the pregnant patient which were performed between 13 and 20 weeks gestation (99–101). General guidelines for laparoscopy during pregnancy were followed including dependent positioning without significant alterations in the standard technique used for nonpregnant patients. In each case, the mother delivered a healthy infant.

Splenectomy

Laparoscopic splenectomy has been shown to be advantageous when compared to open splenectomy and is comparable to open splenectomy in terms of safety and efficacy in nonpregnant patients (110).

> Laparoscopic splenectomy has been shown to be advantageous when compared to open splenectomy and is comparable to open splenectomy in terms of safety and efficacy in nonpregnant patients.

Some authors advocate laparoscopic splenectomy as the procedure of choice for hematological conditions in nonpregnant patients (111). Autoimmune thrombocytopenic purpura is the most common autoimmune disorder encountered in the pregnant patient (112). ITP appears during pregnancy with an incidence of 1–2 cases per 10,000 pregnancies (113). No consensus has been reached as to the management of ITP during pregnancy. Maternal IgG antibodies cross the placenta leading to thrombocytopenia in the fetus and increased maternal platelet counts in response to treatment may not reliably predict fetal platelet counts. Maternal ITP may lead to intracerebral hemorrhage in the fetus or cause the fetus to experience life-threatening bleeding during the normal trauma of delivery. While immunoglobulin therapy is considered safe in pregnancy, it is expensive and steroid therapy may increase the incidence of pregnancy-induced hypertension, gestational diabetes, and infection (114).

Splenectomy has become the recommended treatment option during pregnancy for patients who are unresponsive to medical therapy (112,115). As more experience is obtained with splenectomy during pregnancy for ITP, surgery may play a larger role in the future as has happened with other procedures during pregnancy. To date, there have been four reported cases of laparoscopic splenectomy during pregnancy. The indications for surgery were refractory hematological disorders including antiphospholipid syndrome, hereditary spherocytosis, and autoimmune thrombocytopenia purpura (113,114,116,117). All patients did well postoperatively and delivered healthy infants.

Ureterolithotomy

Urolithiasis complicates one of 1500 pregnancies. Although there are metabolic and anatomic alterations during pregnancy that might predispose the pregnant patient to increased stone formation, urinary stones occur at similar rates in pregnant and nonpregnant patients (118). The modern approach to urolithiasis in pregnancy is initially conservative medical management (rest, hydration, analgesia, and antiemetics), as 70% to 80% of pregnant patents with symptomatic calculi will pass their stones. Patients with colic refractory to medical treatment, sepsis, obstruction of a solitary kidney, or social and psychological reasons may require a more aggressive approach (119,120).

Invasive therapy usually involves either (1) cystoscopy and stent placement with or without stone manipulation, (2) ureteroscopy and stone manipulation, or (3) placement of a percutaneous nephrostomy tube (118). Open surgery, while rarely indicated, is a viable alternative in selected patients. Premature delivery rates have been reported in 6.5%, 8.6%, and 11.9% of patients during the first, second, and third trimester, respectively (120). Extracorporeal shock wave lithotripsy and percutanteous nephrolithotomy are contraindicated in pregnancy.

Laparoscopic ureterolithotomy is considered a safe and reliable salvage intervention in nonpregnant patients using either a transperitoneal or retroperitoncoscopic approach (121,122). To date, there are no reports of laparoscopic ureterolithotomy during pregnancy.

Nephrectomy

The frequency of laparoscopic transperitoneal or retroperitoncoscopic nephrectomy for various diseases in nonpregnant patients has been increasing since its first report in 1991 (121). Although there are no reported cases of laparoscopic nephrectomy during pregnancy, it is possible that as experience with laparoscopy during pregnancy increases this may become a reasonable option.

COMMON GYNECOLOGIC LAPAROSCOPIC PROCEDURES

Adnexal Mass and Adnexal Torsion

The incidence of adnexal masses during pregnancy is 2% (123). Adnexal torsion, which is more common during pregnancy, occurs in about one in 1800 pregnancies (34,124). Most adnexal masses discovered during the first trimester of pregnancy are functional cysts and resolve spontaneously by the second trimester (18). Persistent masses are most commonly functional cysts or mature cystic teratomas, with the incidence of malignancy reported at 2% to 6% (125). Presenting symptoms of adnexal torsion include an abrupt onset of severe pain lateralized to the right or left lower quadrant of the abdomen, which is commonly associated with nausea and vomiting. Many pathologic diseases of the ovary and/or fallopian tube cause abnormal enlargement, which increases the risk of adnexal torsion. Prolonged torsion of the adnexa may lead to infarction of the fallopian tube and ovary, which if left untreated may ultimately lead to peritonitis and death (72). Complications from adnexal masses such as torsion, rupture, and hemorrhage requiring emergency surgery have been reported to occur in as high as 28% of patients, leading to adverse pregnancy outcomes including spontaneous abortion and preterm delivery in as many as 40% (126).

The two most common management strategies of adnexal mass during pregnancy are operative extirpation of the mass or expectant management (72). Multiple authors recommend expectant management of adnexal masses ≤6 cm with 82% to 94% of these resolving spontaneously (127,128). The high incidence of adverse pregnancy outcomes associated with emergency surgery as well as malignant potential has led some authors to recommend elective removal of all masses that persist until 16 weeks and are >6 cm (125,126). Torsion usually occurs between the 6th and 14th weeks of gestation (129). Current conservative management of adnexal torsion involves unwinding the adnexa and assessing its viability. Only the gangrenous adnexa needs complete removal of the adnexa (130). When an ovarian cyst is present, a complete ovarian cystectomy should be performed for histologic diagnosis (131). If rupture and bleeding occur, laparoscopic cystectomy and coagulation of the base is appropriate in the hemodynamically stable patient (72).

> Laparoscopy has become the preferred approach for both the diagnosis and management of adnexal torsion.

Laparoscopy has become the preferred approach for both the diagnosis and management of adnexal torsion (132). Ten percent to 15% of adnexal masses undergo torsion, and if diagnosed before tissue necrosis, adnexal torsion may be managed laparoscopically with adnexal-sparing laparoscopic detorsion, followed by progesterone therapy if the corpus luteum is removed (133,134). Laparotomy with salpingo-oophorectomy is required for necrosis and peritonitis (88). Previous case reports have demonstrated the safety of laparoscopic surgery performed during pregnancy for the management of adnexal torsion and adnexal mass with good outcomes for both the mother or fetus (131,135–140). Finally, a recent retrospective review, which included 88 pregnant women, examined the maternal and fetal outcomes following laparoscopy versus laparotomy for adnexal pathology in the first two trimesters of pregnancy and found no statistically significant increase in the rate of miscarriages, neonatal malformations, or preterm births between the two groups (17).

RECOMMENDATIONS

More information has accumulated recently as laparoscopy has become more common during pregnancy. However, most of the data is found in case series and retrospective reviews, which limits the ability to provide absolute guidelines. Further controlled clinical studies are needed to clarify these guidelines, and revision may be necessary as new data appear. The current recommendations for laparoscopy during surgery are summarized in the following:

- Operative intervention may be performed in any trimester if warranted by the patient's condition.
- Pneumatic compression devices should be utilized.
- Fetal heart tones should be monitored pre- and postoperatively.
- Lead shielding and brief shots of fluoroscopy may be used judiciously.
- Either the Hasson or Verres technique may be used for initial abdominal cannulation depending on surgeon preference and level of comfort with each technique.
- Dependent positioning should be utilized to shift the uterus off of the inferior vena cava and the aorta.
- Pneumoperitoneum pressure should be kept between 10 and 15 mmHg.
- Obstetrics consultation should be obtained preoperatively.
- Maternal end tidal CO_2 should be maintained between 30 and 40 mmHg.
- Tocolytics should be used for perceived or documented uterine contractions.

SUMMARY

- Laparoscopy is being performed with increasing frequency during pregnancy for both obstetric and nonobstetric indications.
- While pregnancy was once considered an absolute contraindication to laparoscopy, numerous reports have demonstrated that laparoscopy may be performed safely in all trimesters of pregnancy without increased maternal or fetal morbidity or mortality.
- As laparoscopic techniques and instrumentation improve, it is likely that additional indications for laparoscopic surgery in the gravid patient will be identified.

INTRODUCTION AND BACKGROUND

The primary goal in care of the injured patient is to quickly control hemorrhage; thus the role of laparoscopy has traditionally been limited. However, as laparoscopic surgical skills and equipment have improved, laparoscopy and thoracoscopy have increasingly been used for diagnostic and therapeutic purposes in hemodynamically stable trauma patients.

The role of laparoscopy in trauma was first described in the 1920s for its ability to identify hemoperitoneum (1). In the United States, Gazzangia in 1976 described the first series of trauma patients with either blunt or penetrating trauma, where laparoscopy was used for diagnosis (2). Laparoscopy has gained favor in many trauma centers due to decreased morbidity, pain, and potential complications associated with major operative wounds seen in standard laparotomy and thoracotomy incisions. At the same time, other minimally invasive techniques have been increasingly used in trauma, including observation with selective nonoperative management and the use of angiography.

Although laparoscopy has become the standard treatment for some general surgical operations (e.g., cholecystectomy), more traditional approaches such as computed tomography scanning, ultrasound, diagnostic peritoneal lavage, observation, and laparotomy remain as the standard of care in trauma. Yet, it is recognized that when laparotomy is used for diagnosis traditionally the negative or nontherapeutic laparotomy rates have been relatively high, ranging between 12% and 40%. Furthermore, the potential complications associated with negative laparotomies makes laparoscopy a desirable alternative. In addition, laparoscopy provides the potential ability to diagnose injuries missed as compared to use of imaging studies alone. Laparoscopy must be weighed against these approaches in deciding its appropriateness in the management of a given patient. Specifically, laparoscopy offers good visualization of the anterior and lateral abdominal walls but is more limited in its ability to visualize the retroperitoneal structures.

When laparoscopy was utilized either for diagnostic or therapeutic purposes, a decreased rate of negative laparotomies was clearly seen, as well as an overall decreased length of hospital stay.

Conversely, laparoscopy entails some additional patient risks over nonoperative options. Specifically, there is exposure to anesthesia and the possibility of creating a carbon dioxide pneumothorax (when a diaphragmatic injury is present), visceral or diaphragmatic injury, increased intracranial pressure, and potential hernia formation. In addition, there are costs associated with laparoscopy which would not be present if observation alone was employed.

Table 1 reviews the findings of eight studies of laparoscopy in trauma conducted between 1991 and 2003.

Eight studies examined the potential laparoscopic benefits in 1193 patients (Table 1) with abdominal trauma. When the goal was diagnostic alone, laparoscopy was successful in 53% to 81% of the cases. Laparoscopy was used therapeutically in 0% to 13% (19–47% of the cases were converted to laparotomy).

Currently, the role of laparoscopy in trauma is strictly limited to hemodynamically stable patients.

Hemodynamically unstable patients require a streamlined, rapid approach in obtaining a diagnosis and providing treatment. As such, any delay (e.g., time necessary to perform a laparoscopic procedure) can potentially compromise patient care and is inappropriate.

The operating room has traditionally served as the forum for performing laparoscopic procedures. With the advent of smaller cameras that fit through a single Veress needle after insufflation, such procedures are also being performed in some emergency departments. The ability to safely perform laparoscopy in the emergency department on a stable patient by providing sedation and local anesthesia has the advantage of definitively ruling out intra-abdominal injuries. Combining such results with other diagnostic findings can potentially allow a patient to be discharged from the emergency department rather than be admitted for observation (a potential in saving costs to the patient and the hospital). However, as computed tomography scanning and ultrasound techniques have improved, the interest in this has waned.

PENETRATING INJURIES

Laparoscopy plays an important role in penetrating injury (2,4,7,9,11–22). In the absence of such findings, hospitalization may be unnecessary.

> Specifically, in patients who sustain thoracoabdominal wounds, diagnostic methods such as peritoneal lavage, ultrasonography, and computed tomography scan are not as accurate, nor as helpful as laparoscopy in ruling out penetrations, allow. Laparoscopy for visual inspection of the diaphragm, evaluation of hepatic and splenic lacerations, and even identification of pericardium for possible hemopericardium, as well as anterior abdominal wall injury evaluation.

Specifically, in patients who sustain thoracoabdominal wounds, diagnostic methods such as peritoneal lavage, ultrasonography, and computed tomography scan are not as accurate nor as helpful as laparoscopy in ruling out penetrations, allow. Laparoscopy for visual inspection of the diaphragm, evaluation of hepatic and splenic lacerations, and even identification of pericardium for possible hemopericardium, as well as anterior abdominal wall injury evaluation (7,11–13,24).

Laparoscopy is helpful in the tangential gunshot wound, where there is a concern for intra-abdominal injury. Should peritoneal penetration be ruled out via direct visualization utilizing this technique, further hospitalization of such patient is unnecessary. Laparoscopic management of selected abdominal gunshot wounds can be accomplished without morbidity (7,12,13,16–18,25). Such benefit extends to selected patients with missile wounds of uncertain trajectory through the peritoneal cavity. Zantut et al. reported that 58% (113 of 194) of stable patients with gunshot wounds, who were evaluated with laparoscopy, were discharged home with confidence after a brief hospital stay without the need for laparotomy (9).

> Laparoscopic management of penetrating chest injuries has also been described.

Laparoscopic management of penetrating chest injuries has also been described. Laparoscopic evaluation of 110 patients with a penetrating wound to the left lower chest was described by Murray et al. in 1997. Importantly, all the patients were hemodynamically stable and without other indications for a celiotomy. Overall, 24% of the patients sustained a diaphragmatic injury (26). Spann et al. found in 31% of the patients, where a hemo- or pneumothorax was identified on chest X-ray, a diaphragmatic injury was later identified by laparoscopy. Some of these injuries were repaired laparoscop-ically, and others were repaired after conversion to celiotomy (27).

Diaphragmatic injury from penetrating trauma has also been evaluated utilizing thoracoscopy. Ochsner et al. and Uribe et al. found 9 out of 14 (64%) and 9 out of 28 (32%), respectively, of their patients with penetrating thoracoabdominal injury to have a diaphragm injury. In all of the above described patients, thoracoscopy was deemed to be a safe procedure (27–29).

> A debate exists as to the preferred mode of approaching diaphragmatic injuries.

A debate exists as to the preferred mode of approaching diaphragmatic injuries.

Proponents of laparoscopy argue that the incidence of associated abdominal injuries for penetrating thoracoabdominal injuries is significant enough to warrant an evaluation of the diaphragm and the peritoneal cavity simultaneously. Furthermore, the utilization of double lumen intubations, which carries its own risks, is avoided. Those who favor thoracoscopy argue that this technique avoids insufflation pressures utilized with laparoscopy, which are associated with pneumothorax and hemodynamic changes. It is also argued that this technique is able to avoid violation of the peritoneal cavity in patients who do not have a diaphragmatic injury. Guth and Pachter evaluated 70 patients with penetrating abdominal or lower chest injuries with laparoscopy, yet found two patients who subsequently underwent thorocotomy, suggesting that when laparoscopy is utilized primarily, significant intrathoracic injuries may be missed (30).

Different techniques for laparoscopic evaluation of the peritoneum are described, one such approach includes initially placing a 5 mm scope 4 cm above the umbilicus (port 1). Two additional 5 mm ports are placed, one in the suprapubic region (port 2) and a second in the region of the midline (port 3). The peritoneal cavity is inspected for blood or bile. Upon completion, the scope is moved to port 2. Utilizing atraumatic bowel graspers, the bowel is "run" from the ligament of Treitz to the ilium (9). Importantly, a missed bowel injury including perforation is a potential fatal complication. So, laparotomy must be performed in patients where any doubt of injury remains (22,23).

BLUNT TRAUMA

> Computed tomography scan is the mode of choice in evaluating the hemodynamically stable patient with blunt trauma.

Computed tomography scan is the mode of choice in evaluating the hemodynamically stable patient with blunt trauma.

Certain circumstances have been described in which computed tomography scan results cannot completely rule out abdominal organ injury. For example, patients with pelvic fractures or retroperitoneal hematomas, who already have abdominal tenderness (thereby limiting clinical evaluation), are at increased risk for missed blunt hollow organ injury. Similarly, such occult findings may also exist in patients who suffer head or spinal cord injury. Although diagnostic peritoneal lavage, ultrasound, or repeat computed tomography scan may detect the injury, early laparoscopy establishes the diagnosis, thus allowing for earlier definitive treatment.

> Some urologic injuries can be diagnosed and treated laparoscopically. In patients with blunt trauma to the abdomen consisting of an isolated bladder injury, one can laparoscopically evaluate the bladder and repair the injury with intracorporeal suturing techniques.

Some urologic injuries can be diagnosed and treated laparoscopically. In patients with blunt trauma to the abdomen consisting of an isolated bladder injury, one can laparoscopically evaluate the bladder and repair the injury with intracorporeal suturing techniques.

Furthermore, in a similar manner, patients with isolated ureteral injury can also be managed laparoscopically, usually with repair over a ureteral stent. When laparoscopy is used in the evaluation of gunshot wounds, any trajectory traveling close to the path of the ureter should be evaluated and explored laparoscopically to rule out injury. A final use of laparoscopy in urologic trauma is in performing planned laparoscopic nephrectomy for the management of the delayed atrophic traumatic kidney or for refractory renal hypertension secondary to renal arterial injury.

LAPAROSCOPIC ULTRASONOGRAPHY

Osamu Ukimura

Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute,
Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

GENERAL PRINCIPLES OF LAPAROSCOPIC ULTRASOUND

Laparoscopic ultrasonography has been integrated into advanced laparoscopic urological surgery in recent years. This technology was initially applied in gastrointestinal surgery during the early 1990s since dedicated high-resolution B-mode (gray-scale two-dimensional image) laparoscopic ultrasound probes became available (1). Laparoscopic ultrasonography can provide the laparoscopic surgeon with information that may be unobtainable by laparoscopy alone.

Inability to palpate tissues remains one inherent limitation of laparoscopic surgery; however, laparoscopic ultrasonography can compensate for the loss of tactile feedback in laparoscopic surgery by enabling the surgeon to "look" into tissues being operated upon.

Laparoscopic ultrasonography can identify and characterize lesions seen on preoperative imaging and may potentially discover new lesions not detected by preoperative imaging or intraoperative laparoscopic inspection. The essential advantage of laparoscopic ultrasonography is the visualization of tissues beyond the two-dimensional laparoscopic picture, thereby enhancing the information available to the surgeon (2). As such, laparoscopic ultrasonography may enhance intraoperative surgical decision making.

Laparoscopic ultrasonography has the potential to improve anatomic localization of tumor or pathologic lesion, to improve visualization of cancerous extension, to guide real-time needle biopsy or ablative therapy, and to optimize the extent of surgical resection regarding completeness of tumor excision and preservation of functional anatomy.

TECHNIQUE

Linear-array transducer with frequency of 5–10 MHz (typically 7.5 MHz) is employed for laparoscopic ultrasonography. Laparoscopic ultrasonography probe consists of transducers mounted on or near the tip of a slender shaft. The shaft is usually 10 mm in diameter and at least 15–20 cm in length, and is introduced into the peritoneal or retroperitoneal cavity by way of a 10 mm port.

The depth of ultrasound penetration with 7.5 MHz transducers is approximately 6–8 cm, which is commonly adequate for laparoscopic surgery, because laparoscopic ultrasonography scanning is performed directly on the surface of the target organ or lesion (contact scanning). Laparoscopic ultrasonography can detect small lesions such as stones as small as 1 mm, cysts as small as 2 mm, and tumors as small as 3 mm with reliable accuracy (3).

Margin notes:

Inability to palpate tissues remains one inherent limitation of laparoscopic surgery; however, laparoscopic ultrasonography can compensate for the loss of tactile feedback by enabling the surgeon to "look" into tissues being operated upon.

Laparoscopic ultrasonography has the potential to improve anatomic localization of tumor or pathologic lesion, to improve visualization of cancerous extension, to guide real-time needle biopsy or ablative therapy, and to optimize the extent of surgical resection regarding completeness of tumor excision and preservation of functional anatomy.

The depth of ultrasound penetration with 7.5 MHz transducers is approximately 6–8 cm, which is commonly adequate for laparoscopic surgery, because laparoscopic ultrasonography scanning is performed directly on the surface of the target organ or lesion (contact scanning). Laparoscopic ultrasonography can detect stones as small as 1 mm, cysts as small as 2 mm, and tumors as small as 3 mm with reliable accuracy.

There is sufficient moisture naturally to allow good acoustic contrast, although sterile saline or gel may be used as acoustic coupling medium, if necessary. A strictly rigid system often loses acoustic coupling because of its inability to maintain direct contact with the organ surface. Major limitations of laparoscopic ultrasonography are the facts that the probe entry is limited through the established laparoscopic port, and also that freedom of rigid-shaft movement is restricted. Because the rigid shaft is pivoting, the freedom of the scanning direction is limited, such that it is often difficult to maintain the probe in standard transverse and longitudinal orientations. An alternative, although suboptimal, approach to contact scanning using a nonflexible system is to fill the surgical cavity with fluid and scan through the fluid as an acoustic medium (stand-off scanning technique). The use of a flexible probe toward multiple directions is a more versatile approach and reduces the number of laparoscopic port sites and scanning time. Movement of the flexible portion of the probe is controlled by the operator using an external lever mechanism similar to that of a flexible endoscope. The ability to flex or extend the probe is of critical importance in maintaining contact with organs having curved surfaces such as the kidney.

> In practice, during contact scanning, three basic probe maneuver techniques are used: lateral (sliding), rotational (angulation), and withdrawal (advancement) techniques.

In practice, during contact scanning, three basic probe maneuver techniques are used: lateral (sliding), rotational (angulation), and withdrawal (advancement) techniques (4).

In lateral movement technique, the probe shaft slides horizontally in contact with the surface of the target while the probe-to-surface geometry is maintained. In rotational technique, the probe shaft in the port is rotated (clockwise or counterclockwise). In withdrawal technique, the transducer surface is maintained in the same direction while the probe shaft is manipulated longitudinally using an advancement–withdrawal maneuver. Occasionally, combinations of these two or three scanning maneuvers are performed simultaneously. Using a combination of these techniques, the complete laparoscopic ultrasonography examination of, for example, the kidney takes less than 10 minutes. Although the learning curve for laparoscopic ultrasonography has been speculated to be between 20 and 50 procedures (5), the author believes that with the acquisition of basic ultrasound principles and a good knowledge of surgical anatomy, laparoscopic ultrasonography can be a straightforward procedure for many urologists. Working with an experienced partner or collaboration with the radiologist may accelerate the learning curve for urologists interested in laparoscopic ultrasonography. Laparoscopic ultrasonography can be performed at any time during laparoscopic surgery, most frequently, early during the course of surgery. Because laparoscopic ultrasonography can provide information regarding adequacy of tumor extirpation, it is recommended to keep the laparoscopic ultrasonography equipment available and the probe sterile until the end of the procedure so that laparoscopic ultrasonography scanning can be repeated whenever indicated. Picture-in-picture capability displays the laparoscopic ultrasonography image on the same screen as the laparoscopic image; the laparoscopic ultrasonography echo image is usually shown in the corner of the screen. This capability has eliminated the need of a separate screen for the ultrasound image, reducing surgeon strain and minimizing operating room equipment (2).

DOPPLER ULTRASOUND

> Doppler ultrasound facilities allow identification of vessel anatomy and characterization of blood supply of and within the lesion. Spectral-wave-form analysis has capabilities to distinguish between arterial and venous flow, and to measure velocity as well as resistive index.

Doppler ultrasound facilities allow identification of vessel anatomy and characterization of blood supply of and within the lesion. Spectral-wave-form analysis has capabilities to distinguish between arterial and venous flow, and to measure velocity as well as resistive index.

Current laparoscopic ultrasonography probes can use B-mode and Doppler (color Doppler and/or power Doppler with spectral Doppler flow analysis) functions simultaneously.

In color Doppler mode, movement of objects toward the probe typically is presented in red, while movement away from the probe is in blue.

> In color Doppler mode, it is useful to determine flow direction and velocity. The advantage of power Doppler function is that blood flow sensitivity is increased by a factor of three to five times in comparison with conventional color Doppler function. Power Doppler is much less angle dependent.

In color Doppler mode, it is useful to determine flow direction and velocity. The advantage of power Doppler function is that blood flow sensitivity is increased by a factor of three to five times in comparison with conventional color Doppler function. Power Doppler is much less angle dependent.

In power Doppler mode, the hue and brightness of the color signal represents the power in the Doppler signal, which is related to the number of red blood cells producing the Doppler shift. Power Doppler can visualize smaller vessels as well as slower flow vessels, achieving improved visualization of vascular borders and contours. The duplex imaging of both gray-scale and (color or power) Doppler allows one to distinguish between vascular and cystic structures.

Particularly, vascular involvement or extent of tumor thrombus within the vessels (especially renal hilum) can be delineated. Therefore, laparoscopic ultrasonography is capable of enhancing the accuracy of staging laparoscopy.

UROLOGIC UTILITY OF LAPAROSCOPIC ULTRASONOGRAPHY

Real-time visualization of blood flow will also provide significant physiologic and pathophysiologic information including tumor vascularity, lymph node involvement along vessels, and tumor resectability.

Adrenal Surgery

Recently several authors reported the utility of laparoscopic ultrasonography for surgical planning during laparoscopic adrenalectomy (6–12).

Critical anatomic information provided by laparoscopic ultrasonography for technical success of laparoscopic adrenalectomy includes demonstration of fat plane between the adrenal gland and the aorta, inferior vena cava, kidney, renal pedicle, pancreas, liver, and diaphragm; ruling out local invasion into adjacent organs; locoregional lymph adenopathy; exclusion of adrenal vein thrombus; and dimension of adrenal gland, extracapsular extension, or lack thereof.

Intraoperative laparoscopic ultrasonography screening of the area of interest entails slow advancement–withdrawal technique coinciding with slight rotational technique. To facilitate the ultrasound examination, saline irrigation can be added to the surgical field with the patient in the head-down position. Application of Doppler function is helpful in identifying the small vessels surrounding the adrenal gland, and maybe crucial in determining the distal extent of the adrenal and/or renal vein thrombus (12). Heniford et al. suggested that intraoperative laparoscopic ultrasonography effected a change in intraoperative technique in 68% of the 18 patients undergoing laparoscopic adrenalectomy, and that venous drainage of the adrenal organ could be delineated in all cases (6). Brunt et al., reporting in their experience with 28 patients, suggested that laparoscopic ultrasonography contributed to successful completion of the procedure in 11 of 28 cases (39%) and the adrenal vein was visualized in six cases (21%) (7).

Pautler et al. reported the use of laparoscopic ultrasonography during laparoscopic partial adrenalectomy in seven patients with a hereditary multifocal pheochromocytoma. Intraoperative laparoscopic ultrasonography differentiated normal adrenal parenchyma from the adrenal tumor mass, facilitating laparoscopic partial adrenalectomy (10). In select patients with significant concomitant intraperitoneal and retroperitoneal scarring from prior major abdominal or renal surgery, laparoscopic adrenalectomy assisted by laparoscopic ultrasonography can be performed by the transthoracic transdiaphragmatic approach (9). In addition, Hwang et al. reported that laparoscopic ultrasonography facilitated laparoscopic removal of paragangliomas in three of five cases, and not only assessed tumor margins but was also used to search for other potential retroperitoneal or adrenal masses not seen on preoperative imaging or laparoscopic inspection (12).

Renal Surgery

With growing experience, the repertoire of laparoscopic surgery for renal cell carcinoma has been cautiously expanded to select patients undergoing laparoscopic radical nephrectomy for locally invasive tumor, as well as for patients undergoing complex laparoscopic partial nephrectomy (13). Current experience has already confirmed the essential benefits of intraoperative laparoscopic ultrasonography during these difficult laparoscopic surgeries for renal cell carcinoma. Laparoscopic ultrasonography is now integral to our more technically advanced renal cancer cases.

Desai et al. reported their experience with laparoscopic radical nephrectomy in the presence of renal vein thrombus. Laparoscopic ultrasonography with color Doppler imaging was felt to be an essential intraoperative tool in patients suspected of having renal vein thrombus involvement, because it provides confident identification of the proximal extent of the tumor thrombus (14).

With the placement of the laparoscopic ultrasonography probe directly on the vena cava and renal vein, tumor-bearing and tumor-free areas in the proximal renal vein could be easily identified, despite the lack of tactile sensation (14,15).

Laparoscopic ultrasonography with Doppler imaging showed the uninvolved proximal segment of the renal vein with evidence of retrograde turbulent flow from the vena cava without any intraluminal mass, even after control of the renal artery.

In patients undergoing nephron-sparing surgery for tumor, intraoperative laparoscopic ultrasonography is used to precisely delineate tumor size, depth of intraparenchymal extension, distance from the collecting system, and to evaluate for any unsuspected satellite renal masses (16). Such information gives the surgeon an excellent three-dimensional concept about planning the line of parenchymal incision vis-à-vis the deep margin of the tumor.

A proposed line of parenchymal incision is scored circumferentially around the tumor under laparoscopic ultrasonography guidance, maintaining an adequate margin of normal parenchyma. Steinberg et al. reported their experience in three complicated cases involving kidneys with concomitant main renal artery disease, wherein laparoscopic ultrasonography contributed to precise localization of the renal artery stenosis, aneurysm, and stent, thereby preventing injury during hilar clamping (17).

Renal Ablative Techniques

New minimally invasive energy-based probe ablative technologies are currently being applied to nephron-sparing surgery. Laparoscopic ultrasonography is used for precise placement of the ablative needle probe and real-time monitoring of cryoablation or other ablative procedures for the small renal tumor.

Cryoablation remains the most well-studied ablation alternative, especially laparoscopically (18–22). The first percutaneous application of cryosurgery for two patients with renal tumor was reported by Uchida et al. in 1995 (23).

Intraoperative ultrasound provides excellent real-time visualization of the edge of the evolving ice ball, which itself is anechoic. This leading edge is clearly identified as a hyperechoic rim at the interface between frozen and unfrozen normal renal tissue.

The use of end-fire laparoscopic ultrasonography probe has been reported to guide renal cryoablation (24); however, because the deepest margin of the mass is most at risk for incomplete freezing, use of a flexible side-fire laparoscopic ultrasonography probe positioned on the renal surface opposite to the tumor is preferable (25).

By contact scanning from the renal surface opposite to the tumor, the deepest margin of the tumor is visualized; real-time visualization of obliteration of the deep margin of the tumor by the enlarging hyperechoic rim of the growing ice ball is one of the intraoperative parameters determining adequacy of cryoablation.

Chosy et al. (26) reported that complete renal tissue ablation occurred at temperature around $-20°C$, and Baust et al. (27) showed that tissue destruction is achieved at 5–6 mm inside the edge of the advancing ice ball. Because injury of adjacent normal structures (such as the intestine, colon, pancreas renal hilum, and ureter) is a major concern, laparoscopic approach using real-time laparoscopic ultrasonography seems to be the safest approach for accurate targeting and reliable monitoring, with the advantage of surgically retracting organs and preventing incidental cryoinjury (22).

Gill et al. reported their experience with laparoscopic renal cryoablation in 56 patients for a mean tumor size of 2.3 cm. Over a follow-up of three years, average percent reduction in cryolesion size was 77% compared with the cryolesion size on postoperative day 1. No cryolesion could be identified in 38 patients at three years (19). Follow-up computed tomography-guided biopsy revealed persistent renal tumor in two patients, both of whom subsequently underwent uncomplicated laparoscopic radical nephrectomy, and who are currently alive with no evidence of disease. The longest and most rigorous clinical report of laparoscopic ultrasonography-assisted laparoscopic cryosurgery reported by Gill et al. has established the essential role of real-time laparoscopic ultrasonography monitoring during laparoscopic renal cryotherapy (19).

Radio-frequency ablation is being applied clinically in the treatment of small renal tumors (28–30). The radio-frequency ablation needle can be delivered percutaneously or laparoscopically, with progression of treatment being visualized under real-time ultrasonography. During ultrasound-guided radio-frequency ablation, the tumor surrounding the electrode becomes variably and irregularly hyperechoic, which usually resolves within minutes of initiating radio-frequency ablation; these ultrasonographically visible changes are thought to be due to microbubbles generated during tissue ablation.

It is essential to recognize that real-time ultrasound monitoring of the evolving radio lesion is unreliable and inaccurate.

It is necessary to investigate newer methods of real-time and in vivo monitoring of the spatial distribution of intraparenchymal patterns to achieve better monitoring of the evolving radio lesion. Varghese et al. reported that newer ultrasound thermal mapping technologies might fulfill this goal of temperature monitoring using a cross-corre-

lation algorithm applied to radiofrequency ultrasound echo signal data acquired at discrete intervals during heating (31).

High intensity–focused ultrasound for renal cell carcinoma is yet an experimental treatment modality. The first application of high intensity–focused ultrasound for four human renal tumors was reported by Vallancien et al. in the early 1990s (32,33). Vallencien et al. observed a hyperechoic spot with a back shadow, which appeared at the focal zone during high intensity–focused ultrasound insonation and which disappeared within a few minutes thereafter. The increased echogenicity of the insonated tissue may be related to a cavitation effect, which generates highly echogenic gas bubbles in the tissue. However, the appearance of such a hyperechoic spot does not guarantee adequate treatment. Accuracy of percutaneous high intensity–focused ultrasound effect may be limited by interference with the rib and by respiratory movement.

Variations in the extent of renal tissue damage, unpredictable complication of skin damage, and difficulty in assessing adequacy of treatment have prevented the wider spread use of percutaneous high intensity–focused ultrasound for kidney cancers compared to transrectal high intensity–focused ultrasound for the prostate (34).

Recently Paterson et al. developed and tested in the minipig model a laparoscopic probe that allows real-time ultrasound imaging during partial renal ablation using high intensity–focused ultrasound (35). This laparoscopic probe provides ultrasound imaging and energy delivery through the same probe. Thus, high intensity–focused ultrasound energy can be applied with direct contact on to the exterior surface of the kidney tumor under laparoscopy.

Renal Cyst Surgery

Although percutaneous aspiration of renal cyst is diagnostic and may be therapeutic, unfortunately cysts typically recur. Laparoscopic decortication of the rare renal cyst that is symptomatically an effective minimally invasive alternative to percutaneous aspiration or open surgery.

Laparoscopic ultrasonography may be helpful for laparoscopic localization and drainage of difficult renal cysts (36–39).

Brown et al. employed laparoscopic ultrasonography in 21 patients with symptomatic renal cysts, allowing intraoperative identification of previously undetectable renal cysts (37). Elashry et al. reported their experience in two patients who underwent five laparoscopic ultrasonography-guided cyst marsupializations, suggesting that 10 MHz Color Doppler imaging contributed to discrimination of peripelvic cyst anatomic vasculature, permitting safe decortication of cysts adjacent to hilar vessels (38). This technique may also be helpful in patients with polycystic kidneys. Lee et al., in their recent reporting of their seven-year experience with laparoscopic cyst decortication for autosomal dominant polycystic disease patients with debilitating pain, opined that extensive laparoscopic cyst decortication can provide durable relief, improvement in blood pressure, and preservation or stabilization of renal function (39).

Lymphocele Surgery

Definitive management of the symptomatic lymphocele, following renal transplantation or pelvic lymph node dissection for prostate cancer, consists of surgical deroofing (marsupialization) and intraperitoneal drainage of the lymphocele. Percutaneous drainage and sclerotherapy is a suboptimal treatment because of high-recurrence rates and risk of infection. Laparosopic lymphocelectomy is an excellent alternative to the conventional open surgical approach, and is considered to be the primary treatment of choice today (40,41).

By providing intraoperative real-time information, laproscopic ultrasound precisely guides the surgeon in selecting the safest location for initial laparoscopic entry into the lymphocele cavity, which is the most important step in this surgery.

To reduce the risk of complication, the use of laparoscopic (or intraoperative percutaneous) ultrasound is an essential adjunct, especially in the more complex, difficult-to-identify lympocele (small; deep within the pelvis; and posterior, caudal, or medial to a renal allograft). ultrasound precisely localizes the lymphocele cavity and identifies its proximity to vital structures such as the iliac vessels, allograft, bowel, native ureters, and bladder (41–44).

Stone Surgery

Most urinary stones are now treated by endourologic techniques and shock wave lithotripsy. However, occasionally, in the select patient with a combination of unique anatomical location, laparoscopic surgery may be indicated. Van Cangh et al. initially

---

Marginal notes:

Variations in the extent of renal tissue damage, unpredictable complication of skin damage, and difficulty in assessing adequacy of treatment have prevented the wider spread use of percutaneous high intensity–focused ultrasound for kidney cancers compared to transrectal high intensity–focused ultrasound for the prostate.

Laparoscopic ultrasonography may be helpful for laparoscopic localization and drainage of difficult renal cysts.

By providing intraoperative real-time information, laproscopic ultrasound precisely guides the surgeon in selecting the safest location for initial laparoscopic entry into the lymphocele cavity, which is the most important step in this surgery.

reported the technique of laparoscopic nephrolithotomy in a patient with a 2 cm renal calculus who had previously failed extracorporeal shock wave lithotripsy and whose anteriorly located stone-baring calyx precluded percutaneous extraction (45).

Laparoscopic approach assisted by laparoscopic ultrasonography with color Doppler function facilitated accurate localization of the calculus and optimal selection of a relatively thin, avascular site for the nephrotomy, allowing complete stone fragment clearance.

Miller et al. reported laparoscopic approach for symptomatic caliceal diverticula with thin overlying renal parenchyma, or for anterior lesions inaccessible to endourological techniques (46). Laparoscopic ultrasonography was a crucial adjunct for stone localization, particularly when parenchyma was not thinned or the precise diverticular cavity site was not readily apparent. Laparoscopic ultrasonography may also aid in locating stones within the renal pelvis during laparoscopic nephro/pyelolithotomy (47). Gill et al. reported combining flexible laparoscopic nephroscopy and flexible laparoscopic ultrasonography to identify calyceal calculi during laparoscopic ureterocalicostomy (48).

Retroperitoneal Space (Ureterolysis and Lymphadenectomy)

In fibrous retroperitoneal tissue after surgery, chemotherapy, or primary retroperitoneal fibrosis, laparoscopic identification of the ureter and the great vessels is sometimes difficult due to the scar formation with loss of normal anatomical landmarks. Trombetta et al. utilized a 7.5 MHz semiflexible laparoscopic Doppler ultrasound probe to identify the ureters adherent to the iliac vessels during a case of ureterolysis for retroperitoneal fibrosis, as well as the location of the renal vein, aorta, and mesenteric artery during retroperitoneal lymphadenectomy in a patient with testicular cancer (49). Laparoscopic ultrasonography can visualize and characterize tissues or lesions beyond these identified by laparoscopic examination, thus extending the repertoire of minimally invasive surgery.

Prostate Surgery

During laparoscopic radical prostatectomy, precise intraoperative identification of the neurovascular bundle, the prostate apex, and location of cancer nodule may potentially enhance postoperative functional outcomes and surgical margin status. Transrectal ultrasonography is currently one of the most precise imaging modalities for the prostate. Ukimura and Gill investigated the technical feasibility and utility of intraoperative real-time transrectal ultrasonography guidance during laparoscopic radical prostatectomy (50–52). The potential advantages of real-time transrectal ultrasonography guided laparoscopic radical prostatectomy were noted to be as follows: (i) visualization of the anatomical course of neurovascular bundle with special reference to its dimension and distance from the edge of the prostate, (ii) objective measurement of the physical adequacy of neurovascular bundle preservation during laparoscopic radical prostatectomy, in terms of preoperative and postoperative dimensions of the neurovascular bundle, number of visible vessels, and resistive index of the arterial flow within the neurovascular bundle, (iii) accurate identification of the prostate apex, (iv) provision for precise dissection of posterior bladder neck, vas deferens, and seminal vesicle, and safe release of the rectal wall, and (v) identification of the location of any hypoechoic nodule with or without suspicious extraprostatic extension in an attempt to decrease positive surgical margins (50–52).

PROSPECTS AND LIMITATIONS FOR LAPAROSCOPIC ULTRASONOGRAPHY AND NEW TECHNOLOGY

The most common applications of laparoscopic ultrasonography have been for hepatobiliary, pancreatic, gastrointestinal, and gynecological surgery. Several authors have reported that laparoscopic ultrasonography has the potential to enhance laparoscopic detection of intraabdominal metastasis and multifocal tumors in patients with gastroesophageal, liver, or pancreatic tumors (53–58). However, laparoscopic ultrasonography is sensitive in detecting macroscopic but not microscopic metastatic pelvic lymph nodes in patients with cervical carcinoma (59).

The recent availability of three-dimensional ultrasonography is an exciting arena for future investigation. Future aspects include the use of navigated three-dimensional laparoscopic ultrasonography in computerized simulation tools for multiple applicators, use of ultrasound energy for reliable tumor destruction, the possibility of highly precise monitoring of the therapeutic ablation while avoiding unnecessary sacrifice of adjacent blood vessels or collecting system (60).

Novel ultrasound technologies including the four-dimensional (dynamic three-dimensional, i.e., three-dimensional plus time) ultrasound imaging system, and the

ultrasound and computed tomography fusion system technology (real-time virtual sonography, providing real-time ultrasound image along with synchronized computed tomography/magnetic resonance imaging) (61) have been reported. These modalities are likely to enhance real-time guidance during tissue ablative therapy. Finally, laparoscopic ultrasonography tissue elastography imaging may help to compensate the laparoscopic surgeon's inability to palpate tissue, which has remained a significant limitation of laparoscopic surgery.

SUMMARY

- ■ Reliable and reproducible real-time intraoperative visualization, without radiation exposure, is a definitive advantage of laparoscopic ultrasonography.
- ■ There is evidence that laparoscopy in combination with laparoscopic ultrasonography results in better outcomes in laparoscopic surgeries such as nephron-sparing surgery, adrenalectomy, decortication of symptomatic renal cysts, marsupilization of difficult pelvic lymphoceles, or renal stone surgery.
- ■ With increasing experiences in minimally invasive, ablative, functional-sparing, or reconstructive procedures, the role of intraoperative ultrasound is likely to expand.

FINANCIAL ASPECTS OF UROLOGIC LAPAROSCOPY

Yair Lotan and Jeffrey A. Cadeddu
Department of Urology, University of Texas Southwestern Medical Center, Dallas, Texas, U.S.A.

INTRODUCTION

The rise in national health-care costs has appropriately led to close scrutiny of the cost of new technologies. As the field of laparoscopy has matured, the focus is shifting from feasibility of techniques to utility and effectiveness. Along these lines, one aspect that is increasingly emphasized is the financial implications of laparoscopy. Prior to introduction of the technique, such issues as operative time and length of hospital stay did not play an important role in managing health-care costs. However, with the advent of laparoscopy, the decreased morbidity associated with laparoscopic techniques has highlighted cost advantages associated with decreased hospital stays. On the other hand, increased operative times and expensive equipment are noted as detrimental financial aspects.

This chapter is written to evaluate the various aspects of laparoscopy that impact health care-related costs and financial issues. There is no doubt that the safety and efficacy of a laparoscopic procedure is the most important determinant of whether a procedure should be performed. However, one cannot ignore the importance of cost in today's society and must recognize that responsible medical care requires physicians to consider the cost implications of various treatments. We will focus on costs associated with equipment, operative time, length of hospital stay, reimbursement rates, and both direct and indirect costs associated with laparoscopic surgery.

THE IMPORTANCE OF PERSPECTIVE

Any discussion of financial implications of laparoscopy must be examined from the perspective of the payer. However, in the U.S. health-care system, there are three "payer" perspectives: that of society, the hospital, and the patient. The perspective of the patient is the most difficult and subjective to evaluate as it depends on the patient's individual insurance, deductible level, and employment status.

The hospital's perspective usually includes most of the direct costs and is easier to measure. Furthermore, the patient perspective cost is directly related to this as the hospital cost is eventually charged to the patient. The hospital costs include the resources required to perform a procedure and immediate postoperative care. These, in addition to physician fees, represent the majority of costs from surgical procedures that do not include long-term postoperative care. Importantly, one should note that within each hospital system, the budget is divided into different departments. Savings garnered by decreased length of stay may decrease overall hospital cost, but may increase operating room supply costs (e.g., laparoscopy). Hospital administrations must, therefore, take a broader look at the financial implications of new technologies as they affect different cost centers in different ways.

The perspective of society involves both direct and indirect costs. As Medicare plays a large role in financing health care, a significant percentage of direct costs affect the overall national health-care budget. Society also is influenced by loss of productivity that results during the recovery phase of the postoperative period. These indirect costs can be difficult to measure, but can represent a significant loss of gross national revenue.

COST VS. CHARGE

It is difficult to evaluate the cost-effectiveness of a technique without comparing similar units of measurement. Many published evaluations use charge figures provided by the hospital system (1). These numbers are typically easier to obtain than cost figures, but do not reflect the true resource allocation as they account for profit margins. Different services in a hospital have different cost-to-charge ratios. Furthermore, rates for items, such as room and board, typically are determined based on the need to pay for both utilities, such as electricity and water, as well as services such as nurses' salaries. Also, as third party payer reimbursement of charges varies, what a hospital health-care system charges for laparoscopic surgery, gets paid, and actual costs can be very different. As such, when evaluating health system costs of a procedure or technology across a spectrum of hospitals and payers, actual costs, and not charges, must be reported.

Nevertheless, cost analyses of laparoscopic surgery can still be ambiguous. One issue is difficulty with the accurate assessment of the cost of capital equipment. Such items as a robot, laparoscopic ultrasound, camera, and televisions are usually paid from operating room capital budgets and amortized over many years. Depreciation costs and usage per case can only then be estimated. Conversely, costs of disposable equipment can be established with more accuracy but are still influenced by the vendor contract, which varies based on the volume of purchase.

Direct Costs

The three main components that determine the cost-effectiveness of laparoscopic procedures are laparoscopic equipment, operative time and length of hospital stay (2–8).

Equipment

A major difference in operative costs between open and laparoscopic surgery results from the added expense of specialized equipment. Equipment costs associated with laparoscopic surgery include capital and individual case costs. Items included in capital costs can have a relatively low per case cost, such as monitors, cameras, and CO_2 insufflators or can be expensive, such as the *da Vinci*® Surgical Robot.[a]

■ Capital equipment that is multipurpose (i.e., used for endoscopy—monitors and cameras) and is used by different specialties contributes minimal added expense on a per case basis.
■ On the other hand, the *da Vinci* robot, which costs over $1.4 million with a $100,000 yearly service contract, can add over $1000 per case even if utilized for 300 cases per year and amortized over seven years (7).

Such costs are not reimbursed to the hospital on a case basis and, in the case of the robot, can represent a significant financial burden.

The cost of operative equipment used during laparoscopic surgery can also vary significantly. Certain items such as trocars can be reusable or disposable while the decision about which hemostatic technology to use [e.g., Hem-O-Lok® clips[b] ($20) vs. an endoscopic stapler (Endo-GIA® at $144 or with reticulating load at $161) or endoscopic 5-mm clip applier[c] ($183)] can significantly influence the overall operative cost. For those performing hand-assisted laparoscopic procedures, a Gelport® Kit[d] comes with a 10-mm clip applier, 2- to 12-mm and 2- to 5-mm trocars, but costs $495. In specialized procedures, such as laparoscopic partial nephrectomy, the cheapest option to achieve hemostasis is suturing but this is technically difficult. Adjunct technologies such as

---

radiofrequency coagulation can add over $1000 per case in equipment cost (8). Furthermore, agents such as fibrin glue and FloSeal® Matrix^e can cost an additional $410 and $192, respectively (9).

One factor that will affect operative cost is the change in cost of laparoscopic equipment with time. Though one would expect equipment costs to decrease with time (analogous to the retail personal computer market), in evaluating costs from two major suppliers of generic laparoscopic equipment (trocars, clip-appliers, staplers, endocatch bags) from the year 2000 to 2004, we found an increase in prices across the board of greater than 4% annually for hospitals with high volume contracts, despite an increase in number of procedures performed nationwide. The increase was even greater for hospitals with lower volume. Unfortunately, there is also no incentive at this time for reducing the cost of robot-related products due to the lack of market competition.

Operative Times

Operative times play a large role in determining overall operative cost as most hospitals incur a start-up cost for a procedure with additional costs calculated at 15- or 30-minute intervals.

> Operative times play a large role in determining overall operative cost as most hospitals incur a start-up cost for a procedure with additional costs calculated at 15- or 30-minute intervals.

The cost of anesthesia also increases at similar time intervals. As such, each additional hour in the operating room can range between $600 at our county hospital and $1400 at the local children's hospital (6,10). Since the learning curve for many laparoscopic procedures is reflected in the operative time, urologists at the start of their learning curves will incur significantly more costly procedures overall. The impact can be significant as learning curves vary widely by procedure. For hand-assisted laparoscopic nephrectomy, Patel et al. reported that their operative time decreased from over 275 to less than 175 minutes only after their first 40 cases (11). Even more discouraging, Guillonneau et al. performed laparoscopic radical prostatectomy in over four hours for the first 100 cases before reaching a rate just under three hours (174 minutes) (12). On the other hand, some claim shortened learning curves and operative times with use of robot-assisted technology. Ahlering et al. noted a learning curve of only 12 patients to reach four-hour proficiency for robot-assisted prostatectomy with the mean operating time subsequently decreasing to 3.45 hours (range 2.5–5.1) (13). Whether this is sufficient to overcome the costs of the robotic technology remains to be demonstrated (7).

Hospital Stay

> The main financial advantage for laparoscopy is the decreased hospital stay.

The main financial advantage for laparoscopy is the decreased hospital stay. Room and board costs per day at our institution are approximately $400 and charges are significantly higher. As such, the reduced number of inpatient hospital days and earlier return of diet allows for costs saving both in room and board and intravenous fluids and medication. Such savings can compensate for added expenses in the operating room and result in cost superiority of some procedures, such as laparoscopic partial, radical and donor nephrectomy (2,8,14). Other procedures can become cost-equivalent/superior depending on the surgeon's operative time and length of stay at the hospital (3,4,6).

Reimbursement Rates

There are two competing issues that affect urologists' income from surgical procedures: reimbursement rates and operative time. While the operative approach should not be affected by prospective income from a procedure and, in an ideal world, a urologist should be reimbursed for the work and effort provided, this is not the case. In general, Medicare reimbursement rates for urologic procedures have decreased over the last 10 years. The Medicare reimbursement rates in Texas over the last 10 years for radical retropubic prostatectomy and radical nephrectomy decreased $668 ($2262 vs. $1594) and $457 ($1700 vs. $1243), respectively (15). Fortunately, reimbursement for laparoscopy procedures, such as radical nephrectomy, prostatectomy, and pyeloplasty, has stayed stable (<$30 change) from 2001 to 2004. However, laparoscopic Medicare reimbursement rates, in 2004, are only slightly higher than open equivalent reimbursement rates for nephrectomy ($92), prostatectomy ($95), and pyeloplasty ($147).

> The net effect is a disincentive to perform laparoscopy due to the learning curve and increased operative times for many procedures.

The net effect is a disincentive to perform laparoscopy due to the learning curve and increased operative times for many procedures.

Literature reviews performed to compare operative times for common procedures uniformly demonstrate shorter times for open versus laparoscopic procedures.

Open surgery is shorter than laparoscopic pyeloplasty (168 minutes vs. 180 minutes) (4) and radical retropubic prostatectomy is on an average 40 minutes shorter than laparoscopic prostatectomy (160 minutes vs. 200 minutes) (7,12,16–19). Although nephrectomy times reported are similar between open and laparoscopic techniques among experienced laparoscopists (20) the (6,21–24) times are achieved only after the learning curve has been overcome. Urologists early in their learning curve have longer operative times. As such, the current reimbursement rates may not provide equal compensation for laparoscopic procedures on an hourly basis (15).

Indirect Costs

While the direct costs associated with laparoscopy are easiest to evaluate, the indirect cost advantages of laparoscopy should not be overlooked. Many patients who require urologic procedures are productive participants in the national economy. So, loss of global revenue due to loss of work impacts the entire health-care system. The earlier return to work that has been demonstrated for numerous laparoscopic procedures should not be overlooked. Dunn et al. reported a 4.5-week quicker return to normal activity for laparoscopic nephrectomy patients compared with a matched series of open nephrectomy patients (1). Buell et al. noted that patients after hand-assisted donor nephrectomy returned to work 25 days earlier than after open donor nephrectomy (29.1 days vs. 54.3 days; $p < 0.05$, respectively). Bhayani et al. found that time to complete convalescence was 30 days versus 47 days after laparoscopic radical prostatectomy and radical retropubic prostatectomy, respectively (25). Similar findings were found by Rassweiler et al. with a convalescence time of 27 days versus 52 days after laparoscopic radical prostatectomy and radical retropubic prostatectomy, respectively (19). As such, patients after laparoscopic procedures routinely return to work earlier and contribute to the national economy. According to the 2001 Census of Population and Housing from the United States Census Bureau, the average American worker earned approximately $141 per day in 2000 dollars. So, a 15-day difference in return to work has a value to society of $2115, which would clearly eliminate the incremental cost of most laparoscopic procedures.

CURRENT FINANCIAL STATE OF LAPAROSCOPIC PROCEDURES

As experience with laparoscopy has increased and operative times have improved, some laparoscopic procedures such as laparoscopic nephrectomy and partial nephrectomy have been shown to be cost superior despite higher equipment costs (2,8). On the other hand, procedures such as laparoscopic pyeloplasty, hand-assisted nephrectomy, donor nephrectomy, retroperitoneal lymph node dissection, and prostatectomy are more expensive but can reach cost-equivalence depending on a surgeon's individual operative time and length of hospital stay (3,4,6,7,26).

At this time, however, robot-assisted prostatectomy is significantly more costly than open surgery due to the cumulative added expense of robot purchase and maintenance, along with individual case equipment costs (7).

Currently, the most common urologic diseases to which laparoscopic techniques are applicable include kidney and prostate cancer. Understanding the economics of these procedures offers insight into the direction of laparoscopy as a whole.

LAPAROSCOPIC NEPHRECTOMY

While initial evaluations of laparoscopic nephrectomy found that the technique was more costly than open nephrectomy (1,27), we found that reductions in operative time and length of stay have allowed laparoscopic nephrectomy to be cost superior (Table 1) (2,14). Sensitivity analyses demonstrate that laparoscopic nephrectomy is cost superior with length of stay less than four days and operative time less than four hours (Fig. 1). Patients after laparoscopic nephrectomy are routinely discharged in less than four days (2,21,28,29) and operative times by experienced laparoscopists are invariably less than four hours (2,20–23). Short operative times can also compensate for increased equipment costs (Fig. 2).

As such, laparoscopic nephrectomy is a cost superior procedure when evaluating both direct and indirect costs.

Margin notes:

At this time, however, robot-assisted prostatectomy is significantly more costly than open surgery due to the cumulative added expense of robot purchase and maintenance, along with individual case equipment costs.

As such, laparoscopic nephrectomy is a cost superior procedure when evaluating both direct and indirect costs.

TABLE 1 ■ Cost Comparison of Open and Laparoscopic Nephrectomy

	Laparoscopic nephrectomy (mean ± SD)	Open nephrectomy (mean ± SD)	p value[a]
Anesthesiologist fees[b]	348 ± 64	335 ± 36	0.625

LAPAROSCOPIC PROSTATECTOMY

Radical prostatectomy is the most common therapy for patients with prostate cancer and accounts for approximately half of the $1.7 billion cost of prostate cancer treatment (30). In evaluating the cost of radical retropubic prostatectomy as compared to laparoscopic and robot-assisted prostatectomy, we found that radical retropubic prostatectomy was the least expensive approach with a cost advantage of $487 and $1726 over laparoscopic radical prostatectomy and robot-assisted prostatectomy, respectively (Table 2) (7). Even if the initial cost of purchasing a robot is excluded, the cost difference between radical retropubic prostatectomy and robot-assisted prostatectomy is $1155.

Cost center	RRP ($)	LRP ($)	RAP[a] ($)
Overall cost	5554	6041	7280
Operating room cost	2428	2876	2204
Equipment	75	533	1705
Surgeon professional fee	1594	1688	1688
Hospital room and board	988	514	474
Intravenous fluids/meds	150	78	72
Robot cost/case (purchase + maintenance)	NA	NA	857

[a]Robot purchase cost included.

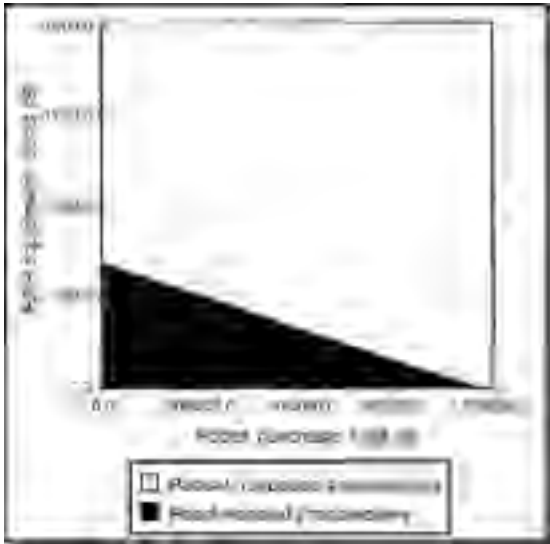

FIGURE 3 ■ Two-way sensitivity analysis evaluating costs of robot purchase and RAP (robot-assisted prostatectomy) equipment (assuming $100,000 per year maintenance cost). *Abbreviation*: RAP, Robot-Assisted Prostatectomy. *Source*: From Ref. 7.

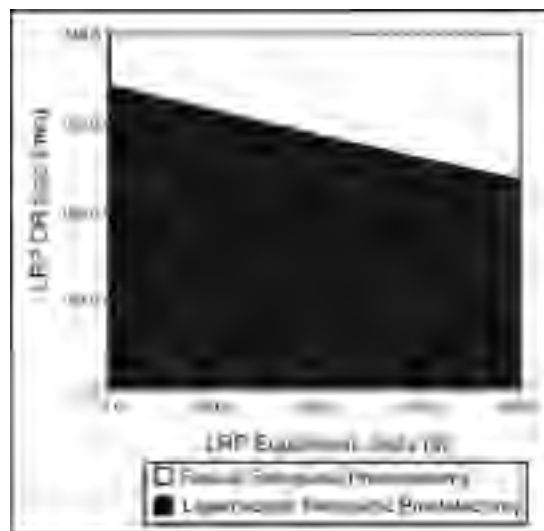
FIGURE 4 ■ Two-way sensitivity analysis evaluating laparoscopic radical prostatectomy length of stay and operating room time. *Source*: From Ref. 7.

This large difference in radical retropubic prostatectomy and robot-assisted prostatectomy costs resulted from a cost of $857 per case, to pay for purchase and maintenance of the robot, and the high cost of equipment of $1705. Even shorter operating room time (140 minutes vs. 160 minutes) and length of stay 1.2 days vs. 2.5 days) did not compensate for the added expenditure. At current costs for the robot (purchase, maintenance, and equipment) there is no individual decrease in length of stay or operating room time that would make robot-assisted prostatectomy cost-equivalent to radical retropubic prostatectomy. In order for robot-assisted prostatectomy to realistically become cost-equivalent or superior, there needs to be a decrease in both the purchase price of the robot and the cost of equipment per case (Fig. 3) (7).

Laparoscopic radical prostatectomy also costs more than radical retropubic prostatectomy primarily secondary to equipment costs ($533) as the shorter length of stay (1.3 days vs. 2.5 days) compensates for the longer operating room time (200 minutes vs. 160 minutes). However, decreases in both length of stay and operating room time for laparoscopic radical prostatectomy will allow cost equivalence with radical retropubic prostatectomy (Fig. 4). Similarly, small decreases in equipment costs in conjunction with shorter operating room times can make laparoscopic radical prostatectomy financially superior (Fig. 5). Thus, while radical retropubic prostatectomy is currently the least costly approach, laparoscopic radical prostatectomy is cost-competitive with radical retropubic prostatectomy, whereas robot-assisted prostatectomy will require a significant reduction in the cost of the device and maintenance fees to be financially justified.

FIGURE 5 ■ Two-way sensitivity analysis evaluating laparoscopic radical prostatectomy equipment costs and operating room time. *Source*: From Ref. 7.


SUMMARY

■ The cost of a procedure should always be a secondary factor in determining the best treatment for an individual patient.

■ However, with increasing national health-care costs, economic considerations are playing a greater role in medical care.

■ Institutions and insurance companies are closely supervising expenditures and do influence the types of treatments available to physicians and patients.

■ The development of drugs and new technologies by the health-care industry is also strongly driven by economic considerations.

■ In order for physicians to be able to continue to provide the best and least morbid treatment, there is a need to understand the economic implications of different treatment modalities and strive to practice with fiscal responsibility.

INTRODUCTION

Urologic laparoscopy has dramatically progressed over the past 10 years (1). To date, however, the large experiences exist mainly at academic centers.

> The true virtue of any medical technology is its ability to cross into the community setting. Only a portion of urologic disorders amenable to laparoscopic management are currently performed in this manner.

The true virtue of any medical technology is its ability to cross into the community setting. Only a portion of urologic disorders amenable to laparoscopic management are currently performed in this manner (2–4).

Despite the increase in urologic laparoscopy fellowship training programs and laparoscopy experience in residency training programs, the current patient demand exceeds the availability of this surgical approach (5,6). This chapter focuses on the feasibility and methods of developing a full-service urologic laparoscopy practice in a community setting. These concepts, based on the experience of a nonfellowship trained surgeon, are pertinent to both the inexperienced and the formally trained laparoscopist. Regardless of previous training, continuous development is essential to succeed in this demanding arena.

THE PRIVATE PRACTICE MODEL

Between August 1995 and April 2004, 1092 advanced urologic laparoscopic procedures were performed by a single surgeon in a metropolitan area serving a population greater than three million people. Although these procedures took place in eight different facilities, more than 75% occurred at the same 450-bed hospital in order to simplify reproducibility. Because the early 1990s marked the infancy of modern urologic laparoscopy, no formal training was readily available. However, previous exposure included involvement in approximately 20 pure laparoscopic nephrectomies and various other less demanding laparoscopic procedures during residency training. Although only a small number of procedures were performed in the first year, the volume subsequently grew exponentially as a member of a four-physician group. During the third year, further growth occurred after merging with a large group totaling thirty urologists. However, partner referrals have only comprised between 15% and 40% of total laparoscopic procedures performed annually. The low proportion of internal referrals reflects initial reluctance to embrace the technology, geographical logistics, increasing outside referrals, and improved laparoscopic skills of the other physicians within the group.

Extreme care was used to balance the difficulty of the procedure with the level of "expertise" at the time. The chief considerations were patient anatomy (e.g., body habitus, previous surgery), comorbid conditions, and complexity of the urologic condition. With time, the indications for laparoscopic management of common urologic disorders expanded widely. Table 1 depicts the variety of patient characteristics. With experience, seemingly challenging endeavors can be overcome. Although various types of

Largest renal tumor	14 cm
Extra/retroperitoneal	96%
Prostate size	18–166 g

With carefully planned strategies, advanced urologic laparoscopy in a community setting can yield results comparable to major academic centers. The importance of balancing the complexity of procedures with the experience of the surgeon cannot be overemphasized.

TABLE 2 ■ Procedure Types

Miscellaneous	128

nephrectomy comprise the majority of cases, nearly half of the procedures represent a laparoscopic approach to a multitude of other urologic disorders (Tables 2 and 3).

Pure laparoscopic techniques were employed routinely, with the exception of 12 hand-assisted procedures. Almost 90% of cases were retroperitoneal or extraperitoneal. This approach was a surgeon preference based on attempts to decrease operative time, decrease patient morbidity, and mimic open surgery (7,8).

PATIENT OUTCOME

With carefully planned strategies, advanced urologic laparoscopy in a community setting can yield results comparable to major academic centers (9). The importance of balancing the complexity of procedures with the experience of the surgeon cannot be overemphasized.

Operative time, an important factor in the private practice setting (10), has become very reasonable (Table 4). In many cases, the operative time matches that expected for the equivalent open procedure. As shown in Figure 1, procedure time decreases with experience. Hospital stay has averaged less than 1.2 days, ranging from the same day to 32 days. Even when including total hospital days for related readmissions, the average remains below 1.2 days. The fairly consistent next-day discharge is felt to be a result of the predominantly extraperitoneal or retroperitoneal approach.

A total of 12 open conversions occurred during 5 nephrectomies, 3 partial nephrectomies, 2 prostatectomies, and two pyeloplasties. This low conversion rate (1.1%) is the result of careful patient selection and attempts toward detailed reproducibility of all procedural steps. The failure to progress in accordance with standard surgical principles was the typical reason for conversion. Emergent conversion for bleeding was never required. A global complication rate of 7% as detailed in Table 5 is comparable to previously published series (11–15). As a result of careful case selection, this rate remained stable from year to year (Fig. 2). Neither of the two deaths was related directly to an intraoperative issue. One patient expired from an acute myocardial infarction on postoperative day three. The other death was a result of a multitude of comorbid conditions including near end-stage renal disease, malignant hypertension, and severe vascular disease.

Increased operative time for laparoscopic versus open procedures is a common criticism. The three positional complications were defined as any new musculoskeletal or sensorimotor complaint, separate from the operative sites, lasting greater than two weeks. All three eventually resolved. When including thrombotic events (5) and pneumonia (6), all possibly time-related complications comprise only 1.3% of the total number of patients. One patient with a postoperative urinoma underwent both a stent placement and a percutaneous drain placement, thereby

accounting for two of the seven returns to surgeries. Following failed laparoscopic pyeloplasty, one patient underwent laparoscopic nephrectomy, and three others were managed endoscopically. In addition, one patient required urethrorectal fistula repair following failed laparoscopic rectal repair during laparoscopic prostatectomy. One bowel injury required open conversion, but the others were managed laparoscopically. All patients with postoperative ileus or partial small bowel obstruction were managed nonoperatively.

As shown in Table 6, of the 459 patients with presumed renal cell carcinoma, 23 were actually benign and 19 were lost to follow-up. Overall disease-free survival is 96%. Of the 107 patients with greater than five-year follow-up, 91% are disease free. An additional 10 patients five years beyond surgery have not undergone radiographic imaging within the last 12 months. At least 6 of these 10 patients are known to be alive. These results are comparable to historical open and laparoscopic data (16–19).

Cancer control following nephroureterectomy and prostatectomy is also outlined in Table 6. Although a significant volume of long-term data has not yet accumulated, early outcome compares well with historical open data (20–22). Cancer control following nephrourcterectomy and prostatectomy is also outlined in Table 6. Although a significant volume of long-term data has not yet accumulated, early outcome compares well with historical open data (20-22). The overall prostatectomy positive margin rate was 13%, but this fell below 11% in the last 100 patients. Thus far, only three patients have a detectable prostate-specific antigen.

The pyeloplasty success rate is outlined in Table 7, Similar to other centers, success in this category is defined as resolution of symptoms and postdiuretic half-time clearance of less than 15 minutes during nuclear renogram beyond 6 months (23-25). Asymptomatic failures with improved drainage were followed expectantly. All other failures underwent subsequent corrective procedures.Functional outcomes following laparoscopic radical prostatectomy (Tables 8 and 9) compare favorably to previously reported open and laparoscopic data (26,27). Erectile function was defined as a sexual health inventory for men score (28) of at least 18. Patients less than 12 months following surgery with lower sexual health inventory for men scores were excluded from this data. In addition, patients with a preoperative sexual health inventory for men score less than 23 were also excluded. Of course, the data continue to mature. Due to excellent visualization and precise suture placement, patency rates following laparoscopic anastamoses are excellent. No bladder

neck contractures occurred following laparoscopic radical prostatectomy. All ureteroileal anastomoses and ureteroneocystostomies were successful.

Cost considerations are always difficult to assess. The hospital charges of two predominant procedures are evaluated in Table 10 for both open and laparoscopic methods at a single institution. Minimal difference exists between the two groups. When looking at previously reported data (29–31), a decreasing trend in cost for laparoscopic procedures makes the value-added benefits of this approach economically reasonable.

BUILDING A LAPAROSCOPIC PRACTICE

The average graduating urology resident is adept at performing most urologic procedures. Laparoscopy is the exception. Even a fellowship-trained laparoscopist should expect several years for their skills to mature. Fortunately, there are many ways to hasten the learning curve. The essential elements in achieving success are depicted in Figure 3.

Full-Time Commitment
Central to the process is a full-time commitment. This dedication need not be exclusive, but must be constant and unyielding. In other words, one can still practice general urology but still develop one's laparoscopic ability on a daily basis. Not surprisingly, each of the necessary elements is dependent upon the others.

Education
Education beyond formal training can be challenging. A busy practice and personal life leaves little extra time. Fortunately, many opportunities for learning urologic laparoscopy are available. In addition to traditional textbooks, an abundance of tips on the finer points of laparoscopy exists in the current peer-reviewed literature. With many of these sources available in electronic format, one can easily amass a library of references from the Internet.

Obviously, the best way to progress is to learn from the experience of others. Didactic lectures, live case observation, and videos are valuable methods. Although nothing duplicates the true operative experience, animate and inanimate labs are good options for developing specific technical aspects such as suturing (32–36). For the inexperienced laparoscopist, a preceptor or mentor should be mandatory prior to delving into any advanced case (37–39).

Videotaping procedures for future self-review or review by an experienced laparoscopist can be helpful, particularly when matched with patient outcome (40). In laparoscopy, past performance often predicts future returns.

Technique
As with any procedure, the setting can require a modification of the technique. In a private-practice setting, operative time can be more of a factor than in an academic institution. Willingness toward early open conversion for failure to progress will build

TABLE 7 ■ Pyeloplasty Success Rate

Abbreviation: ppd, pads per day.

Videotaping procedures for future self-review or review by an experienced laparoscopist can be helpful, particularly when matched with patient outcome. In laparoscopy, past performance often predicts future returns.

Specific technical modifications are often appropriate for the community urologist. For instance, in the absence of a motivated intern, the task of holding the camera is often best handled by the surgeon.

	Open	Laparoscopic
Prostatectomy	US $19,500	US $22,235
Radical nephrectomy	US $16,500	US $15,600

To a large degree, laparoscopy markets itself. However, one must take care to promote accurate expectations. Aggressive advertising and cash-only boutique practices imply near-perfect results. The best approach to marketing exists in the form of education. Sources for patients include a practice web site, brochures, prior patients, and community-targeted talks.

confidence in tackling more challenging procedures, thereby expanding the pool of potential laparoscopic cases.

Specific technical modifications are often appropriate for the community urologist. For instance, in the absence of a motivated intern, the task of holding the camera is often best handled by the surgeon.

In this series, the surgeon holds the camera greater than 50% and 90% of the operative time for radical prostatectomy and a retroperitoneal nephrectomy, respectively. This modification reduces both surgeon and assistant fatigue. In reality, with the exception of suturing, only one hand is usually used at a time for surgical maneuvers; the secondary hand usually holds a retractor, a task easily accomplished by the assistant. In any case, the multitude of steps involved in any procedure should be a collection of techniques used by others, molded into one's own style.

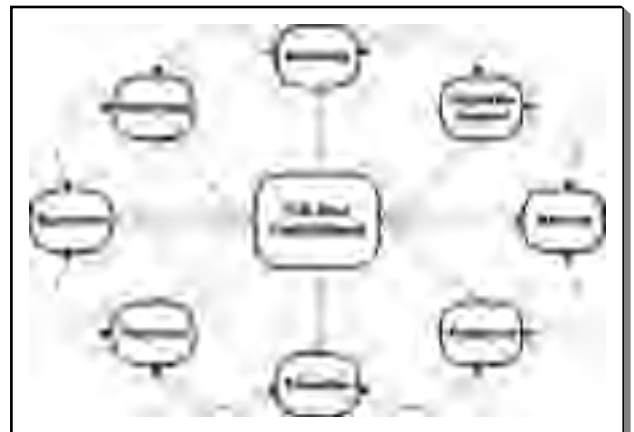
Equipment
Fortunately, laparoscopic equipment is readily available in any setting. The biggest problem is awareness. Companies that supply instrumentation often target their marketing efforts toward high volume institutions. Good sources of information include laparoscopic periodicals, trade shows, and Internet sites. However, the allure of the latest and greatest can be a double-edged sword. Although the right grasper could save 10 minutes off of a procedure, the best-engineered instrument will not replace proper technique. The most important equipment considerations revolve around multiuse, ergonomics, and patient safety, particularly early in one's experience.

Personnel
Every laparoscopic procedure is a team effort. The key personnel fulfill many functions beyond assisting the surgeon. Every aspect of success is dependent on the behind-the-scenes preparation, whether the day of the procedure or months prior. Input should be constantly recruited from everyone in the room. Key observations and modifications have been developed in this manner.

Corporate Support and Marketing
Corporate support is also a very important aspect in developing a laparoscopic practice. Equipment companies, hospitals, and one's own practice are great facilitators. This support comes in the form of training, educational materials, marketing opportunities, financial support, and patient referrals. An entire chapter could be dedicated to marketing a laparoscopic practice.

To a large degree, laparoscopy markets itself. However, one must take care to promote accurate expectations. Aggressive advertising and cash-only boutique practices imply near-perfect results. The best approach to marketing exists in the form of education. Sources for patients include a practice web site, brochures, prior patients, and community-targeted talks.

Of course, the best facilitators are hospital staff (particularly operating room staff), office staff, fellow physicians, and prior laparoscopic patients (and their family members). The smallest marketing opportunity can yield dividends in the future. As one's experience matures, data outcome analysis becomes the most valuable source of marketing material.

FIGURE 3 ■ Elements for building a laparoscopic practice.


Networking

Networking is a valuable tool for both education and marketing. The most important form of networking involves other laparoscopic surgeons, both within and outside the field of urology. Presentations at meetings and contributions to peer-reviewed literature help open this door. Of course, less formal networking opportunities exist almost on a daily basis. Friends, business associates, and community organizations are often interested in learning more about this fascinating field.

The proper balance among all of the essential elements in Figure 3 is the key ingredient for success. The aspiring urologic laparoscopist must balance complexity with ability, tools with technique, and technology with personnel. Most importantly, success will never be achieved if the demanding workload exceeds the enjoyment.

SUMMARY

- With carefully planned strategies and proper balance between the complexity of procedures and the experience of the surgeon, advanced urologic laparoscopy in a community setting can yield results comparable to major academic centers.
- A nonexclusive, but constant and unyielding full-time commitment is crucial to develop laparoscopic ability while practicing general urology.
- To develop specific technical aspects, didactic lectures, live case observation, videos, animate and inanimate labs are valuable methods. For the inexperienced laparoscopist, a preceptor or mentor should be mandatory prior to delving into any advanced case. Videotaping procedures for future self-review or review by an experienced laparoscopist can be helpful, particularly when matched with patient outcome.
- Specific technical modifications are often appropriate for the community urologist.
- Technical nuances of surgical equipment can be found in laparoscopic periodicals, trade shows, and Internet sites.
- Reliable teamwork can be achieved creating a laparoscopic team founded on mutual respect, which encourages the same personnel to be present for all laparoscopic cases.
- To a large degree, laparoscopy markets itself. However, one must take care to promote accurate expectations. The best approach to marketing exists in the form of education. Sources for patients include a practice web site, brochures, prior patients, and community-targeted talks. The smallest marketing opportunity can yield dividends in the future.
- Keys to successful laparoscopy in the community setting include the balance between complexity and ability, tools and technique, technology and personnel, and most importantly, workload and enjoyment.

LAPAROSCOPIC SURGERY: MEDICOLEGAL ASPECTS

Michael Perrotti, Peter J. Millock, and Michael E. Moran
Capital District Urologic Surgeons, Albany, New York, U.S.A.

INTRODUCTION

The medicolegal aspects of the burgeoning field of laparoscopic urologic surgery can be perceived as lagging behind the actual clinical applications. This should not come as any great surprise to those who have been at the forefront of laparoscopic urologic surgery. The rapidly changing nature of technology on the practice of urology is best seen in the application of laparoscopic techniques. Many aspects that have heretofore not been of significance are now increasingly apparent. For instance, the implications of training, skill acquisition, residency training and certification, the need for advanced postgraduate training, the learning curve for advanced laparoscopic surgery, robotic surgical interfaces, and our professional society's and association's guidelines or lack of them are now beginning to become important.

Laparoscopic complications are uniquely different in some aspects to their open counterpart. The complications themselves are directly proportional to the skill of the surgeon. These issues are essential to the understanding of the medicolegal aspects of laparoscopic urologic surgery and they must be mentioned with their attendant implications.

In New York State, these issues are further complicated by the Health Department's Memorandum, H-18, on June 12, 1992 because they outline the importance of making the patient aware of the "learning curve" and the right of a patient to know the surgeon's experience (1).

Every urologist interested in practicing laparoscopic surgery should be aware of these issues. In fact, the significance of the New York State's memo has begun to shift responsibility, liability, and litigation aspects to the detriment of the practitioner.

Absolute knowledge of the laparoscopic procedure, the patient's understanding, and current trends in urology are necessary. The perception that "minimally invasive surgery" means decreased risk should also be dispelled. Any disclosure of risks to the patient should be thoroughly documented in the medical record. As with any new procedure, the performance of a laparoscopic procedure early in a urologist's "learning curve" requires extensive counseling and impeccable documentation of disclosure to patients and their families.

Defining Negligence

When assuming the duty of care for another individual, one may be accused of breach of that duty. It is not surprising that a recent review indicated that urologists are not immune to such risk, and may be named the primary defendant in a medical malpractice lawsuit

> Laparoscopic complications are uniquely different in some aspects to their open counterpart. The complications themselves are directly proportional to the skill of the surgeon.

> In New York State, these issues are further complicated by the Health Department's Memorandum, H-18, on June 12, 1992 because they outline the importance of making the patient aware of the "learning curve" and the right of a patient to know the surgeon's experience.

in the course of their career (2). Kahan et al. reported 259 medical malpractice claims against urologists consecutively closed between the years of 1995 and 1999 and carried by the St. Paul Insurance Companies.

These investigators found that the greatest percentage of claims arose from the categories of inpatient, adult, and surgical procedures, and that endourological procedures resulted in the greatest incidence of surgical claims. This was in contrast to an earlier report in 1977, which had shown vasectomy to be the most common claim generating procedure (3).

A medical malpractice suit implies negligence on the part of the physician. In discussing negligence, it is essential to examine the concept of "duty of care" (4). Negligence is a tort, that is, a civil rather than a criminal wrong. To prove negligence, the plaintiff (claimant, injured patient) must prove three essential components of the tort, and these are: (i) the existence of a duty to care to the patient, (ii) a breach of that duty by failing to adhere to the standard of care for that treatment or procedure, and (iii) as a consequence of that breach the patient suffers damage or harm.

In the relationship between the surgeon and patient, the duty of care unquestionably exists. The reported legal decisions address whether someone other than the surgeon, i.e., the hospital where the surgery is performed also has a duty (5,6). In accepting this duty as a physician, one accepts to take measures to avoid acts or omissions that one can foresee would be likely to injure one's patient. The importance of duty of care in the introduction of emerging technological advances to clinical practice is evident. This is made more complex by lack of defined guidelines for training and credentialing in new technologies, and a learning curve for the procedures that is ill defined. The court must first assess whether it is fair and just to impose a duty of care in the circumstances arising to a claim.

Whether or not there is a breach of duty of care will depend upon several factors. Important is whether a reasonable person (i.e., qualified peer) would have acted in the same way under the same circumstances.

Crucial factors are: foreseability of harm, magnitude of the risk imposed, the practicality of taking precautions, and reasonableness of the urologist's actions.

The claimant will need to show that a reasonable person would have foreseen the risk of an adverse event, and must show that a reasonable person would have taken steps to avoid it. It is incumbent upon the physician to take all reasonable steps to minimize risks to the patient. In one case of inadvertent ureteral obstruction following hysterectomy, where the operating surgeon had taken reasonable steps to identify the ureters and had passed contrast medium through them to demonstrate their patency after hysterectomy and clearly documented the same, the Court was satisfied that all practical steps had been taken and the surgeon was not held to be negligent (7). By contrast, in another case where there was no mention that these steps were taken, the court did not rule in favor of the surgeon (8).

Reasonableness is assessed by measuring the acts of the urologist against the standard of care in that area as practiced by other professionals. The plaintiff must show that the doctor did not act in accordance with accepted practice. If the physician's actions are opposed by many healthcare professionals in the field, the doctor will have great difficulty in defending those actions.

New technologies and the absence of well-defined guidelines for skill acquisition and accreditation (i.e., laparoscopic partial nephrectomy) by professional societies may increase the liability of urologists performing these new procedures. It will be difficult to argue that a breach of duty of care did not occur. In such cases, there may be no "customary practice" and a court may focus more on whether physician secured the patient's informed consent through full disclosure of the significant risks associated with the proposed procedure and alternative therapies.

When appropriate, the surgeon must disclose and document the experience with the procedure and the results the surgeon has achieved (9,10). It is not acceptable for a urologist simply to advise the patient of the general results in the field and imply that his outcomes will be similar.

In a medical malpractice action, the plaintiff must show that a loss was suffered as a direct consequence of the breach of duty of care. The claimant's burden of proof is met if the claimant shows on the balance of probabilities (i.e., where it is considered more likely than not, to be the truth). Juries in malpractice cases rarely find against a physician for lack of informed consent alone without concomitant injury (11).

Informed Patient Consent

To obtain informed consent, the physician must have disclosed adequately all facts about the nature of the treatment, the risks involved, the available alternatives and risks,

and reasonable expectations for the outcome of the proposed treatment (12,13). In this manner, the patient may come to understand the available treatment options for approaching the patient's medical condition.

> There are three key elements of consent. The patient must be competent to give consent, the patient must be informed, and consent must be voluntary.

There are three key elements of consent. The patient must be competent to give consent, the patient must be informed, and consent must be voluntary (14).

The actual consent form documents that risks and alternatives were discussed with the patient, but a signed piece of paper sufficient to show that the requirements for informed consent have been met needs to be obtained. Consent entails disclosure, which is the information shared with the patient. It is recommended that such discussion occur on more than one occasion for elective procedures, and that family members or other individuals close to the patient be present during these discussions. Documentation that such discussions occurred, the nature of these discussions, the specific treatments, and risks all need to be in the patient record. The importance of documentation is emphasized when a patient alleges that if the risks associated with a given procedure would have been known, then the patient would not have agreed to undergo treatment (15).

Reasonable guidelines regarding disclosure can be found in a report from the Australian Law Reform Commission (16). In that report, it is recommended that the physician discuss the magnitude of possible harm by addressing specific serious adverse events. The greater the likelihood of risk, the greater is the obligation to discuss the more frequent adverse events.

> An honest estimate from personal experience is preferable to simply reporting results from the literature.

An honest estimate from personal experience is preferable to simply reporting results from the literature. As simple as this may seem, there may be a lack of consensus among surgeons regarding given risks of a particular procedure and their importance, and hence the informed consent will vary in practice among patients and physicians. This was illustrated by McManus and Wheatley (16) in studying the frequency of disclosure of certain risks prior to laparoscopic cholecystectomy in England. Two-hundred surgeons were asked to comment on the frequency with which they instructed their patients preoperatively about the risk of nine specific potential complications. The average number of laparoscopic cholecystectomies performed by the group annually was 72. Forty-four percent provided written information to patients preoperatively. For the nine potential risks (e.g., bile duct injury, retained calculi, port site hernia, shoulder tip pain, open conversion, wound infection, respiratory complications, thromboembolic complications, and death), only three of the nine were mentioned more than 50% of the time. Surprisingly, 25% never discussed bile duct injury, 22% mentioned it rarely, 27% always mentioned it, and 17% usually did. Quality-standardized written information may serve to be useful as an adjunct to oral discussions between physician and patient. Investigators in Belgium have evaluated patient opinion on the addition of a clear written explanation of risk to a preoperative information packet prior to laparoscopic surgery (17). These investigators propose that such written information would serve to better inform the patient compared to reliance on oral instruction only, and that such practice may lead to reduction in physician liability. In 100 consecutive patients undergoing laparoscopic surgery who received this information preoperatively, the majority of patients reported being pleased to receive information regarding the surgical technique (91%) and associated risks (97%). Although 41% reported feeling worried by the explanation of risk, none cancelled surgery, and the majority (95%) of patients agreed with such an approach to informed consent (18).

The concept of informed consent is very critical to the medicolegal issues surrounding laparoscopic surgery.

Delegation and Communication

Communication as it relates to medical liability is twofold: (i) communication between health care professionals, and (ii) communication between the doctor and patient who has experienced an adverse event. Just as timely intervention may lead to a good clinical outcome, a delay in recognition of the early signs of an adverse event may have disastrous results (i.e., hypotension following laparoscopy due to trocar injury to blood vessel treated with fluid administration for "patient being behind" with no hematocrit check. Delegation of responsibility to a junior doctor or surgical resident without proper supervision may lead to lack of recognition of the clinical signs and symptoms of complications. Similar confusion may occur when an insufficient sign out is given to a covering physician, or when the covering physician lacks experience with the procedure performed (i.e., laproscopic nephrectomy). The covering physician may be unaware not only of specific events related to the case that day, but the procedure in

general and associated risks. If a physician pioneering a new laparoscopic technique lacks support by nursing staff that have received in-service training about the procedure, they may not be aware that certain postoperative events should be cause for concern. Medical experts reviewing laparoscopic litigation will often be asked to discuss whether the recognition of injury was timely or delayed (19).

When the going gets tough ... the tough communicate!

Too often a physician will avoid seeing frequently a patient who has experienced an adverse event, and will find it difficult to communicate with family members of the patient. This is deleterious because the treating physician knows the patient best and may be the most qualified to provide ongoing care in a challenging environment. Consultants will benefit from the surgeons' input in piecing together the facts of the case. Any professional reviewing the case will evaluate not only the timeliness of the recognition of injury by the physician but will also be asked to comment on whether the correction of injury was standard, effective, or deleterious (19). For new techniques and in applying emerging technologies, a myriad of unforeseen complications may exist and a "standard" approach to the same is likely to be absent. In such cases, efforts should be made to obtain input from physicians who may have managed similar complications.

The importance of communicating with patients and their families cannot be overemphasized, particularly following an adverse event where many questions may arise (i.e., when will the tube be removed; what is the blood count; can a family member donate blood, etc.). Here again, as in the informed consent, documentation remains important. Patient representative groups have been emphasizing for years that most patients only seek an explanation of what has occurred and what to expect. The truly litigant patient is rare. Patients and family members who find the doctor difficult to contact will become increasingly frustrated.

Laparoscopy and Litigation

Laparoscopic cholecystectomy was widely adopted in 1990. Just four years later, litigation centering around bile duct injury for the laparoscopic technique surpassed similar litigation for open cholecystectomy by more than 20-fold (19). Kern suggests that this was in part due to the great deal of negative press surrounding laparoscopic injuries during cholecystectomy. In 1992, the *New York Times* reported, "Surgeons who rushed to use a new technique to remove gallbladders without adequate training have botched many procedures, New York State health officials and surgical experts say" (20). Certainly, the fact that bile duct injury may require reoperation, prolonged hospitalization, and potential long-term consequences such as biliary cirrhosis and portal hypertension must be considered a factor as well. Claims related to laparosocpic cholecystectomy remained the most common in a recent report by the Physician Insurers Association of America (21). The Physician Insurers Association of America obtains information from 19 medical insurance companies under a data sharing agreement. Fifteen companies are from the United States, and four are from Canada, the United Kingdom, and Ireland. The 2000 study analyzed 535 cases. The 163 cases that were settled resulted in payments to the plaintiff totaling $34 million, and the average payment was $212,000. After laparoscopic cholecystectomy, the laparoscopic procedures that followed in decreasing order of frequency were exploratory laparoscopy, tubal ligation, and laparoscopically assisted vaginal hysterectomy. Common injuries involved the bile duct, bowel, and ureter. Failure to identify the injury, once it occurred, predicted severity of outcome. Missed detection was likely due in part to the limitation of visualization to the working field during laparoscopic procedures or "keyhole" surgery. The injury was not identified in two-thirds of cases until after the procedure was concluded, and in some cases this delay was shown to result in serious adverse outcomes. Vascular injuries were more likely to be recognized immediately compared to bowel in which detection was delayed in over 50%. Trocar injuries were a significant cause of morbidity in this report, not only initial entrance but also all subsequently placed access ports.

The urologist may be relieved at the apparent absence of laparoscopic urologic procedures among the frequent offenders. One must note, however, the relatively recent adoption of laparosocopy in urology compared to general surgery and gynecology, which embraced laparoscopy over a decade ago. Also, the Physician Insurers Association of America reports an average lag time of 21 months from injury until a suit is filed, and an average of two to five years until a suit reaches a conclusion, and is, thereafter, available for our review (22). It would seem, therefore, that the magnitude of litigation in urology would increase.

There is evidence that laparoscopic injuries are more severe than their open counterpart (23). This may explain why laparoscopic injuries are associated with higher

rewards to the plaintiff. A case presented in Ref. 24 offers some insight into the potential seriousness of laparoscopic injuries. In that case, a 22-year-old female underwent laparoscopic cholecystectomy. With the exception of some "hypotension intraoperative," a laceration to a major vascular structure was missed and required reexploration six hours postoperatively. At return to surgery, the patient received an excess of blood products, had vascular repair, but ultimately expired. A lawsuit charged the attending surgeon with negligently inserting the trocar resulting in vascular laceration and lack of informed consent. The suit was settled in favor of the plaintiff. Serious vascular injury has been shown to occur in 0.7/1000 cases of laparoscopic cholecystectomy (25). The primary trocar insertion in involved in the majority of cases.

Gawande (26) utilized records from the Physician Insurers Association of America to examine injuries during laparosocpic entry that provoked malpractice claims. The study was comprised of 135 cases reported in the United States between 1980 and 1999 and 111 cases from insurers in Europe, Australia, and Canada. There were 293 injuries in 246 patients overall. Injured structures were the small bowel ($n = 89$), colon ($n = 56$), iliac artery ($n = 48$), inferior vena cava or iliac vein ($n = 28$), mesenteric vessels ($n = 11$), urinary bladder ($n = 9$), aorta ($n = 8$), abdominal wall vessel ($n = 7$), liver ($n = 6$), stomach ($n = 4$), and other ($n = 27$). Injury recognition occurred sooner in the United States, and for all cases mortality increased with increasing delay in injury recognition. Delayed recognition in patients older than 59 years was significantly associated with a fatal outcome ($p < 0.001$). Over five years following the event, a greater percentage of cases remained open in the United States. In the United States there were 53 cases reported closed with payment (median, $127,000; maximum, $4,980,086), and outside of the United States there were 13 cases closed with payment (median, $55,000; maximum, $215,955).

Risk Management

Medical litigation has been referred to as a growth industry and will probably play a continuing role in the life of the physician (27). It is generally recognized that adverse events in the course of medical care far exceed the number of cases in litigation (28). Risk management includes discovery of the events surrounding adverse events. Discovery allows for identification of risk factors in practice and modification and implementation of safeguards and protocols. Often, a system is in place to assure that patient and family complaints are handled appropriately and open communication maintained between patient and caregivers. At our own institution, we recently discovered that the wrapping material for a patch applied during laparoscopic partial nephrectomy was neither counted nor radiopaque. When the surgeon postoperatively was concerned that this wrapping had not been removed from the patient, laparoscopic reexploration was performed and indeed the wrapping was located and removed. Following this case, a system was implemented to include counting of the wrapping and use of a radiopaque material.

The importance of recognizing potential physician liability when new laparoscopic techniques are introduced in clinical practice cannot be overstated. Urologists are implementing laparoscopy over a decade following our colleagues in general surgery and gynecology. It is essential to introduce these evolving complex minimally invasive procedures into clinical practice while maintaining patient safety and keeping our professional liability to a minimum.

> The importance of recognizing potential physician liability when new laparoscopic techniques are introduced in clinical practice cannot be overstated. LAPAROSCOPIC COMPLICATIONS

In any discussion of the medicolegal aspects of laparoscopic urologic surgery, careful consideration of complications is mandatory to better understand the litiginous potential.

> In any discussion of the medicolegal aspects of laparoscopic urologic surgery, careful consideration of complications is mandatory to better understand the litiginous potential.

The morbidity and mortality associated with laparoscopic surgery is widely known (29–46). The relativity of these complications depends upon the literature and varies widely from earlier gynecologic series from the 1970s through the 1990s. In large series, the risk of a complication has been quoted to range from 0.19% to 2.9%. The mortality rate has been reported to approximate 0.057 deaths per 1000 procedures. The general surgical literature also has large numbers with advancing complexity of procedures from the 1980s through to the present. The complication rates have ranged from 2.3% to 5.1%. Mortality has been reported from 0% to 0.5%. It has been suggested that since most of this information comes from retrospective evaluation of large numbers of cases, that the true incidence of complications might be even higher. In addition, the gynecologic literature has been suspect when applications to other specialties, such as general surgery and urology because their series have a weighted preponderance

of young, healthy females. Many urologic and general surgical procedures are done on elderly patient populations with significant comorbid disorders such as diabetes and/or significant vascular disease. Specific complications have been evaluated and are known or approximated as follows: pneumoperitoneum complications = 0.7%, bleeding = 0.6%, perforation injuries = 0.3%, electrical injury = 0.2%, infections postoperatively = 0.1%, bowel burns = <0.1%, cardiac arrest = <0.1%, open laparotomy rate = 0.6%. These numbers are generated by review of large, principally gynecologic surveys, and do not include the complications that might be related to anesthesia such as aspiration pneumonia.

There are well-known factors that influence the risk of a laparoscopic procedure. These include environmental factors such as the integrity of instrumentation, the upkeep and quality of the technology. Another factor is the skill and experience of the surgeon. Widely quoted but with few studies to evaluate its impact is the "learning curve" for various types of laparoscopic procedures. It is known for many complex laparoscopic procedures that the complication rate is higher, when the case log is near its beginning. This issue is central to discussions of complications and complexly bound to discussions of training, credentialing, privileges, and competency. Phillips in 1977 stated that operator experience is the primary determinant of the incidence of laparoscopic complications. Phillips further noted an inverse correlation between the number of laparoscopic procedures performed and the incidence of complications: decreased numbers after 50 and 100 laparoscopic procedures. Other factors showing correlation with increased risk include previous abdominal surgery, obesity, male gender, advanced age, and diabetes mellitus. Some of these increased risk factors have been questioned recently, but the laparoscopic surgeon should be aware of the literature.

Complications can also be discussed in terms of their severity. Minor complications include subcutaneous emphysema, hand–shoulder syndrome (pain from retained gas beneath the diaphragm), ecchymosis at a trocar site. More significant complications are perforation of a viscus or major blood vessel, electrocautery injury, gas embolus, and open conversion. Most would argue that an open conversion from the laparoscopic approach is not a real complication; however, since an open operation carries with it more convalescence and risks, it deserves mentioning and can serve as a yardstick in measuring certain laparoscopic procedures and series. The Physician Insurers Association of America utilizes a National Association of Insurance Commissioners severity index score from 1 to 10, with 1 being emotional injury and 10 being death.

The most severe and potentially lethal complications associated with laparoscopic surgery are those injuries to the bowel and major vascular structures. Laparoscopic-associated injuries to vasculature or bowel are unusual and potentially catastrophic. Estimates of occurrence range from 0.06% to 0.3%. Manifestations can be early or delayed. Delayed diagnosis is definitely related to increased patient morbidity.

Mechanism of Injury

Access Injury

Laparoscopic surgery always carries the risk of inadvertent injuries that usually occur during the "learning curve" of various procedures. The exceptions to this rule, and some of the most feared injuries facing the laparoscopic urologist are those to vascular structures or bowel. These injuries are fortunately infrequent. The best method of managing these injuries is avoiding them. This is best accomplished by a thorough understanding of the equipment utilized during laparoscopy, high-risk maneuvers, mechanisms of injury, and recognizing when injury is present. Overall estimates of vascular and bowel injuries in large series are predominately quoted from older gynecologic literature. Vascular injuries have been difficult to quantify but occur at least in 0.1% of the cases. Bowel injuries have been variously reported between 0.06% and 0.3% (46).

Mechanisms of injury vary, however, most occurring during blind access maneuvers with the pneumoperitoneum needle or first trocar placement. The takeoff of the right common iliac artery lies directly below the umbilicus. It is crucial to angle the pneumoperitoneum needle 30° to 45° caudally and carefully control forward pressure to insure abdominal access yet avoided excessive forward penetration. The same approach holds for trocar insertions. Bowel injuries from needle or trocar insertions usually occur in the presence of adhesions. Access should be planned to stay as far away from previous surgical incisions as possible or utilize open techniques. A summary of major series and the data from Chandler et al. (47) is shown in Table 1.

The risk of an injury may be associated with the operative procedure as well as its complexity. As the type of surgery moves away from the linea alba, as so often occurs in urologic laparoscopy, the possible risk of injury to the abdominal wall itself may increase.

> The risk of an injury may be associated with the operative procedure as well as its complexity. As the type of surgery moves away from the linea alba, as so often occurs in urologic laparoscopy, the possible risk of injury to the abdominal wall itself may increase.

Source: From Ref. 28.

Many complex laparoscopic surgery reports are published but seem to ignore the potential for access injury. Leibl et al. (28) have reviewed the general surgical literature in 1999 and reported in Table 2.

> The Veress needle and laparoscopic trocar's design has been implicated as a potential source of laparoscopic access injury. Several interesting reports and literature reviews have focused upon this issue. Despite advances in trocar technology such as safety shields, the incidence of injury has not altered appreciably.

The Veress needle and laparoscopic trocar's design has been implicated as a potential source of laparoscopic access injury. Several interesting reports and literature reviews have focused upon this issue. Despite advances in trocar technology such as safety shields, the incidence of injury has not altered appreciably.

In addition, the most common method of laparoscopic access remains the blind insertion of a Veress needle, followed by insufflation, and then a second blind trocar insertion. There now exist many types of devices for laparoscopic access. These include Veress needle, open trocars (Hasson-type), shielded pyramidal trocars, shielded blade trocars, conical trocars, radial expanding trocars, short-stroke knife optical trocars, and winged cone optical trocars. Chandler et al. (47) used three data sources to identify access injuries reported with all types of these devices: The Physician Insurers Association of America on U.S. laparoscopic injuries and a second Physician Insurers Association of America database from Europe, Australia, and Canada. The third database came from the United States Medical Device Reports to the Food and Drug Administration. Their study encompassed more than 280,000 laparoscopic procedures and is injury-based instead of procedure-based, thus providing little data on the true incidence or relative safety. The results by type of access device are summarized in Table 3 (47).

Basically all categories of contemporary access devices have been reported to cause some type of injury. In the Medical Device Reports reports, the Veress needle only accounted for 2% of reported injuries whereas the Physician Insurers Association of America noted them in 13% to 19% (which is probably closer to actual). From these databases, it is also known that injuries from secondary trocar insertion are rare. There were nine entry injuries from the Medical Device Reports data and nine from the Physician Insurers Association of America data. Five from the Medical Device Reports set were associated with shielded pyramidal trocars, three from shielded blade trocars, and one small bowel puncture with a radially expandable device. The severity of the injuries was also recorded from these data sets. More than half of the patients suffering an access injury (55% overall from all three cohorts) were scored using the National Association of

TABLE 3 ■ Chandler's Results from Several Large Databases Regarding the Type of Trocar Used and the Subsequent Injury

Device	MDR (n)[a]	%	PIAA (U.S.)/foreign (n)[a]	%U.S./%foreign

Radially expandable sheath	4 (4)	1.7	− / −	− / −
Open blunt (Hasson)	2	0.8	16/ −	12/ −
Multiple-use pyramidal	2	0.8	− / −	− / −
Conical	1	0.4	− / −	− / −
Total	242 (12)	100.0	133 (1)/113	100/100

[a]*n* numbers in parentheses indicate that 12 of 235 (5%) devices other than the Veress needle or an open blunt cannula without prior insufflation.

Insurance Commissioners injury severity index indicating a major impairment or disability. In addition, there were 65 deaths from access injuries, all from primary access except one secondary trocar injury to the duodenum. Mortality was significantly lower in the two U.S. cohorts compared to the international group (11% vs. 22%, $p = 0.0008$). The international group had a more significant number of bowel injuries and a significantly greater proportion of patients presenting with a delay in diagnosis (60% international vs. 17% in the United States, $p < 0.001$) (47).

Lest the reader think that the open methods for laparoscopic access have no risk of injury, think again. Open techniques have been associated with serious potential risks of both major vascular and bowel injuries (48). The mechanisms for these injuries are nearly identical to the closed methods. That is the route of access is via a small incision down through the rectus fascia. The peritoneum is grasped and either opened with scissors or knife. This forward vector of force is all that is necessary in thin patients to injury a closely apposed vessel or bowel. Injuries have also been reported with this technique by placing holding fascial sutures that inadvertently catch underlying bowel. In addition, a Hasson cannula has been reported to injure the small bowel by constant pressure applied "off camera" during a prolonged laparoscopic surgery.

Pneumoperitoneum Injury

The complications of pneumoperitoneum are presented in Table 3. Certainly, not all patients experience detrimental complications associated with CO_2 insufflation, otherwise there would be no widespread interest in this approach to treating uropathology. Most of the consequences mentioned above are transient and the operative procedure can continue with continuous monitoring of the patient. Overall, Parsons et al. (49) has estimated that during urologic laparoscopic procedures that insufflation problems occur in about 3.5% of the cases.

Instrument Injuries

Instruments can cause unintended injury as well as the trocars used for laparoscopic access. Most of these injuries affect the bowel most commonly with lacerations, injury to the mesentery with bleeding being the most frequent. Since these types of injury are most prevalent during the operative dissection, they are frequently observed (50).

The most common type of nonobserved instrument injury comes from retraction. These can be punctures, lacerations, or hematomas from overzealous traction during exposure (51). Retraction instruments should always be positioned with video control, and any repositioning should be observed and monitored.

Following prolonged retraction with such devices, the retracted organ or area should always be thoroughly inspected. Small lacerations of the bowel's serosa can be oversown. Deeper lacerations or frank perforations should be individualized, but classic teaching would suggest open conversion and close inspection of the injury and debridement and closure. There has been successful laparoscopic management of bowel lacerations reported in the literature. Such patients should be managed with bowel rest, nasogastric suction, and antibiotics. Injuries have also been reported during both

> The most common type of nonobserved instrument injury comes from retraction. These can be punctures, lacerations, or hematomas from overzealous traction during exposure. Retraction instruments should always be positioned with video control, and any repositioning should be observed and monitored.

laparoscopic renal and adrenal surgery to the liver and spleen (52). If the injuries are superficial, attempts to control the injury laparoscopically with gel foam, avitene, or with an argon beam coagulator have been reported. Open exploration for these injuries has likewise been described.

Electrocautery Injury

The explosion of laparoscopic procedures both in general surgery and urology has lead to rekindled interest in the risks of monopolar electrocautery, the use of alternative energy sources such as bipolar cautery, lasers, argon beam coagulation, and ultrasound activated devices (harmonic scalpel). These energy sources are predominately utilized for bloodless dissection and control of vascular structures, critical for the performance of laparoscopic surgery. In the survey of the American College of Surgeons, 86% of all surgical laparoscopists were using monopolar cautery. In a more recent survey in Germany, about 84% of all surgeons used monopolar cautery routinely in all laparoscopic cases. In an open surgical environment, monopolar electrocautery is relatively safe, with the major significant risk being skin burns (53). In the laparoscopic environment, however, potential complications are far more serious with mortality rates approaching 25% or more for inadvertent injuries to small and large bowel. The need for thorough review of the potential implications will greatly aid in the development of safe laparoscopic procedures for urologists in this burgeoning field. One should not forget the admonitions of experienced gynecologic surgeons from the 1970s and 1980s where routine editorial comments on the potential for harm with the indiscriminant use of monopolar electrocautery were published (54–56).

In review of the large volume of literature on high-frequency electrosurgery in laparoscopic environment, seven possibilities exist for a laparoscopic electrocautery injury (57). Thorough understanding of these mechanisms of potential laparoscopic injury will help facilitate the safe advancement of skills in laparoscopic surgery. The first potential modality of electrocautery injury laparoscopically is the application of an active electrode to nontargeted tissue. This occurs when an electrically charged instrument is inadvertently activated such as stepping on the foot petal at the wrong time or touching another conductive instrument with cautery activated. Since the surgical field of view tends to be rigidly controlled to the point of surgical dissection, these injuries are usually noticed by the surgeon at the time of injury. The second possibility for electrocautery injury occurs when a restricted return pathway is encouraged. This happens when over cautery is achieved at the tip of the active electrode, increasing tissue impedence and alternative return pathways must be sought by the active electrode. Here, for instance, when dividing adhesion to a visceral structure, if the peritoneal side is stringently cauterized the pathway may return by way of the bowel and cause inadvertent bowel injury. These two are often in the direct line of sight during operative procedures and careful avoidance of utilizing too much monopolar electrocautery where tissue charring occurs should be avoided. The third mechanism of potential electrocautery injury occurs when overheating of the active electrode is present. Here, again, if the tips of electrocautery instrument become charred or stuck with tissues, heat dissipation by free flow of the electrical current is impaired and the tips of the active electrode become quite hot. By simply touching an adjoining visceral structure with the hot electrode thermal damage can ensue. This typed of injury has been reported in the urologic literature, where the obturator nerve was injured during laparoscopic lymph node dissection with what appeared to evolve as a conductive thermal burn, but progressed even after the first week postoperatively. The next four other methods of possible electrocautery injury in a laparoscopic environment have a tendency to occur outside of the surgeon's line of sight and, therefore, have much greater potential for patient morbidity and mortality. The fourth type of injury occurs when conductive instruments are energized inadvertently. The classic example of this would be where the surgical instruments are all converging toward the targeted area of dissection, the electrode is activated and the instrument is too close to another such as the laparoscope itself, which then conducts the current in a stray fashion to a structure outside the line of sight.

Electrocautery injuries are often not noticed and can be quite severe, resulting in delayed presentation of peritonitis secondary to fecal contamination or urinary extravasation 7 to 10 days following the surgical procedure. Patients often present with very minimal symptoms but rapidly decompensate and, in many instances, may require more than one surgical intervention for repair.

The fifth potential method of inadvertent electrocautery injury occurs when insulation failures occur on the active electrode within a trocar cannula. There are two subcategories where the type of injury depends on the type of trocar used and whether or not a plastic fascial screw is present in the abdominal wall. Obviously, when an

Electrocautery injuries are often not noticed and can be quite severe, resulting in delayed presentation of peritonitis secondary to fecal contamination or urinary extravasation 7 to 10 days following the surgical procedure. Patients often present with very minimal symptoms but rapidly decompensate and, in many instances, may require more than one surgical intervention for repair.

insulation failure occurs within the trocar, the trocar will become electrified if it is a conductive medium. Even in instances where the trocar is not conductive, such as with plastic cannulas, failures in these can result in inadvertent conduction to the abdominal wall. Studies with biopsy of the skin sites from laparoscopic cannula sites have proven that thermal necrosis occurs at trocar sites, both metallic and plastic. When a plastic fascial screw further insulated the trocar from the abdominal wall, an insulation failure within the trocar is potentially even more dangerous. The activated electrode can build up a capacitance charge and leaking from this can arc to a nearby visceral structure. These will often be missed since they are outside of the targeted area of laparoscopic surgery and can have the same devastating consequences of the previous electrocautery injuries described. The sixth mechanism of a laparoscopic electrocautery injury occurs when insulation failure occurs outside of the trocar on the active electrode. These insulation failures are often small and not noticed and the potential for current arcing to a nontargeted viscus is highly likely (58). If the surgeon is careful to inspect the tract of the pathway of the surgical procedure, these can be identified during the laparoscopic procedure. There have been reported cases of insulation failure injuries with electrothermal injury to the small and large bowel, corrected laparoscopically at the time of the primary procedure. Careful inspection of all active electrodes should occur outside of the abdomen prior to instigating the laparoscopic procedure.

These types of injuries are best avoided by simple inspection of the instruments and routine maintenance of the instruments. All insulation can eventually wear down and insulation failures are a real clinical dilemma.

Disposable instruments are less likely to have insulation failure since they are one time use and are discarded at the conclusion of each case. If, however, during the course of a complex laparoscopic procedure, the same instrument is passed multiple times through a trocar, the insulation can get worn down through the process of insertion and reinsertion. The seventh and final modality wherein inadvertent laparoscopic electrocautery injuries occur are secondary to capacitive leakage of current from the active electrode. This probably occurs in a laparoscopic environment more than previously thought. As the electrode is activated, the charge builds up and moves through the conductive electrode. If at any point the flow is interrupted by restricting the return pathway or any point wherein the active electrode becomes close enough to another conductor, current can leak from the active electrode to another return site pathway by discharging this built-up current. Since this can occur at any location along the insertion site of the active electrode, many times it will occur outside of a surgeon's operative view and again poses a major potential risk for subsequent electrothermal injury.

There are entire textbooks, meetings, and courses on the rational use of electrocautery in laparoscopic surgery. Methods exists however to minimize these risks. First, always know your laparoscopic electrosurgical generator (59). The patient should be well grounded, with a broad return pathway (pad) in correct orientation. The electrocautery instruments and any other instrument in the peritoneal cavity should be inspected to insure adequate insulation. When the cautery is activated, it should only be applied by the surgeon and no assistant movement should be allowed. There should be no use of forced coagulation, but recent investigations utilizing spray coagulation suggest it might have utility. The newer microprocessor-controlled electrocautery units should be preferred over the older units. One such instrument is called "Instant Response™"a (60). This is a self-regulating, feedback-controlled electrosurgical unit that allows tissue conditions to be fed back to the microproccesors within the electrical generator. These capabilities allow the generator to tailor the electrical output to local laparoscopic conditions. Cutting and coagulation performance are enhanced in these new age systems; this may allow safer performance of monopolar electrocautery in the future. In addition, the behavior of the insulation material on the outside of laparoscopic instruments, usually plastic, is being evaluated. Alterations of this coating may improve the efficiency and alter the desired effects making tailored devices of the future possible. Bipolar systems have an advantage over monopolar electrocautery by confining the energy between the twines of the active electrode and return electrode at the instrument's tip. Complex microprocessing electrosurgical generators and improved instrument manufacturing have improved these devices significantly (61). Such a device was used by Guilloneau et al. to perform the first large series of laparoscopic radical prostatectomies in Paris. If alternative methods of cautery are available and the surgeon is comfortable with the technology, the harmonic scalpel accomplishes similar

_____
aValley Lab, Boulder, CO.

tasks to the electrocautery without an active current being utilized (62,63). Cutting and coagulation can be accomplished using either electromagnetic or mechanical energy, thus avoiding electrocautery completely. Electromagnetic energy sources rely on heat derived from either light (lasers) or radiofrequency waves (electrosurgery) to produce tissue cutting and coagulation (62). The tissue temperatures from these sources often reach 100°C or greater (64). Since collagen denaturation and protein coagulation occurs between 60°C and 80°C, tissue desiccation and charring ensue. Using mechanical energy, the ultrasonically activated devices (harmonic scalpel) rely on vibratory motion to generate heat from internal tissue friction to cut and coagulate. This method generates lower tissue temperatures from 80°C to 90°C, which is sufficient for coagulation but not for desiccation or charring. Using either a laser or an ultrasonically activated device totally avoids the risk of inadvertent electrocautery injury.

Vascular Injury

Major vascular injury during access for laparoscopic surgery is a well-described and much-feared complication (65). This probably is because of its dramatic presentations such as near instantaneous instability of the patient's hemodynamic state or sudden large volume blood from the Veress needle or trocar and also because of the high rate of mortality.

Major vascular injury as the cause of death following a laparoscopic surgery is second only to anesthesia complications, at 15%. Pneumoperitoneum needle injuries account for the vast majority of major vascular injuries reported.

In reviewing the gynecologic literature, 11 of 15 such injuries were noted from needle placement and only two out of fifteen from trocar placement (66). The distal aorta and right common iliac artery are not surprisingly the most prone to injury. This is because the distance from the anterior abdominal wall to the retroperitoneal vasculature may be as little as 2 cm in thin people. Injuries to the inferior vena cava, the left hepatic vein, the abdominal aorta, and the inferior phrenic vessels have all been reported as well. These injuries are most often the result of the laparoscopic dissection, and not from laparoscopic access methods. Hallmark features of these injuries include immediate bloody return from the needle and/or rapid deterioration of the hemodynamic status of the patient (67). Once a major vascular injury is suspected, the Veress needle or trocar should not be moved medially or laterally. The offending access portal should be left in place and open exploration should be performed. At exploration, bleeding is typically confined to the retroperitoneum even with extensive vascular lacerations. Most arterial injuries can be oversewn with simple, nonabsorbable sutures after obtaining proximal and distal control of the injured vessel. Rarely, the iliac vein has been lacerated along with the iliac artery. More extensive injuries have required prosthetic replacement of the injured blood vessel (68,69). These vascular injuries are the reason why open surgical instruments should be immediately available during all laparoscopic cases. At least two reported deaths are attributed to laparoscopic vascular injuries, and sequelae resulting from peripheral ischemia have resulted in successful litigations in the United States (70,71).

Although best avoided by careful instrument placement, and thorough understanding of anatomy and procedures it is equally important to be prepared for a major vascular catastrophe. An adequate response in a controlled yet rapid fashion can spare further morbid sequelae.

An adequate response in a controlled yet rapid fashion can spare further morbid sequelae.

Early involvement by skilled vascular surgeons is associated with less permanent disability. Anticipation of this injury is essential. An open set of operative instruments should be available. If injury occurs during pneumoperitoneum insertion, avoid lateral displacement of the needle and remove it. Observe the patient's vital signs and draw a stat baseline hemoglobin and hematocrit. If vitals and serum parameters remain stable, open laparoscopic access should be accomplished or the procedure should be terminated and rescheduled another day. If vital signs indicate instability or serum parameters indicate continued hemorrhage, immediate laparotomy is indicated. Trocar injuries are usually more severe. The first indication may not be blood in the trocar but hemodynamic instability of the patient. If vascular injury is suspected do not remove the trocar or desufflate the abdomen but turn off the insufflator to avoid massive CO_2 embolization. A midline celiotomy is performed and the trocar is used to guide the exploration. The trocar should not be touched until proximal and distal vascular control is obtained. Vascular injuries can also be encountered during dissection. These are usually smaller vessels or branches and rarely laceration of larger veins (femoral vein). Pressure is usually sufficient to tamponade the bladder until the field can be cleared and carefully explored to attempt laparoscopic salvage. During pelvic lymph adenectomy

bleeding from an accessory obturator vein or artery can be very difficult to control laparoscopically. Despite the greatest care, these vascular structures can be inadvertantly torn or cut. Electrocautery or argon beam coagulation is not advisable choices in this scenario because of the risk of thermal injury to the obturator nerve (72). All alternatives to augmenting hemostasis should be considered. Chemical augmentation of hemostasis is possible with microfibrillar collagen (Endo-Avitene™ᵇ) or fibrin glue (73). Occasionally the bleeding is severe and significant, warranting immediate exploration. Again, leave the trocars and pneumoperitoneum intact so that celiotomy can be performed quickly. The laparoscope can be placed in the midline to aid in countertraction for the knife during this maneuver.

Finally, major lacerations to large veins can go unnoticed during laparoscopic procedures because of the pressure of pneumoperitoneum.

It is advisable that inspection of the operative site at the conclusion of the procedure be accomplished with minimal abdominal pressures, 2–4 mmHg, prior to removal of any trocars.

In addition, a good rule of thumb for all laparoscopic surgery is that the first instrument active on the table is the laparoscopic suction/irrigation unit, and that it is the last off the table for the conclusion.

The vasculature of the anterior abdominal wall can also be injured during laparoscopy (74), most often secondary to trocar injuries to the inferior or superior epigastric artery or vein. The inferior epigastric vessels are much more commonly injured than the superior epigastric vessels.

Anterior Abdominal Wall Injury

This has been attributed to the more lateral course of the inferior epigastrics along the rectus muscles compared to the more medial distribution for the superior epigastrics. The inferior epigastric artery is also larger than the superior epigastric. It has been reported that injuries to the superior epigastric artery are more likely to stop on its own than the inferior epigastric. Multiple techniques have been described for controlling bleeding from these sites. Resectoscopes have been placed via the trocar site and fulguration of the bleeding point has been described. This is difficult if the bleeding is significant or if a large amount of adipose tissue is present. Medial or lateral displacement of the trocar may temporize hemorrhage by pressure tamponade. A Foley catheter has successfully been placed via the trocar, insufflated with 30 cm³ of saline, the upward traction utilized to tamponade the bleeding. Percutaneous sutures placed via a Stamey needle have also successfully ligated abdominal wall bleeding (75). Because the epigastrics are anatomically located in predictable patterns, just medial to the lateral border of the rectus abdominus these injuries should be avoidable. But as pointed out previously, the more complex the operation, the more likely that staying within the safe boundaries of known drainage patterns can be compromised. It is best to identify the anterior abdominal wall vasculature by transillumination with the laparoscope prior to placing any trocars near the vicinity of these vessels. By using the smallest trocar necessary, the risk of a major injury to the epigastric vessels is also reduced. Some have suggested not angling the trocar radically towards the midline from lateral locations to avoid shear that could damage vascular tributaries. Use of cone-shaped blunt-tip trocar or a radially dilating "step trocar" can minimize chances of injury to the inferior epigastrics. Finally, it is critically important to inspect all trocar sites both at the beginning of the laparoscopic case and at its conclusion. Trocars have been known to damage a blood vessel but not result in serious bleeding until it has been removed. This is thought to occur secondary to tamponade of the vessel by the trocar and pneumoperitoneum.

Liebl et al. (28) investigated the risk of abdominal wall injuries by evaluating bleeding from access sites in complex general surgical cases. They noted that the risk of injury of a blood vessel in the anterior abdominal wall was not only associated with the type of surgery being performed but also the type of trocar utilized. The trocar's tip design is itself a significant factor in causing bleeding from access via the abdominal wall. They reviewed the surgical literature and found very rare accounts of this problem in laparoscopic hernia surgery (0.8%), in laparoscopic Nissen fundoplication (3%), and in laparoscopic colon surgery (3.4%). In evaluating various trocar tip designs, they noted that the rate of anterior abdominal wall bleeding was reduced from sharp-cutting tipped trocars (0.83% to 0.33%) to 0 when cone-shaped trocars were used.

Bowel Injury

The other group of catastrophic injuries a urologic laparoscopist could encounter involves the bowel (76). These injuries represent the third most common cause of death from laparoscopic surgery following anesthesia complications and major vascular injury.

Unlike major vascular injury, many bowel injuries go unrecognized at the time of the laparoscopic procedure. This is because they have a tendency to be small and often out of the line of sight during the laparoscopic procedure. That is to say, they occur off camera and are thus easily overlooked.

Consequently, patients present in a delayed fashion often after being discharged from the hospital and return complaining of abdominal pain or frank peritonitis. This delay fosters fecal contamination and increases the potential morbidity and mortality of this complication. Bowel injuries usually are penetrating stab wounds secondary to pneumoperitoneum needle or trocar punctures. They can also occur secondary to lacerations of the mesentery and subsequent devascularization, lacerations from retraction, and thermal injuries from electrocautery. Predisposing conditions, such as previous surgery with adhesion formation have already been mentioned (77). Again, the gynecologic literature is the dominant source for large series (78). Estimates are that almost half (42.8%) of intestinal injuries are undetected at the time of laparoscopy. Obviously, these injuries are best dealt with at the time of occurrence. Pneumoperitoneum needle injury need not be sutured, unless a laceration is also present with fecal contamination. Miniperforations of the colon have been successfully followed with conservative measures, bowel rest, and intravenous antibiotics (79). Trocar injuries are usually much more extensive. Historically, acute large bowel perforations have been treated by prompt laparotomy, often with creation of a temporary stoma. The problem is fecal contamination from the unprepped colon (80). Increasing reports of traumatic series where closure and drainage are effective therapeutic modalities following copious irrigation. The increasing ability to be able to reconstruct visceral abdominal structures has yet to be demonstrated to produce adequate repairs.

Currently, a contaminating injury to the small or large bowel is best handled by open repair with or without proximal fecal diversion.

Delayed presentation of bowel injury represents the other major group of patients (50,51,76). This includes those patients who have a needle or trocar injury that are missed during the laparoscopy are usually present with peritonitis between 14 and 72 hours post procedure. Thermal injuries to the bowel are also capable of delayed perforations and peritonitis. These perforations can present from 7 to 12 days following the laparoscopic procedure. In one series, a total of 10 thermal bowel injuries were noted in 3600 laparoscopic sterilization procedures (0.3%), again half were unrecognized (35). Of those recognized, four out of five were superficial serosal burns <0.5 cm in diameter and were managed successfully by observation, bowel rest, and intravenous antibiotics.

Laparoscopic urologic surgery is not similar to gynecologic sterilization procedures or laparoscopic cholecystectomy (78). The exact risks inherent in these newer procedures are not yet known. Early reports from multi-institutional series of laparoscopic pelvic lymph node dissection demonstrate a 15% complication rate (55 out of 372 cases). Of these complications, 7 out of 55 (12.7%) required immediate exploration, three vascular, and one bowel injury. An additional 6 out of 55 (10.9%) required delayed explorations, of which half involved bowel injuries (66).

Injuries to vascular structures and bowel are an ever-present possibility during laparoscopic surgery. They are best avoided by a thorough understanding of the equipment, meticulous attention to detail, and systematic inspection of the abdomen upon entrance and prior to exiting. Patient mortality is the major risk or missing an injury to either of these structures. Morbidity can be diminished by prompt identification of the injury and open exploration.

Urologic Injury

The most commonly injured urinary organ is the bladder, and the most common instrument causing injury is the Veress needle (81). Primary trocar injuries of the bladder have also been reported and secondary trocar injury to this structure is rare, with few reported cases.

Although gynecologic pelvic surgery is the most likely type of surgical procedure to produce a laparoscopic bladder injury, an impressive number have been reported from relatively small (by comparison to the gynecologic literature) numbers of laparoscopic pelvic lymph node dissections for staging prostate cancer (82–85).

In addition, laparoscopic herniorrhaphy series have a growing literature of this complication as well. The most common site within the bladder to be injured is in the midline dome. This most commonly occurs when the bladder is overdistended and a suprapubic trocar is being inserted (86). Small bladder stab wounds are capable of closing spontaneously if adequate drainage is maintained. Larger, more irregular injuries require formal closure, usually sutured two or three layered plus adequate drainage with a large Foley catheter and a drain. This has been accomplished laparoscopically by many authors. Fortunately, the diagnosis of bladder injury is made during the laparoscopic procedure. This is noted when the indwelling Foley catheter bag is filled by CO_2 gas, if the urine turns bloody, or in high-risk cases by distending the bladder with sterile saline at the conclusion of the case.

Less common injuries have been reported to the ureter, the urachus, and the kidney (87). The urachal report was noted to occur during placement of an access trocar and patency of the normally obliterated connection to the bladder. Ureteral injuries are most common during laparoscopic-assisted vaginal hysterectomy when taking down the vascular ovarian pedicles. Additional injuries have been reported from thermal coagulation with electrocautery and laser ablation of endometriosis. Nezhat and Nezhat (83) has described the laparoscopic correction of ureteral transection with the performance of a laparoscopic ureteroneocystomy (Lych–Gregoir type). Injuries have also been published with laparoscopic colon resections, pelvic lymph node dissections, and laparoscopic radical prostatectomy series. These injuries are always rare, and their incidence appears to be not rising (49,88–94). A final rare reported complication has been noted during a laparoscopic nephrectomy in a patient with an antecedently placed percutaneous nephrostomy catheter. In this case, the kidney was ruptured secondary to the tethering effect of the nephrostomy tube during placement of one of the trocars (87).

Delayed Complications
Hernias
There is a growing amount of literature on the risk of postoperative laparoscopic hernia formation following trocar removal (95–99). The standard custom has been to close the fascia in all trocar sites 10 mm in diameter or above. The literature would suggest that although the risk of port site herniation is uncommon below the 10 mm cutoff it is by no means certain. In fact, children and obese patients are significantly at risk of herniation from the 5 mm trocars and smaller (100).

> The estimated risk of developing a trocar site hernia is about 0.77% to 3.0%.

The estimated risk of developing a trocar site hernia is about 0.77% to 3.0%. This compares to the open operative counterpart risk of 10% of all cases following conventional laparotomy. The smallest trocar site currently reported with postoperative complication is a 3 mm umbilical port site. The umbilicus has been investigated as the site most likely to develop this complication. In fact, this has not held up to scrutiny (101). Any laparoscopic trocar site appears to be likely to develop herniation. Organs that can be herniated and cause symptoms include the bowel, omentum, preperitoneal fat, and rarely the large bowel (or mesentery) (102). It is important to realize that an outward pressure is produced as the laparoscopic cannulas are removed, which fosters entrapment of loose tissues such as the small bowel or omentum. This is even more likely to occur if the flapper valve of the trocar is held open during its removal. This creates a suction-like effect drawing any underlying structures into the trocars transabdominal path (103). Much work remains to be done regarding the optimal method of access site management. The evolution of the science behind this fundamental part of laparoscopic surgery is burgeoning and the potential for needless injury from this source is beginning to be questioned (104).

Wound Infections
Laparoscopic wounds, trocar sites, are different from open surgical wounds. A foreign body is introduced through the anterior abdominal wall or flank, it is locked into position with sutures or fascial screws, and it is manipulated throughout the operation by instruments that are passing and extracting to perform the work of surgery remotely (105). Infection at the trocar site has long been a clinical concern but there is no evidence that the incidence of wound infection is higher than in open surgery. In fact, there is some evidence that the risk of wound infection is less with laparoscopic procedures particularly in some high-risk populations (106–110).

The need for routine laparoscopic cases to receive prophylactic antibiotics remains controversial (111,112). In large series of laparoscopic cholecystectomy this probably is not necessary, but these cases tend to be much quicker than the usual urologic

laparoscopic case (49). In one recent prospective, randomized study on the use of prophylactic antibiotics, there was no effect on incidence and severity of infections between both groups (113). Multivariate analysis showed that diabetes mellitus and colic episodes within 30 days before surgery were independent factors significantly associated with the onset of infectious complications. Laparoscopic surgery performed for known infectious diseases such as appendicitis do show significant benefits for the routine use of prophylactic antibiotics. In a large prospective multicenter evaluation of patients operated on for appendicitis, Koch et al. demonstrated that in this high-risk group wound infections occurred in 2.5% of 4968 patients. Laparoscopic wound infections were again statistically significantly lower than with open appendectomy ($p < 0.001$) and that routine use of prophylaxis resulted in lowering the rate in both the open and laparoscopic groups. Other high-risk surgeries for wound infection have been operations upon the bowel. Laparoscopic surgical resection of the small bowel is necessary for radical cystectomy and ileal conduit formation. In a recent publication of 500 consecutive laparoscopic colorectal resections, Poulin et al. reported an incidence of postoperative wound infections of 7.2% (includes infections of both the anterior abdominal wall and perineum) (114).

> Poulin et al. stated that the laparoscopic procedures have the same rate of infectious complications compared to the open counterpart. As such, the complexity of the surgery and the actual laparoscopic procedure may affect the rate of postoperative trocar site infection.

Poulin et al. stated that the laparoscopic procedures have the same rate of infectious complications compared to the open counterpart. As such, the complexity of the surgery and the actual laparoscopic procedure may affect the rate of postoperative trocar site infection.

In the urologic literature, several large series estimates that the postoperative trocar site infection rate is very low, 0.06 (49,88–90).

Port Site Metastases

Incisional metastases following open resection for cancer is an infrequent but known risk of cancer surgery (115). The first reported case of cancer recurrence was in 1978 in a patient with ovarian cancer (116). Reports for certain kinds of cancer such as colon cancer have notoriously high rates, ranging from 0.6% to 0.8%. The laparoscopic port site risk has been noted to be as high as 1.1% raising some concern about laparoscopic caner surgery. Though rare, incisional metastatic disease is a morbid complication to patients nearing the end of life and decreases the potential for cure in patients to near zero. The port site has been portrayed to be a breeding site for tumor implantation because of the trauma that occurs in the port site (117). If viable tumor were to be seeded into such a tract, some have speculated that port site recurrence might occur. Little science and few clinical trials are available to evaluate this phenomenon but recent work has been progressing. In urologic practice, one large extensive, retrospective review identified etiologic factors such as natural malignant disease behavior (transitional cell carcinoma), host immune status, local wound factors, laparoscopy-related factors such as aerosolization of tumor cells (harmonic scalpel vs. electrocautery plumes), type of insufflant gas (CO_2, nitrous oxide, helium, and room air), and surgical skill. Suffice it to say, that the risk of port site metastasis in urologic laparoscopic surgery seems not to be rising with associated increase in the numbers of cases (118). Methods to reduce risk should be actively employed. Attempts at reducing manipulation of the specimen should be employed during all laparoscopic procedures. Wu et al. (119) clearly demonstrated that by decreasing the inoculum of intraperitnoeal cells lead to a decreased wound implant rate. Others have shown that the use of potentially cytotoxic agents such as providone-iodine solution and chemotherapeutic agents will decrease tumor implantation rates (120).

Others

A whole host of other injuries have been reported in the expanding literature of laparoscopic surgery. Hypothermia during surgery is a well-recognized result of having patients exposed for surgery in relatively cold ambient operating room environments (121). In addition, the insufflation of the abdomen with room temperature CO_2 gas might increase the potential incidence of this condition.

> CO$_2$ gas is typically at 21.1°C at insufflation, whereas the peritoneal cavity is 35.52°C to 36.2°C.

CO_2 gas is typically at 21.1°C at insufflation, whereas the peritoneal cavity is 35.52°C to 36.2°C. Fortunately, the peritoneum and its contents expose the insufflated gas to a large surface area, and the gas usually reaches equilibrium temperatures rather quickly. The mesenteric circulation receives 10% of the cardiac output and the estimated surface area of the peritoneal cavity is equal to that of the cutaneous surface (1–2 m^2). One study by Ott (121) showed that 5 L of CO_2 gas took only 7.5 minutes to reach equilibrium to the previous intra-abdominal temperature (121).

Core temperatures decreased at a rate of 0.3°C for each 50 L of CO_2 used during continuous infusion during a laparoscopic case. It is advisable, especially during prolonged laparoscopic procedures to warm the patient with an external warmer throughout the procedure to minimize the risk of hypothermia.

Adhesion formation following laparoscopic procedures is often thought to be reduced secondary to a lessened inflammatory response; however, they can and do occur (122,123). Intraperitoneal adhesion formation with the formation of long-term complications of bowel obstruction can be due to inflammation caused by fibrin clot accumulation or direct manipulative injury and subsequent repair processes to the bowel. In numerous studies, laparoscopic procedures routinely demonstrate less risk of subsequent adhesion formation than the open counterpart (123). Controversy continues as to whether instilling a solution of lactated Ringer's or normal saline with or without an antibiotic leads to even fewer adhesions. In addition, additives such as heparin, hyaluronic acid, and tolmentin have also been postulated to decrease the risk of this unusual complication (124).

Other rare risks of laparoscopic surgery include injury to nerves (125). The most commonly injured nerve would be the motor obturator nerve during a laparoscopic pelvic lymph node dissection. Injuries can be direct, that is cutting, lacerating, or crushing the nerve. More likely however, is an indirect nerve injury that can occur by conduction of electrical current (72). These types of nerve injuries manifest insidiously during the postoperative recovery period. Since the nerve is not transected, it gradually becomes less viable and incomplete nerve conduction gradually gives way to a more complete injury. This injury has been also reported to occur with the long thoracic nerve that can be injured with a conductive injury to the inner aspect of the anterior abdominal wall. These patients demonstrate loss of motor function such as inability to adduct the leg with injury to the obturator nerve and winging of the scapula with injury to the long thoracic nerve. Most of the time, a thermal conductive injury to the nerve will resolve over time. This is probably secondary to axonal regeneration. Severed nerves however will not recover unless repaired. An observed injury to a major motor nerve should prompt repair of the injury.

Another category of rare laparoscopic injuries are those associated with retained foreign bodies (126). It is hard to imagine that with the abdomen closed and only trocars traversing the abdominal wall that foreign bodies could be left behind, but in fact this has occurred. As complex intraperitoneal laparoscopic surgeries arise, the inherent complexities and the use of more portals for assistance and retraction will carry an increased risk for foreign body retention. Retroperitoneal dilation balloons can rupture and pieces of the balloon are capable of being left behind (127,128). In one of the largest reported series of retroperineoscopy, Gaur noted that in 351 procedures the retroperitoneal balloon ruptured in several cases, but Gaur et al. (127) state that balloon rupture causes no tissue damage. Adams et al. (128) did report that balloon rupture could lead to excessive times for hunting for fragments. Since the balloon material is typically not radiopaque, only visual exploration can discover their presence. Moore et al. (129) noted that a balloon inflated with liquid created less energy release than a similarly inflated balloon with gas. Laparoscopic clips likewise are foreign and if left behind can cause future consequences (130). Migration of these metallic foreign bodies can happen (131). Finally, the urinary bladder has been identified as the final repository of some of these foreign bodies, such as microtacks that are becoming popular for the performance of laparoscopic hernia repairs (132).

Prevention

It is always preferable to have no complications. This is rarely ever entirely possible, but there are many factors that can be controlled and deserve mentioning here.

First and foremost, the inexperienced or unskilled laparoscopic surgeon is more likely to have significant complications (133). Gaining experience and skill is mandatory. This is best done in a supervised well-controlled environment. Second, the instruments and equipment should be thoroughly familiar with the surgeon (71). Dull trocars, too small of an incision, uncontrolled forward force are all capable of producing catastrophic consequences, particularly major vascular injuries. Simple positional changes can facilitate complex maneuvers such as access, displacement of viscera, or allow straighter trajectory for an instrument. Perpendicular insertion of access instruments such as the Veress needle or trocar can lead to uncontrolled forceful insertions, which is asking for trouble. Lateral deviation of the needle or trocar can also shear into the abdominal wall or any underlying structures and should be avoided until full visual control has been established. An inadequate pneumoperitoneum reduces the working

space for the surgeon and impairs the ability to see peripherally. Whenever the field of view appears to become obscured, consider loss of pneumoperitoneum.

Forceful thrusting with any laparoscopic device should never occur. As mentioned previously, force, especially in a closed pressurized environment, is never good.

Anatomical landmarks should be sought, for laparoscopic anatomy is more statistical and less visual. That is to say, the probability of variability of anatomical structures especially vascular ones should always be forefront in the thoughts of the laparoscopic surgeon. During dissection and accidentally avulsing an accessory vein or artery is the wrong time to consider the possibility of it being there (134).

Finally, make sure that all trocar insertion sites have an adequate skin incison to avoid insertion with unintended forward thrust.

Port site herniation is an interesting problem from a preventative position. As in open surgery, the surgeon is near the conclusion of the operation and the fundamentals of closure can be at times rapidly applied or not fully attended (101,102). Some simple principles apply: do not remove a cannula with their flapper valves open, use the smallest trocar possible (risk of postoperative herniation varies directly with the trocar size), visualize the removal of each trocar, close the fascia of all cannula sites larger than 5 mm (in children and diabetics consider closing the 5 mm ones as well), shake the abdominal wall after the cannulas are removed and before placing fascial closure stitches to reduce the likelihood of viscera protruding into the trocar paths, and if the peritoneum is going to be closed, do so tightly. There are reports of underlying bowel and omentum protruding into large preperitoneal cavities following attempts to close the peritoneum. This could lead to small bowel obstruction and significant postoperative pain.

Medicolegal Issues

Using Chandler et al.'s data discussed previously, the U.S. claims were more likely to have an indemnity payment than those foreign, but this value was not statistically significant. The mean payment for National Association of Insurance Commissioners severity and outcome codes for 2 to 5 was $18,000; for codes 6 and 7 (significant and major permanent, respectively) was $654,000; and if the outcome was fatal the payment was $351,000. A summary of their claims outcome data is summarized in Table 4 (47).

Complications of laparoscopic surgery are a major concern for the patient and the surgeon. There is no doubt that the incidence of injury is proportional to the skill and experience of the surgeon.

The reasons for these observations are probably related to the mechanical disadvantages of working within a confined environment, isolating the surgeon from the normal tactile and sensory ability that is taken for granted with a patient opened. These drawbacks may be overcome in the future by even more advanced digital fusion technologies such as robotic-assisted surgery and microrobotic surgery, virtual reality simulation similar to aviation trainers, endoluminal surgical techniques, and genetic manipulation (136).

Why would a urologist who has spent half a life time training and improving own skills at open urologic surgery wish to start a laparoscopic practice? The only answer lies in the fact that things go well, as they most often do, the patient does much better having not been traumatized to the degree that occurs during standard operative techniques. As Sir Alfred Cushieri (137) has so eloquently phrased, "the ego of the surgeon must always be subservient to the needs of the patient."

INFORMED CONSENT

The risks of laparoscopy are still significant. It is widely recognized that the risk of litigation is influenced by the thoroughness and documentation of informed patient

---

Sidebar notes (left margin):

TABLE 4 ■ A Summary of Indemnity Payments for Litigation of Laparoscopic Malpractice

Outcomes	United States	Europe/Australia/Canada
Years after event (±SD)	5.4 ± 3.0	5.7 ± 2.2
Open without resolution (*n*)	37 (27%)	83 (70%)
Closed (*n*)	98 (73%)	36 (30%)
With payment	53 (54%)	13 (36%)
Median payment ($)	127,000	55,000
Payment range ($)	7,500–4,980,000	1,500–315,955
Principal payment correlate	Incremental disability	Death

consent and alternatives to the procedures. Complications should be "reasonably" described. Presented here is a detailed description of the risks of urologic laparoscopy from which the physician can more readily generate the required disclosure.

Currently, there is a medical malpractice crisis ongoing in the United States (138). Surgeons are the prime target for burgeoning malpractice litigation. Despite the many "potential" benefits of laparoscopic surgery, medical malpractice concerns could be considered as a potential detriment to the acquisition of these advanced skills. Data from medical insurance companies indicate a definite rise in malpractice claims. The real rise in laparoscopic surgeries began in late 1989 (139). If complications reflect the learning curve of new surgeries and new surgeons, one could have expected a plateau of malpractice activity soon following this date. This in fact, has not occurred. There has been a steady, continuous rise in both the number of malpractice claims and the percentage of claims with pay out to the plaintiff (140). Also, when a jury finds in favor of the plaintiff in a laparoscopic malpractice suit, the probable result will be a higher award than in a similar open procedure. Though no one can say what is the driving force in this evolution, the most compelling explanation is that the patients are going into to these types of "minimally invasive" or "band-aid" operations with unrealistic expectations. That is to say that the patient perceives that something less significant is going to happen to them than if they were to undergo a "real" operation. Patients are told that the laparoscopic procedure will cause less postoperative pain, that they will recover quicker, that they can resume normal activities more quickly, and that they will have little scars. Add an actual complication and the disappointment to the patient is hard to minimize, especially when the patients have to suffer the "horror" of scarring, prolonged hospital stays, and the possibility of several operations to repair an inadvertent injury. It is not a difficult scenario for a jury to find in favor of the plaintiff.

Informed Consent Legalese

The jargon utilized by the legal system can be overwhelming. Some basic definitions are warranted for review (141). A plaintiff is the person who alleges malpractice. The defendant is the laparoscopic urologic surgeon, an assistant, and possibly the hospital where the surgery was performed. A complication is some difficulty, problem, or change in the patient's health that is unintended. Negligence is the failure to exercise the degree of care considered reasonable under the circumstances, resulting in an unintended injury to the plaintiff. Damages are the estimated valuation of the injury sustained. Informed consent is the process, whereby the patient is informed about treatment options, alternative treatment modalities, the risks of treatment, the benefits of treatment and must provide for the answering of a patient's questions (142).

For many patients, the occurrence of a complication automatically demonstrates negligence. The primary defense of a laparoscopic surgeon to an allegation of lack of informed consent is documentation of adequate informed consent.

> For many patients, the occurrence of a complication automatically demonstrates negligence. The primary defense of a laparoscopic surgeon to an allegation of lack of informed consent is documentation of adequate informed consent.

The medical record can be the surgeon's best friend or worst enemy. It behooves the laparoscopic urologic surgical practitioner to understand fully the requirement of adequate informed consent (143). Although persons other than the surgeon may obtain the patient's signature on an informed consent document, may hand out educational pamphlets, and show videos of surgical decision making, the surgeon must go through those obligatory steps just outlined and would be well advised to document it all in the patient record.

The issue of complications rates and trends in laparoscopic surgery are far more advanced in gynecology and general surgery than they are in urology (134,144–146). In fact, there have been little published data on complication rates following laparoscopic urologic surgery because series have tended to be small, follow-up still is short, and multi-institutional collaborations are just beginning to report. Laparoscopic complications can be grouped into those that are generally related to laparoscopy (access, exit, pneumoperitoneum injuries) and those that are specifically related to the procedure (laparoscopic nephrectomy, laparoscopic radical prostatectomy, etc.). It is important to note that procedural-related complications should be independent of the approach, thus unique to the operation being performed. This is important because an individual who has an unusually high procedural-related complication rate indicates an error in judgment or technique. Current trends from malpractice databases indicate that injuries general to laparoscopy are in the minority of lawsuits, under 25%, and declining (146). Knowledge on trends in complications serves two purposes; it allows the surgeon insight into the problems encountered by others practicing similarly. It is obvious that if you are aware of possible complications, you are more apt to try to prevent it from occurring.

The risk of laparoscopic malpractice in general surgery centers around three specific complications in 90% of cases: bile duct injury, perforating bowel injury, and major vascular injury. Currently, about two-thirds of laparoscopic complications are bile duct injuries during laparoscopic cholecystectomy and though interesting for those curious about injury, injury prevention, malpractice issues, and preventative mechanisms, there is little significantly relevant to urologic discussions; so attention will be focused upon the remaining 34% of laparoscopic injuries. Currently 12% of injuries are bowel related, 10% are vascular, and 11% are other injuries. In this other category includes a hodgepodge of various complications including fistula formation (2%), burns (2%), retained gall stones (1%), retained foreign body (1%), and others (ureteral or bladder injury, incidental splenectomy, etc., 6%) (21,26). Because most surgeons still utilize the blind Veress needle method for pneumoinsufflation because the risks are quite small, the primary common access complication is from the initial trocar access. Blind trocar insertion injuries can probably be eliminated or significantly reduced if open insertion techniques are utilized. It has been estimated that the surgeon automatically reduces risk to the patient by 20% by utilization of open laparoscopic access. Open laparoscopic access does not eliminate injury to underlying viscera and vessels, but it reduces the probability (147).

Informed consent is derived from judicial decisions and not statute. One exception is New York Public Health § 2805-d enacted as Chapter 109 of the New York Laws of 1975 (148). A person facing the prospect of surgery must be aware of the untoward side effects that are known to result from the proposed surgical procedure, the intended beneficial effects of the proposed surgical procedure, and the alternative reasonable ways to address the patient's problems. These risks, benefits, and alternatives must be discussed with every patient or the patient's legal guardian in order to insure that informed consent is secured. The problem with these terms comes in the derived method of interpretation. The court differ on how much information must be divulged to each patient in order to make each decision informed? The early rule was that a physician had to disclose what a "reasonable doctor" would provide under the circumstances. Later, courts required physicians to disclose what a "reasonable patient" would wish to know before making a decision (149).

Informed consent cannot be obtained from the patient who is impaired such that the patient lacks capacity to give consent (150). Certainly, it is not wise for a patient to be asked to sign the consent form in the operative holding area (151). Most laparoscopic urologic surgeries are thought of as elective procedures. Therefore, the time afforded the patient to make an informed decision should be documented. With information provided to the patient and family well in advance, the patient may pose questions, confer with other physicians, or ask for a second opinion (152). This ideally minimizes the duress experienced when the consent is obtained. When patients are minors or incapacitated, discussions should be held in the same fashion with the patient's legal guardian. In the case of an emergency, the physician must inform the patient to the best of his ability and within the constraints of time and the patient's severity of illness (150). It should be remembered that there are three varying perspectives that alter negligence: the patient's, the doctor's, and the lawyer's.

Legal counsels recommend four steps to lower your litigation risks (134). First is secured via a thorough informed consent. Second is communicative clarity with the patient. Third is demonstrating concern for the patient's medical condition. Fourth is mastering technically difficult procedures.

The legal implications of any reasonable patient implies that if a surgeon lacks familiarity with a given endoscopic procedure, it is advisable to inform the patient that this is the first time the surgeon is performing the procedure (54).

Some would advise with common knowledge about the "learning curves" of various laparoscopic operations that the patient deserves to know how many the surgeon has performed (154).

The risks of laparoscopic urologic surgery are changing. In 1987, Weinberg et al. (155) were the first to suggest that practical experience and the number of complex ureteropyeloscopies represented a fundamental variable in the number and seriousness of complications. They noted that in centers where greater than 50 ureteropyeloscopies were performed per year the success rate was noted to be 84%, whereas if less than 20 cases were done the success rate was 78% (all stone removals). Major ureteral injury in this review was 4.4% with total complication rates of 10% (including postoperative fever). Complications were twice as likely to occur at centers where fewer than 20 cases were performed versus centers that did more than 50 cases (155). Whether these same trends apply to laparoscopic urologic surgery is not yet known. The abundant surgical literature would support this claim that the complication rates do go down as the number of cases the surgeon performs increases.

Legal counsels recommend four steps to lower your litigation risks. First is secured via a thorough informed consent. Second is communicative clarity with the patient. Third is demonstrating concern for the patient's medical condition. Fourth is mastering technically difficult procedures.
The legal implications of any reasonable patient implies that if a surgeon lacks familiarity with a given endoscopic procedure, it is advisable to inform the patient that this is the first time the surgeon is performing the procedure.

Costs of Training/Ethical Considerations of Certification

Following initial reports of laparoscopic cholecystectomy, surgical practice in the United States has undergone substantial change. There has been a torrential outpouring of interest to learn new endoscopic techniques. The costs absorbed by practitioners to attend courses were hefty and few academic centers availed themselves of the early training experience (156). Some groups started small businesses of training surgeons, as the demand was so acute and the courses themselves proved financially rewarding. This scenario is not entirely different to the training conditions of the late 1800s in the United States, where Halsted (157) stated, "the man who had settled his tuition bill was thus practically assured of his degree, whether he had regularly attended lectures or not."

The history of postgraduate surgical education is very limited. The laparoscopic boom of the early 1990s changed all of this. Traditional academic centers were bypassed by industry and practicing surgeons began courses "for profit" in unregulated fashion, with no defined objectives, and with no consideration of surgical application of skilled technique. Dr. Seymour Schwartz (158) stated at one point, "the speed of change has resulted in a scenario where the more senior educators, usually those responsible for the structure and format of educational programs, are the least informed about modern elements." The patient was the ultimate denominator in this process of an unregulated sprint for application of complex technology to a common clinical condition. Since organized, academic medicine was unwilling or unable to halt this process, the State of New York issued a memorandum in 1992 that training and credentialing surgeons needs further scrutiny (159). As of 1999, according to the American Board of Surgery, the mean number of advanced laparoscopic procedures performed by graduate trainees was fewer than 10 (160). The American Board of Urology has not issued any information regarding graduate training patterns for U.S.-trained urologists, but surveys among endourologists at leading academic centers suggests that no letters of credential support has yet been issued for laparoscopic urologic surgery.

Interestingly, the Society of American Gastrointestinal Endoscopic Surgeons (161) approved guidelines for granting privileges to general surgeons performing laparoscopy in May of 1990. Individual institutions are currently encouraged to develop their own guidelines on accreditation. The Society of American Gastrointestinal Endoscopic Surgeons board of governors developed and issued the "framework of postresidency training" in 1994, to serve as a template for the American Medical Association's guidelines for postresidency training and credentialing. In 1997, in cooperation with both U.S. Surgical Corp. and Ethicon Endo-Surgery, Society of American Gastrointestinal Endoscopic Surgeons commenced biannual courses in advanced laparoscopic surgery. By 1998, Society of American Gastrointestinal Endoscopic Surgeons published its first manual on laparoscopic surgery and began work on an interactive computer-based program to enhance surgical laparoscopic skill, called the fundamentals of laparoscopic surgery program (161). No other organized group, other than the Society of Laparoscopic Gynecologists has been more proactive in the educational concerns that continue to haunt advanced laparoscopic technology and their clinical application. Frank Spencer's (162) presidential address of the International Cardiovascular Society 25 years ago is a poignant today as it was then, "Clearly a large part of education, especially in this age of rapid obsolescence of knowledge within a few years, should be in the postresidency years. This seems particularly significant to me, for over 90% of the operations I currently perform simply did not exist when I finished my residency."

> Postresidency education is such a critical issue in light of modern laparoscopic accomplishments that it should become a central issue to our governing boards and societies.

Postresidency education is such a critical issue in light of modern laparoscopic accomplishments that it should become a central issue to our governing boards and societies.

The American Board of Medical Specialties created a task force to investigate competencies (163). They realized that they must adopt a method of reviews that would cover the training of physicians as a continuum from residency through retirement. "Depth as well as breadth can be discerned as physicians explore levels of expertise ranging from novice to master," states Leach (164) in a recent article. The Accreditation Council for Graduate Medical Education in 1999 endorsed six general competencies: patient care, medical knowledge, practice-based learning and improvement, professionalism, interpersonal and communication skills, and system-based practice. The "Professor," Sir William Osler (165), once stated, "the whole art of medicine is an observation ... but to educate the eye to see, the ear to hear, and the finger to feel take time ... to start a man on the right path, is all we can do."

Medicolegal Considerations

Kohn et al. (166) have estimated that between 44,000 and 98,000 deaths annually have been attributed to medical error in their work *To Err is Human*. As the endoscopic surgeon is entirely dependent upon the technology and skill, there has been increased emphasis

on comparing the laparoscopic surgeon to the airline pilot. In aviation, the pilot is expected to perform with a risk of failure less than 0.0001%. If the same holds to laparoscopic surgery, with laparoscopic cholecystectomy (the most commonly performed laparoscopic procedure in the world) as the yardstick, then bile duct injury rate of 0.5% seems unacceptable (167). Most complications can be prevented by complete control of the technology and the procedure. The fact that an increase in the performance of laparoscopic surgery has led to rise in the numbers of malpractice litigation should not be surprising. In fact, the Association of Trial Lawyers of America set a specialized subdivision in 1994, the Laparoscopic Litigation Group, that advises lawyers on how to approach laparoscopic surgery cases. Most laparoscopic surgery cases that go to a jury verdict, favor the defendant (47). One source of in-depth information comes from the Physician Insurers Association of America involving laparoscopic injuries in the United States. The Physician Insurers Association of America is a trade association of physician- and dentist-owned professional liability insurers, with more than 60 member companies that insure greater than 60% of all U.S. private practice groups. There are also affiliated groups in Europe, Australia, and Canada (24). One recent study abstracted claims from this group from 1980 to 1999 and identified 364 U.S. claims and from 1986 to 1999 identified 137 non-U.S. claims. For each case they utilized the National Association of Insurance Commissioners severity index coding (47).

Chandler et al. (47) found that 594 structures or organs were injured in 506 patients, ranging in age from 9 to 86 years. The mean age was 41.6 years and 86% of the patients were women. Two organs or structures were injured in 64 patients, and three or more structures were damaged in 11 individuals. Laparoscopic cholecystectomies comprised 51% of the Physician Insurers Association of America claims in the United States whereas gynecologic laparoscopy comprised 47% of non-U.S. claims. The most frequently injured structure was the small bowel ($n = 146$, 25.4%), iliac artery ($n = 106$, 18.5%), colon ($n = 70$, 12.2%), iliac or other vein ($n = 51$, 8.9%), mesenteric vessel(s) ($n = 42$, 7.3%), aorta ($n = 37$, 6.4%), inferior vena cava ($n = 25$, 4.4%), abdominal wall vessels ($n = 229$, 3.8%), urinary bladder ($n = 19$, 3.3%), liver ($n = 13$, 2.3%), major visceral vessel ($n = 10$, 1.6%), stomach ($n = 9$, 1.6%), and other ($n = 24$, 4.2%). The severity of the injury using the National Association of Insurance Commissioners score was reflected in the fact that more than half of survivors (55%) were scored as 4, indicating major temporary impairment or disability. Sixty-five fatalities were reported. Mortality was significantly lower in the U.S. cases than in the non-U.S. cases. Logistic regression showed that an age greater than 59 years was the sole significant predictor of survival from a major laparoscopic injury. Injury to major viscera vessels and delay in diagnosis greater than 24-hours were significant variables. Looking at indemnity payments, those made in U.S. cases were significantly greater median payments than those from non-U.S. cases. The mean payment for National Association of Insurance Commissioners severity codes 2–5 was $118,000; for codes 6 and 7 it was $654,000, and for fatal outcomes the award was $351,000. The payment for plaintiffs in the United States ranged from $7500 to $4,980,086. In non-U.S. cases, the range was $1500 to $315,955. These findings particularly underscore the subtleness, lethality, and litigious attractiveness of laparoscopic bowel injuries. Electrosurgery injuries are particularly catastrophic even if they are noticed. The depth of thermal necrosis is difficult if not impossible to assess at the time of occurrence, and perforation might not occur at all. Most electrosurgical injuries occur out of the surgeon's line of sight and are missed. This presents that same subtle presentation, which requires careful attention and high degree of suspicion. These injuries are all more likely to occur during the surgeon's initial experience with advanced laparoscopic procedures (24,47).

SUMMARY

■ Routine urologic laparoscopic surgery is no longer futuristic, but actual clinical practice at some institutions. Horizons for expanding the laparoscopic surgical realm are broad (168).

■ Manufacturers, research engineers, optical engineers, roboticists, computer engineers, software engineers, communications specialists, and surgeons must be able to constructively work together in order to minimize the time to perfect new instruments and procedures (169,170).

■ The doctor–patient relationship must always be of foremost concern to the laparoscopic surgeon. The trust in the surgeon for allowing the patient to be the first to have this procedure done cannot be underestimated. Ethically, the laparoscopic surgeon must be forthright in assessing own skills, the mastery of the laparoscopic procedure, the indications of the procedure, and must maintain healthy skepticism of newer procedures until adequate data are available (171–174).

■ The proctor for laparoscopic urologic surgery has to date benefited from unprecedented legal immunity. Proctoring and peer reviews remain mechanisms utilized by physicians to ensure high-quality outcomes, and as such, continue to receive comprehensive legal immunity in order to prevent reprisals (175). The law is clear that the some kind of proctorship is necessary for physicians to begin to practice advanced technologic surgeries, neither legal cases nor the Joint Commission on Accreditation of Hospitals provides much guidance on the process to fulfill this responsibility (176).

■ New technology has an apparent life cycle with five stages: (i) feasibility (technical performance, applicability, safety complications, morbidity, mortality); (ii) efficacy (benefit for the patient demonstrated in centers of excellence); (iii) effectiveness (benefit for the patient under normal conditions, reproducible with widespread application); (iv) costs (benefit in terms of cost effectiveness); (v) gold standard (177).

THE FUTURE

CHAPTER 93

TISSUE ENGINEERING

J. Daniell Rackley and Anthony Atala

Department of Urology, Wake Forest University Baptist Medical Center,
Winston-Salem, North Carolina, U.S.A.

INTRODUCTION

The entire genitourinary system is subject to a variety of possible insults from the beginning of development through adult life. Tissue loss may result from acquired disease as well as congenital disorders—infection, trauma, malignancy, iatrogenic injury, obstruction, and other disease processes. Also, many children are born with conditions that render their urinary tract organs suboptimal or nonfunctional, such as spina bifida or renal parenchyma loss from posterior urethral valves. In the past, damaged organs have been replaced with autologous and allogenic tissues. While both of these solutions have enabled patients to lead more normal lives, both are fraught with potential complications inherent in the donated tissue. For example, urinary diversion with intestine may have sequential electrolyte abnormalities, and renal transplantation may lead to multiple complications associated with immunosuppression. The field of regenerative medicine stems from the desire to create replacement tissues, for patients whose own tissues are deficient, with functionally and physiologically equivalent tissues that are not subject to rejection by the body's immune system.

Tissue engineering applies the concepts of cell transplantation, materials science, and engineering in an effort to develop biological substitutes that can restore and maintain normal function. As this technology improves and these concepts become more and more clinically applicable, minimally invasive methods of tissue harvest and transfer will be sought. Laparoscopy, no doubt, will be at the forefront, as tissue engineering makes its way into clinical practice.

BASIC PRINCIPLES OF TISSUE ENGINEERING

The source of donor tissue can be heterologous, allogenic, or autologous; autologous is preferred as this method avoids tissue rejection by the immune system and immuno-suppressive drugs can be avoided. When autologous cells are used, a biopsy is obtained from the host and the cells are dissociated and expanded, and later returned to the same host as new tissue that is not immunogenic.

> Tissue engineering "entails" the use of donor tissue that is dissociated into individual cells. The cells are either implanted directly into the host, or expanded in culture, attached to a biodegradable support matrix, and reimplanted after expansion.

Tissue engineering "entails" the use of donor tissue that is dissociated into individual cells. The cells are either implanted directly into the host, or expanded in culture, attached to a biodegradable support matrix, and reimplanted after expansion (1–3).

In its early phases, cell-based tissue engineering was limited by the inability to grow specific cell types in sufficient quantities for implantation. Many cell types, including urothelium, seemed to have a natural senescence that prevented their expansion in vitro. However, several protocols have been developed over the past two decades that have improved urothelial growth and expansion in the laboratory (4,5). Improved understanding of the privileged sites for precursor cells in specific organs and the conditions that promote differentiation has led to techniques that have overcome the difficulties of in vitro cell expansion. Cilento et al. demonstrated that

a urothelial strain from a single specimen, initially covering a surface area of $1 \, cm^2$, could be expanded to cover an area of $4202 \, m^2$ (the equivalent area of one football field) in eight weeks.

Reported studies demonstrated that it would be possible to harvest autologous bladder cells from human patients, grow and expand them in vitro, attach them to a support matrix, and use them in the same patient for reconstructive purposes.

Bladder, ureter, and renal pelvis cells can equally be harvested, cultured, and expanded in a similar fashion. The next step is clinical application of these techniques in humans, and major advances have been achieved in the past decade, which will make the use of autologous cells in patients for expansion a possibility.

BIOMATERIALS FOR GENITOURINARY TISSUE ENGINEERING

Biomaterials should provide a three-dimensional space for cells to form into new tissues; they should allow for delivery of the desired cells for tissue replacement and appropriate bioactive factors (cell adhesion peptides, growth factors) to desired sites in the body, and guide the development of new tissues with appropriate function (6).

In tissue engineering, a scaffold that allows cell adherence and regeneration is essential. The materials that are used as scaffolding should replicate the biologic and mechanical function of the native extracellular matrix.

The majority of mammalian cell types are anchorage-dependent and must have a cell-adhesion substrate for survival; biomaterials provide a cell-adhesion substrate that can deliver cells to specific sites in the body with high loading efficiency. The scaffolding also provides mechanical support against in vivo forces, thereby maintaining the integrity of the predefined structure until the cells have matured into the desired three-dimensional structure.

A foreign body response should be avoided as it leads to rejection and/or necrosis and ultimately failure of the graft. As the scaffolding is metabolized by the host, its degradation products should be nontoxic, nonimmunogenic, and removed from the host at the appropriate rate such that the concentrations of these products remain at a tolerable level. Furthermore, the biomaterial should provide an environment in which cell behavior is not altered. Cell adhesion, proliferation, migration, and differentiation should promote functional tissue formation.

The ideal biomaterial should also be biocompatible. The biomaterial should persist for an appropriate amount of time to allow for adequate replacement of normal tissue, but it should be absorbed by the host without inflammation.

The naturally derived materials have the potential advantage of cellular recognition and biologic response. However, synthetic polymers can be reproduced on a large scale with controlled properties of strength, degradation rate, and microstructure.

Collagen, the most abundant structural protein in the body, is readily purified from both animal and human tissues with an enzyme treatment and salt/acid extraction. Collagen generates minimal inflammatory response, and it has been approved by the U.S. Food and Drug Administration for many types of medical applications, including wound dressings and artificial skin. Collagen implantation is limited by its relatively rapid degradation from sequential attacks by lysosomal enzymes. Acellular tissue matrices are collagen-rich matrices prepared by mechanical and/or chemical removal of the cellular components from tissues leaving only the supportive scaffolding behind. This artificial extracellular membrane slowly degrades after implantation and is replaced by true extracellular matrix proteins synthesized and secreted by transplanted or ingrowing cells.

Three basic classes of biomaterials have been utilized in the engineering of genitourinary organs: naturally-derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa and small intestinal submucosa), and synthetic polymers [e.g., polyglycolic acid, polylactic acid, and poly(lactic-co-glycolic acid)].

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell delivery vehicle and a cell immobilization matrix owing to its gentle gelling properties in the presence of divalent ions such as calcium. Alginate is limited by its lack of a biologic recognition domain and limited range of mechanical properties.

Polyesters of naturally occurring alpha-hydroxy acids, including polyglycolic acid, polylactic acid, and polylactic glycolic acid, are used widely in tissue engineering. The Food and Drug Administration has approved the use of these polymers for a multitude of clinical applications including sutures. These polymers contain ester bonds, which are hydrolytically labile, allowing their degradation by nonenzymatic hydrolysis. Their degradation byproducts are nontoxic—natural metabolites that are eliminated from the

host in the form of water and carbon dioxide. These materials can be constructed such that they degrade in several weeks to several years by altering the crystallinity, initial molecular weight, and the copolymer ratio of lactic to glycolic acid. Also, these polymers are thermoplasts, which allows them to be formed into the appropriate three dimensional scaffolds with a desired microstructure, gross shape, and dimension by various techniques, including molding, extrusion, solvent casting, phase separation techniques, and gas foaming techniques. These techniques can be used to process biomaterials into porous sponges and fiber meshes, which have high porosity and a high surface area-to-volume ratio; these properties enhance the effectiveness of the scaffold. Other biodegradable synthetic polymers including poly(anhydrides) and poly(ortho-esters) also can be used to fabricate scaffolds for genitourinary tissue engineering with controlled properties.

Bladder

Neobladders and bladder augmentations are being performed with increasing frequency. Obviously, there is an enormous need for bladder replacement tissue. The gastrointestinal segments that are currently used lack the physiologic and mechanical properties of urothelium. While gastrointestinal tissues are designed to absorb specific solutes, the urothelium is designed for urine storage, not the transfer of electrolytes. Despite the acceptable functional results of enterocystoplasty and orthotopic neobladder, numerous complications can arise from the combination of intestine (with its associated heterotopic epithelium) and the urinary tract (7). Metabolic, infectious, and calculus complications, as well as the morbidity associated with enteric surgery have driven numerous investigators to explore the use of alternative materials and tissues for bladder replacement or repair.

The success of using cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long-term survival, differentiation, and growth.

Numerous nonenteric biological and synthetic materials have been used for bladder augmentation and bladder replacement in animal models. A variety of complications have occurred with the use of synthetic materials that have limited its widespread use (8). Tissue engineering with selective cell transplantation is a feasible strategy to create new, functional bladder tissue (9).

Using cellular tissue engineering, composite bladder tissue of urothelium and muscle cells can be expanded in vitro and seeded onto a polymer scaffold, generating sheets of cells (4). Other early experiments demonstrated that the engineered bladder tissue implanted into mice formed composite tissue with layers of muscle cells lining multilayered epithelial sheets.

To test the effects of implanting engineered bladder tissue in continuity with the urinary tract, an animal model was used. Subtotal cystectomies were performed in dogs (1,10). Urothelial and muscle cells were separately expanded from an autologous bladder biopsy. A collagen-based matrix derived from allogenic bladder submucosa served as the vehicle for cell delivery.

The augmented bladders demonstrated cellular organization consisting of a trilayer of urothelium, submucosa, and muscle.

Radiographic and urodynamic studies revealed compliant, large-capacity bladders. An average bladder capacity of 95% of the precystectomy volume was achieved in the tissue-engineered bladder specimens (Fig. 1).

Laparoscopic bladder augmentation is being done in humans (11); however, laparoscopic bladder augmentation with engineered tissue has only recently been described in animal models.

The success of using cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long-term survival, differentiation, and growth.	

The augmented bladders demonstrated cellular organization consisting of a trilayer of urothelium, submucosa, and muscle.

Laparoscopic bladder augmentation is being done in humans; however, laparoscopic bladder augmentation with engineered tissue has only recently been described in animal models.

FIGURE 1 ■ **(A)** The native canine bladder prior to trigone–sparing cystectomy. **(B)** The engineered neo-organ is anastomosed to the trigone. **(C)** The implant, decompressed by a transurethral and suprapubic catheter, is wrapped with omentum.

Clayman and coworkers developed a laparoscopic technique for augmentation cystoplasty with engineered tissues in minipigs (12). The animals underwent successful laparoscopic partial cystectomy and closure with patch augmentation utilizing various free grafts (acellular) materials. Cell-seeded graft materials were not used in this study. Laparoscopic partial cystectomy was first performed through a transperitoneal approach. The excised bladder specimen was measured and a biodegradable patch twice that size was used. Four Vicryl corner sutures were placed to assist with intra-abdominal orientation and fixation to the bladder wall. The patch was placed into the abdomen through one of the 12 mm ports and oriented to the bladder wall by aligning the four preplaced sutures with the corners of the bladder defect. The corners were secured with an absorbable Lapra-Ty clip, and the anastomosis was completed with an EndoStitch with 4-0 Vicryl sutures. The bladder was drained with a urethral catheter for one week. Mean operative time was three hours, and blood loss was minimal in all cases. Two of 31 pigs had post-op complications—one control animal had an anastomotic leak, and one animal with a human placental membrane patch developed a leak in the patch. The majority of the augmented bladders contracted over time, because the scaffolds were acellular, and not seeded with cells.

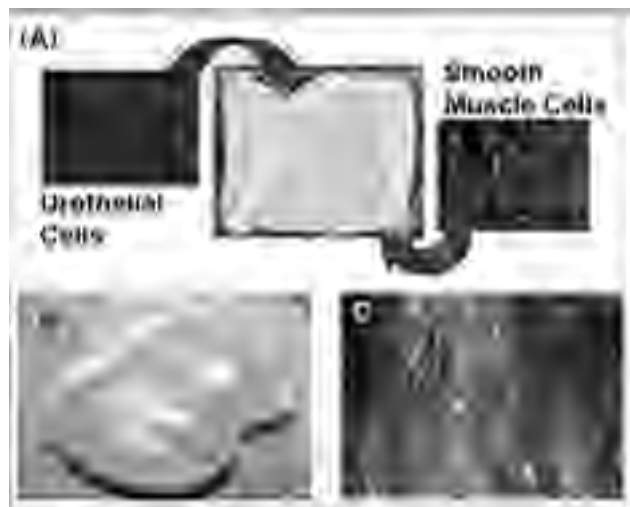
Nonetheless, this animal study demonstrated that laparoscopic bladder augmentation with engineered tissue is technically feasible, and can be performed safely in a large animal model.

Recently, Clayman and coworkers in collaboration with our research team, have performed total bladder replacement with allogenic bladder submucosa coated with urothelial and detrusor cells (13). Five minipigs underwent neobladder creation with acellular bladder submucosa, while 10 minipigs underwent bladder replacement with bladder submucosa coated cells. All surgeries were performed with laparoscopy. All animals were evaluated with urodynamics, radiological studies, and serum chemistry pre- and postoperatively.

The bladder submucosa coated cells was prepared from hemicystectomy specimens obtained from the test animals laparoscopically. Urothelial and muscle cells were cultured using previously described techniques, and expanded separately. The urothelial cells were seeded on the luminal surface of the acellular bladder submucosa, and muscle cells were seeded on the opposite side. The grafts were then fashioned into a neobladder and implanted into the animals after a total cystectomy.

Three technical points should be noted about the laparoscopic neobladder, as this technique has not been previously described. First, the neobladder itself was created by fashioning the bladder submucosa coated cells composite into a 50 cc sphere over an inflated catheter balloon extracorporeally (Fig. 2). The neobladder was closed with running 4-0 Vicryl in a horizontal mattress. Second, the urethral anastomosis was completed by aligning the bladder submucosa coated cells with the urethral stump. This was facilitated by preplacing stay sutures in the bladder submucosa coated cells neobladder at 6 and 12 o'clock position. The remainder of the anastomosis was closed with interrupted sutures. Also, two methods of ureteral implantation were described. Six pigs received end-to-side anastomoses to the dome of the bladder submucosa coated cells with

Nonetheless, this animal study demonstrated that laparoscopic bladder augmentation with engineered tissue is technically feasible, and can be performed safely in a large animal model.

FIGURE 2 ■ Tissue-engineered neobladder. (A) Tri-layer grafts of host urothelial and detrusor cells seeded onto bladder submucosa. (B) Acellular collagen matrix (after cell seeding). (C) Electron microscopy of cellular collagen matrix (after cell seeding).


placement of a JJ (double-J) ureteral stent. Four pigs had the ureteral anastomoses performed using the "dunk" technique. Two small openings were created at the dome of the bladder submucosa coated cells prior to its placement into the abdomen. One of the mobilized ureters was placed through one of the openings and out of the other. The medial surface of the ureter that entered and exited the neobladder was sewn to the medial surface of the contralateral ureter and then gently pulled until both ureteral orifices were inside the bladder submucosa coated cells graft. Each ureter was fixed to the exterior of the neobladder with sutures. This technique precluded the use of stents. Any leaks in the neobladder after closure were closed with 4-0 Vicryl. Omentum was mobilized to cover the neobladder in six pigs. All procedures were successfully completed laparoscopically.

Over time, bladder capacity decreased in both the bladder submucosa coated cells and acellular bladder submucosa groups, but more severely in the acellular bladder submucosa bladders. The mean survival for acellular bladder submucosa and bladder submucosa coated cells bladders was 52 and 65 days, respectively. One animal in the bladder submucosa coated cells group died on postoperative day 2 secondary to leakage at the bladder dome and urinary ascites. The remaining deaths were due to progressive uremia requiring euthanasia. Small contracted bladders with bilateral hydroureteronephrosis were noted on autosopy studies. The urethral anastomoses were narrowed but patent in both bladder types. There were no appreciable differences with regard to ureteral implantation in the end to side or dunk technique. Cystoscopic examination of the bladder submucosa coated cells grafts appeared endoscopically similar to normal bladder with gross appearance of submucosal and surface vessels. All reimplants were patent but somewhat narrowed; each demonstrated reflux on cystograms performed before animal sacrifice.

The creation of a neobladder using engineered bladder tissue and laparoscopic techniques is technically possible.

While more advancements in technology are needed before this approach is clinically applicable in humans, this attempt may represent the future of tissue engineering and laparoscopy.

Kidney—Therapeutic Cloning and Stem Cells

Approximately 70,000 people in the United States are on a transplant wait list due to renal disease. The two currently available options for such patients are dialysis and renal allotransplantation. Both options are life-sustaining, but both are associated with significant morbidity and mortality. Dialysis is often poorly tolerated, and transplantation is burdened with severe donor shortages as well as the complications that accompany immunosuppression. This has motivated researchers to develop alternative solutions for end-stage renal disease. Previous methods of tissue engineering of renal tissue involved extracorporeal systems comprising biologic and synthetic components. Somatic cell nuclear transfer theoretically can reduce or eliminate the immune response of allogenic grafts.

Genetically identical renal tissue has been produced applying the principles of tissue engineering and therapeutic cloning in a large animal model, the cow (Bos Taurus) (14).

Stem cells were created by isolating and microinjecting single bovine skin fibroblast donor cells into the perivitelline space of donor enucleated oocytes (nuclear transfer). Renal cells were isolated from a cloned metanephros and expanded until the desired number of cells was obtained. The renal cells were then seeded onto scaffolds consisting of three collagen-coated cylindrical polycarbonate membranes. Renal devices were constructed by connecting catheters to the ends of three membranes. The catheters functioned as a collecting system that drained into a reservoir, thereby creating a renal neo-organ with a mechanism for collecting excreted fluid. The devices were then subcutaneously implanted back into the same steer from which the genetic material was derived. The renal devices were explanted after 12 weeks and studied.

On gross inspection, the renal units appeared intact, and yellow, urine-like fluid was seen in the reservoirs. Chemical analysis of this fluid suggested unidirectional secretion of urea nitrogen and creatinine, as well as filtration and reabsorption of glucose and other electrolytes (Fig. 3). Histological examination of the retrieved implants demonstrated extensive vascularization of the renal units, and self-assembly into glomeruli and tube-like structures. A continuum between the glomeruli, tubules, and polycarbonate membrane was observed that allowed passage of urine into the collecting system reservoir. Renal specific proteins were detected in the renal units with immunohistochemical analysis and Western blot analysis. Reverse transcription-polymerase chain reaction analysis confirmed the transcription of renal-specific ribose nucleic acid in the cloned specimens. The cloned renal cells also produced both erythropoietin and 1, 25-dihydroxyvitamin D_3, important endocrine metabolites produced by a normal kidney.

The creation of a neobladder using engineered bladder tissue and laparoscopic techniques is technically possible.

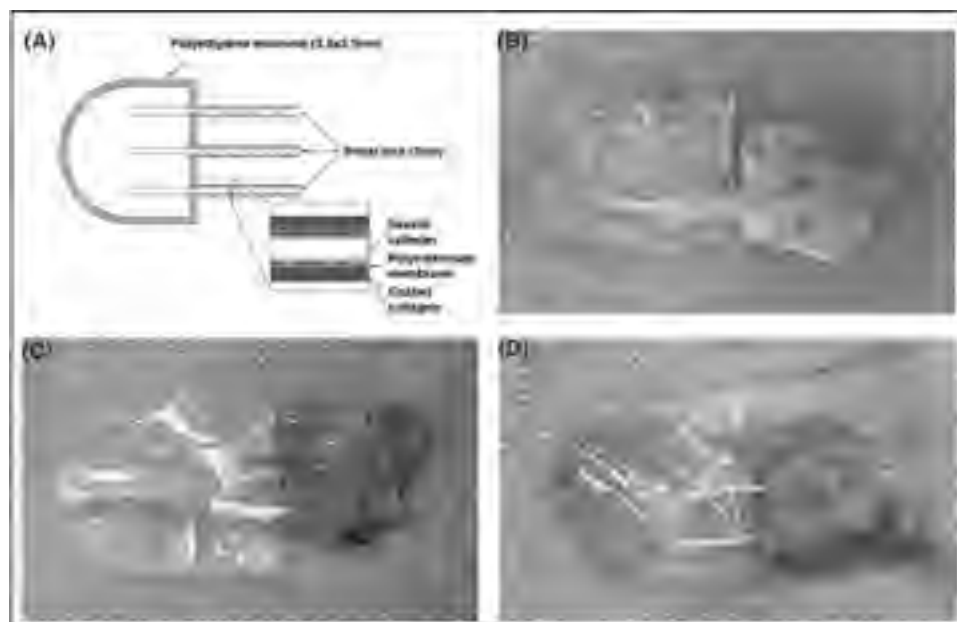
Genetically identical renal tissue has been produced applying the principles of tissue engineering and therapeutic cloning in a large animal model, the cow (Bos Taurus).


FIGURE 3 ■ **(A)** Illustration of renal unit and units retrieved three months after implantation. **(B)** Unseeded control. **(C)** Seeded with allogeneic control cells. **(D)** Seeded with cloned cells, showing the accumulation of urine-like fluid.

The goal of therapeutic cloning, as described above, is to produce tissues that are genetically identical to those of the donor. Other researchers have demonstrated that animals produced by somatic cell nuclear transfer inherit their mitochondria entirely or in part from the recipient oocyte and not from the donor cell (14). Theoretically, these foreign mitochondrial proteins derived from the oocyte could produce an immune response from the donor after transplantation. We investigated the possibility of an immune response to the cloned renal units described above with delayed-type hypersensitivity testing in vivo and Elispot analysis of interferon-gamma–secreting T-cells in vitro. Neither test demonstrated an immune response to the cloned renal tissue, suggesting that rejection will not necessarily occur in the presence of oocyte-derived mitochondrial deoxyribonucleic acid. This finding offers the possibility that renal tissue can be derived via nuclear transfer and that these tissue may be implanted in a host without the histocompatibility issues that plague other forms of allotransplantation.

SUMMARY

■ Both tissue engineering and laparoscopy sit at the forefront of the technological advancements that are being achieved in urologic surgery.

■ Remarkable achievements in laparoscopy over the past two decades have dramatically reduced the morbidity associated with many procedures.

■ Regenerative medicine offers the hope that patients with organ loss can receive tissues that are functionally and genetically identical to those that were lost.

■ Tissue engineering efforts are currently underway for virtually every organ and tissue type within the urinary tract.

■ As these two technologies mature, it may become only a matter of time until their paths cross in a way that will advance the field of organ and tissue replacement.

HYDRO-JET TECHNOLOGY

Bijan Shekarriz

Department of Urology, SUNY, Upstate Medical University,
Syracuse, New York, U.S.A.

INTRODUCTION

The principle of hydrodissection is the use of a stream of water to expand and delineate surgical planes. Hydrodissection was originally described for gynecologic pelvic procedures (1–3), and performed using a suction–irrigation probe (5-mm diameter) by injecting normal saline at 300 mmHg into the subperitoneal space to enter the space of Retzius (2). Hydrodissection was also used to develop tissue planes in the avascular pelvic area during laparoscopic hysterectomy (3). The pressures used were in the range of 200 to 800 mmHg (1). Another indication for hydrodissection was laparoscopic cholecystectomy by injecting 50 mL of saline with a cyst aspiration needle between liver and gallbladder (4). This technique resulted in less bleeding, fewer incidence of gallbladder perforation, and faster dissection.

Although similar in principle, hydro-jet technology utilizes an extremely thin high-pressure stream of saline (5). It has been routinely used in industry as a "cutting tool" for different materials such as metal, ceramic, wood, and glass (6). In the surgical field, hydro-jet has been used for both blunt dissection and cutting. Saline is the currently used fluid for surgical dissection. The application of saline between tissue layers creates surgical planes. Moreover, the high-pressure stream of saline can be used as a sharp knife to cut parenchymal organs depending on the tissue density and the pressure utilized (5). The application of parameters, such as water pressure, probe characteristics (diameter and configuration), and a specific hydro-jet temperature, has made selective dissection and cutting of tissues of various consistencies and elasticities feasible. Papachristou and Barters first used hydro-jet technology for liver resections in dogs (7). Vessels and bile ducts were preserved. Later, hydro-jet technology was used for selective dissection of liver parenchyma during hepatic resection in human. Hydro-jet dissection resulted in decrease blood loss compared to conventional tissue fracture technique during hepatic resection (8). Experimental and clinical laparoscopic hepatic resection using this technology was later reported (9,10). Further experience demonstrated the feasibility of this technology for resection of a wide range of parenchymal organs such as brain, kidney, and lungs (11–14). Clinical experience for dissection of brain parenchyma using hydro-jet has been recently reported (11). Using a maximum pressure of 7 bar, small vessels could be preserved. In a porcine model and recently in human, this technology was applied for laparoscopic cholecystectomy using the newer generation device, Helix™ [a] Hydro-Jet (Fig. 1) (15,16). In a prospective clinical study, 80 patients were randomized to undergo laparoscopic cholecystectomy using standard ($n = 40$) or hydro-jet–assisted ($n = 40$) dissection techniques.

The rate of intraoperative complications including hemorrhage and injury to the adjacent organs was less using hydro-jet dissection compared to standard laparoscopic cholecystectomy. Hydro-jet resulted in a selective dissection of connective tissue preserving blood vessels and the cystic duct.

> The rate of intraoperative complications including hemorrhage and injury to the adjacent organs was less using Hydro-Jet dissection compared to standard laparoscopic cholecystectomy. Hydro-jet resulted in a selective dissection of connective tissue preserving blood vessels and the cystic duct.

FIGURE 2 ■ The angled tip dissection probe of the Helix™ Hydro-Jet device. Continuously monitored and adjustable high-pressure saline is directed through the 120-μm nozzle at the tip, which can also be used for blunt dissection.

Hydro-jet technology facilitates isolation of the cystic artery and duct as well as dissection of the gallbladder so that subsequent coagulation of liver bed was often not necessary.

In the urologic surgery, hydro-jet technology was initially used for experimental applications during open surgical procedures, such as partial nephrectomy using older generation devices (12).

After the introduction of newer generation devices and improved dissection probes, hydro-jet was introduced into the field of laparoscopic urologic surgery.

A major advancement for laparoscopic application was the introduction of an angled tip probe that allowed simultaneous saline application and blunt dissection with the probe (Fig. 2) (5).

> After the introduction of newer generation devices and improved dissection probes, hydro-jet was introduced into the field of laparoscopic urologic surgery.

PRINCIPLES OF DISSECTION

Figure 3 demonstrates the principle of retroperitoneal dissection using hydro-jet technique. Similar principles apply to resection of renal parenchyma.

Retroperitoneal Dissection Using Hydro-Jet Technique

- Saline application results in expansion of the retroperitoneal space and creation of surgical planes (Fig. 3A and B).
- The thin stream of high-pressure saline allows selective separation of surrounding connective tissue components from the vessels and nerves.
- Utilizing a specific range, saline displaces fibrous and collagenous tissue leaving the vessels and nerves intact without injury due to tissue selectivity (Fig. 3C).
- Combined hydro-jet dissection and blunt dissection with the angled tip dissector allow dissection of vital structures such as nerves and vessels (Fig. 3D).
- The flow of saline allows a clear view for the operator.

During partial nephrectomy, the tissue selectivity allows precise cutting through the parenchyma with preservation of vessels and collecting system. These structures can then be selectively coagulated or ligated.

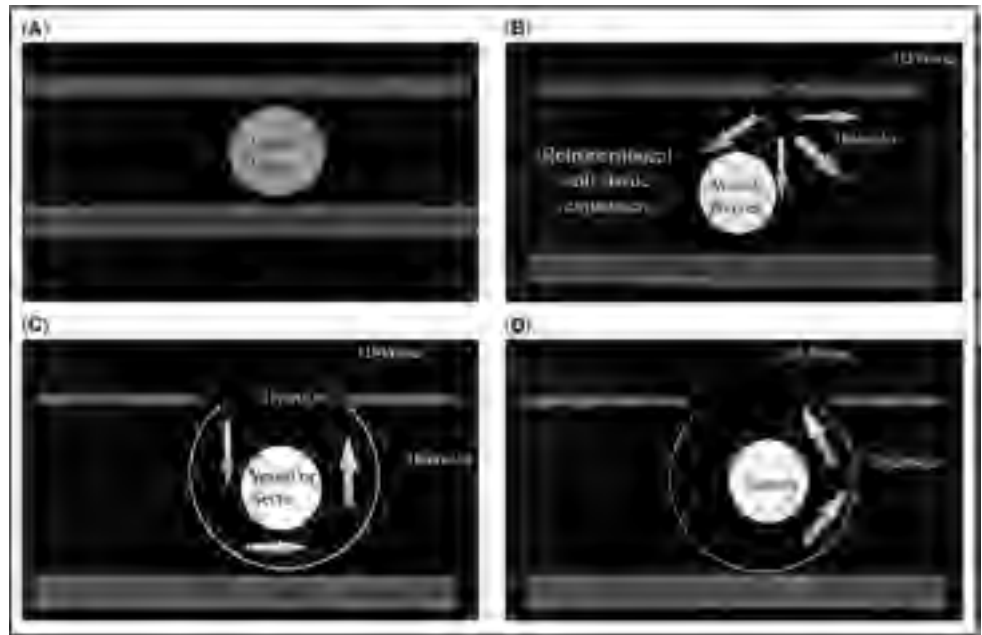
A theoretical question raised is the issue of dissemination of cancer cells while performing hydro-jet dissection for malignant disease. However, the application of saline is performed in the same surgical field as for conventional dissection and away from the pathology to be removed. Therefore, it is unlikely that saline application will result in cancer dissemination. At present, there are no reports of dissemination of cancer cells after various clinical applications.


FIGURE 3 ■ Schematic of the effects of the water jet using the Helix™ Hydro-Jet. (A) Retroperitoneal space prior to application of hydro-jet. (B) Application of saline to the retroperitoneal tissue in a linear fashion results in expansion of retroperitoneal soft tissue. (C) The vessels and nerves are preserved due to tissue selectivity. (D) Using sharp dissection with hydro-jet and blunt dissection with the angled tip probe, the nerve structures and blood vessels are identified, freed and isolated.

EXPERIMENTAL DATA IN UROLOGY

Laparoscopic Nephrectomy

Initially, hydro-jet was employed to perform laparoscopic nephrectomy (5). In an experimental model, 14 pigs underwent unilateral laparoscopic nephrectomy using the hydro-jet and a conventional laparoscopic nephrectomy contralaterally. A Muritz 1000[b] hydro-jet generator was utilized. An adjustable water pressure gauge allowed manual control up to a maximum pressure of 30 bar and coagulation was applied via a bipolar probe. The angled end of the probe allowed both blunt dissections with concomitant high-pressure saline application. Results were compared with regard to ease of anatomic dissection, complications, and operative time between the two techniques. Overall, laparoscopic nephrectomy was successful in all animals. No vascular injury secondary to dissection or significant intraoperative hemorrhage was noted. The minor bleeding was of a diffuse nature secondary to blunt dissection. The estimated blood loss was minimal (<50 mL) in both groups. The mean dissection time was 27 (range: 16–34) and 40 (range: 25–65) minutes for hydro-jet–assisted and conventional technique, respectively ($p < 0.001$). The mean normal saline used during hydro-jet dissection was 195 mL (range, 150–250 mL). No further experimental or clinical studies are currently available using this technology for dissection during laparoscopic nephrectomy.

Laparoscopic Partial Nephrectomy

With the application of laparoscopic techniques for partial nephrectomy, several technical aspects needed to be addressed. The primary technical problems arise mainly from dissection of the renal parenchyma, transection of intrarenal vessels and control of parenchymal bleeding, and closure of collecting system. Inability to complete the dissection safely and hemorrhage were the main reasons for conversion to an open surgical approach. To improve dissection, we conducted an experimental study to evaluate the feasibility of this technique for laparoscopic partial nephrectomy (13). In this pilot study, 10 partial nephrectomies were performed in five pigs using a Muritz 1000 hydro-jet generator. A maximum pressure of 30

[b]Euromed Medizintechnik, Schwerin, Germany.

bar was utilized for cutting of the parenchyma. Temporary hilar control was obtained during this study. Coagulation was applied using a bipolar probe. Laparoscopic partial nephrectomy was successful in all animals with no need for conversion to open surgery. No surgical complications including vascular injuries secondary to dissection occurred. There was no significant intraoperative bleeding. The mean dissection time was 45 ± 9 minutes and the mean warm ischemia time was 17 ± 3 minutes. The average amount of normal saline used during each procedure was 195 mL (range, 250–350 mL). Histological evaluation of renal parenchyma did not reveal any acute changes such as necrosis attributable to hydro-jet use. A clear view of the operative field was maintained at all times.

> The tissue selectivity of Hydro-Jet allowed precise cutting through the renal parenchyma in a virtually bloodless field. The remaining vessels were then coagulated under direct vision. Similarly, renal collecting system was preserved by Hydro-Jet and selectively transected allowing proper closure of the collecting system. Although excellent results were obtained using this technique, the need for hilar occlusion has been debated.

The tissue selectivity of hydro-jet allowed precise cutting through the renal parenchyma in a virtually bloodless field. The remaining vessels were then coagulated under direct vision. Similarly, renal collecting system was preserved by hydro-jet and selectively transected allowing proper closure of the collecting system. Although excellent results were obtained using this technique, the need for hilar occlusion has been debated.

In a recent experimental study utilizing the Helix Hydro-Jet device, no hilar control was obtained. Using lower pressures (16–22 bar), laparoscopic partial nephrectomies were successful (17). It appears that using various pressures, partial nephrectomies can be performed with or without temporary hilar control with respective advantages and disadvantages (18). To address the issue of hilar control and optimal pressure for partial nephrectomy, we performed further experiments in an ex vivo and in vivo porcine model using the Helix Hydro-Jet (18,19). In the ex vivo model, a continuous saline perfusion of renal artery was performed (Fig. 4). A pressure range of 180 to 360 psi (14–25 bar) was utilized. In this model, our results indicated that overall in unperfused kidney, lower pressures were as effective. Optimal pressure in perfused kidney appeared to be 305 psi (21 bar) (Fig. 5). In vivo model, a pressure range of 225 to 290 psi (16–20 bar) with vascular control and a pressure range of 225 to 360 psi (16–25 bar) without vascular control appeared to be optimal for laparoscopic partial nephrectomy. Furthermore, our results indicated that resection of renal parenchyma without hilar control was associated with small vessel hemorrhage from cortical tissue, which may obscure the operating field although larger vessels are preserved. Visualization was improved with vascular control. The combination of Hydro-Jet cutting with bipolar cautery for control of isolated blood vessels was ideal.

> In summary, current experimental data support that temporary hilar control is advantageous for better visualization during laparoscopic partial nephrectomy. Other factors, such as extent and location of parenchymal segments to be resected and tissue vascularity are, however, important variables, which cannot be addressed precisely by experimental protocols. Only a well-performed clinical study can address these issues.

In summary, current experimental data support that temporary hilar control is advantageous for better visualization during laparoscopic partial nephrectomy. Only a well-performed clinical study can address these issues.

Laparoscopic Retroperitoneal Lymphadenectomy

To explore other indications for hydro-jet technology, we evaluated the feasibility of this technology for nerve-sparing retroperitoneal lymphadenectomy. In an experimental

FIGURE 4 ■ Ex vivo kidney perfusion model to study the impact of renal perfusion and various pressures during Hydro-Jet application.

FIGURE 5 ■ Ex vivo demonstration of the effect of Hydro-Jet on renal parenchyma. Note tissue selectivity with separation of renal parenchyma and preservation of a net of vasculature and collecting system.

study, three pigs underwent retroperitoneal lymphadenectomy using hydro-jet dissection (20). Animals were sacrificed at the end of the procedure. The procedure was completed in all animals. All lymphatic tissue below the level of renal artery to the bifurcation of the aorta was removed. The pressure range was 300 to 400 psi (21–30 bar) initially. No injury to adjacent great vessels was noted during dissection while the sympathetic nerve fibers in retroperitoneum were preserved. The dissection time was 20 to 30 minutes and amount of normal saline used was less than 200 mL.

Our experimental data demonstrated the feasibility of retroperitoneal lymphadenectomy using the hydro-jet technology.

CLINICAL APPLICATIONS IN UROLOGY

Limited clinical applications have been reported in urology for partial nephrectomy, radical prostatectomy and retroperitoneal lymphadenectomy using the hydro-jet technique. The majority of these procedures were completed using open technique. In a clinical study, 24 patients underwent open renal sparing surgery for various indications including renal tumors (21). The dissection was performed without hilar control. The dissection time was 14 to 40 minutes with no significant blood loss. A pressure range of 16 to 22 bar was utilized. In a preliminary study at the University of Toronto, we performed six open partial nephrectomies using hydro-jet (unpublished data). The procedure was successful in all subjects with selective preservation of blood vessels, which were controlled using bipolar or monopolar forceps or selective ligation. Temporary hilar control was achieved in the majority of patients. In our experience, lack of hilar control was associated with more blood loss during larger resections. The time spent for dissection was 20 to 30 minutes. The mean estimated blood loss was 265 mL (range: 150–500 mL). There were no intraoperative or postoperative complications. The pathology revealed renal cell carcinoma in all patients. At a mean follow-up of 12 months, all patients were disease free. Currently, there is no reported experience with this technology for laparoscopic partial nechrectomy in human.

Hydro-jet technology also has been used for nerve-sparing approach during open and laparoscopic radical prostatectomy (unpublished data). The use of this technique facilitates isolation and preservation of neuromuscular bundles. However, no long-term functional data are currently available.

More recently, we have reported preliminary data using this technology for nerve-sparing retroperitoneal lymphadenectomy (20). The optimal pressure used for retroperitoneal lymphadenectomy was in the range of 225 to 305 psi (16–21 bar) in human. The dissection properties in this pressure range are similar to higher pressure with preservation of smaller blood vessels and nerves. Retroperitoneal lymphadenectomy was performed in five men with testicular cancer. The lymphadenectomy was primary in two and post chemotherapy in three patients. The primary diagnosis was seminoma in one and nonseminoma in four.

Hydro-jet nerve-sparing retroperitoneal lymphadenectomy permitted tissue selectivity with preservation of vascular structures and sympathetic nerves. The soft tissue and lymphatics were removed with the high-pressure saline stream assisted by blunt dissection. The nerve fibers were grossly resistant to the pressure used and were isolated individually. Sympathetic nerve fibers leading to the hypogastric plexus were isolated and preserved (Fig. 6).

The dissection time was comparable to the conventional technique. The mean estimated blood loss was 450 mL. There were no intraoperative or postoperative complications. The pathology revealed residual embryonal carcinoma in one, teratoma in two and fibrosis in two. At a mean follow-up of 24 months, all patients reported return of ejaculation and no retroperitoneal recurrences have occurred.

FUTURE PERSPECTIVES

The issue of cost of Hydro-Jet technology has not been addressed in the literature as yet. There is initial capital cost and ongoing maintenance. The probes and saline cartridge are disposable. Whether this cost increase can be justified by improved surgical dissection and decreased complication rates remains to be elucidated. For some applications, Hydro-jet dissection may replace existing and often more costly technologies. Furthermore, a multidisciplinary use of this technology for various surgical procedures would potentially improve local utility and spread the costs. Further studies in larger numbers of patients including cost comparisons are necessary to assess the financial burden of this technology.

FIGURE 6 ■ Intraoperative photograph of dissection of the postganglionic retroperitoneal sympathetic nerves using the Helix™ Hydro-Jet. The right nerve roots at the vertebral levels of L2–L4 seen from the patient's right side.

SUMMARY

- Initial experimental and clinical studies with hydro-jet technology demonstrated the feasibility and advantages of this technology as a dissection tool during open and laparoscopic procedures.
- Clinical application of this technology in the field of laparoscopic urology has been limited.
- Further experience and prospective comparative studies are necessary to evaluate the ideal clinical indications in the future.

*Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute,
Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.*

Currently, various vascularized intestinal segments are most commonly used as tissue substitutes for bladder augmentation.

Chronic tissue expansion is an established concept for creating new tissue in plastic surgery.

This multifaceted network is initiated by a mechanical stimulus that sets into play a series of precise reactions through what has been referred to as the stretch-induced signal transduction pathway.

Tissue substitutes for reconstructive procedures of the urinary bladder, such as augmentation cystoplasty, are needed in a variety of acquired and congenital pediatric and adult urological diseases. Amongst the various self-tissue substitutes such as buccal mucosa, scrotal skin, pericardium, or allograft tissues, which can be used for a variety of urologic reconstructive procedures, only vascularized intestinal segments have been successful as regards reconstructive surgery of the urinary bladder (1–5). However, use of intestinal segments in urinary tract reconstruction is associated with significant potential disadvantages, including metabolic complications, complicated infections, stone and tumor formation, and a variety of surgical risks associated with bowel surgery (1). These disturbances are exaggerated in patients with compromised renal function, and in children.

Currently, various vascularized intestinal segments are most commonly used as tissue substitutes for bladder augmentation.

Although it is difficult to estimate the total number of surgical cases performed in the United States, in which such excessive substitute tissue is needed, a recent article from a single pediatric hospital reported their experience with 483 cases of bladder augmentation during 25 years (6). The disadvantages of using intestinal segments in urinary tract reconstruction include metabolic changes, mucus production, high incidence of early and late surgical complications, and stone/tumor formation (1). These disturbances may be exaggerated in patients with compromised renal function, and in children. In a search for more suitable tissue for bladder reconstruction, a variety of sources have been explored (1–5,7). The majority of these sources are still considered experimental, lacking any meaningful long-term clinical or experimental follow-up results.

Chronic tissue expansion is an established concept for creating new tissue in plastic surgery. Expansion of native skin has been successfully employed in various surgical disciplines such as breast reconstruction, craniofacial surgery, and plastic reconstructive surgery in patients with extensive burns (8). The expanded, new tissue, created by chronic stretch, replicates the morphometric and functional characteristics of the native tissue. A large body of literature has been accumulated to explore the mechanisms involved in tissue expansion in response to chronic stretch. This literature demonstrates that the mechanisms behind the principle of stretch-induced cellular growth involve a network of several integrated cascades that include growth factors, extracellular, cytoskeletal and transmemberane structures, ion channels; protein kinases, second messenger systems; and transcriptional factors (9–29).

This multifaceted network is initiated by a mechanical stimulus that sets into play a series of precise reactions through what has been referred to as the stretch-induced signal transduction pathway (9).

PATHOPHYSIOLOGY

Chronic stretch-induced tissue expansion is accompanied by increased expression of several growth factors and receptors that may contribute to cell proliferation and tissue remodeling required for expansion. In smooth muscle cells, these proteins include members of the transforming growth factor, epidermal growth factor, basic fibroblast growth factor, platelet-derived growth factor, and nerve growth factor families (9–14). In bladder smooth muscle cells, mechanical stretch increased expression of heparin-binding epidermal growth factor-like growth factor and one of its receptors, ErbB1, resulting in inhibition of apoptosis (10). Stretch also induced production of nerve growth factor by urinary tract smooth muscle cells (11), and lower urinary tract obstruction induced hypertrophy of bladder afferent and efferent neurons that appeared to require increased nerve growth factor expression (12). The latter finding supports the hypothesis that obstruction-induced tissue expansion induces remodeling of the neural networks.

Stretch-induced tissue expansion also involves extracellular matrix production, which is required for stretch-induced cell proliferation (9). In vascular smooth muscle cells, mechanical strain-induced fibroblast growth and extracellular matrix production were accompanied by increased expression of transforming growth factor-β1 and inhibited by a transforming growth factor-β1 neutralizing antibody (13). Rapid tissue expansion also may injure ureteral tissue more seriously than slow expansion, with associated ischemia and inflammation. transforming growth factor-β1 may be the main regulating factor for both the repair process and inflammatory response. We observed two to threefold increases in transforming growth factor-β2 expression in porcine chronic expanded versus native ureteral tissues (30).

Chronic tissue expansion has also been shown to induce angiogenesis, with associated ischemia, which in turn can stimulate production of vascular endothelial growth factor (14). Ischemia induced by tissue expansion may also determine the degree of any ensuing fibrosis. In our preliminary study, no change in vascular endothelial growth factor expression was observed in the expanded ureteral tissue (30). It should be noted that all of the above-cited literature regarding mechanisms of stretch-induced tissue remodeling pertains to cutaneous (skin) tissue expansion on cultured cells.

VISCERAL TISSUE EXPANSION IN URINARY TRACT

Tissue expansion techniques have also successfully been used in genitourinary tract tissues in the experimental setting (30–33). In 1996, Lailas and colleagues (31) initially reported chronic ureteral expansion for subsequent open ureterocystoplasty in a rabbit model. Ten rabbits underwent unilateral ligation at the ureterovesical junction and ipsilateral nephrectomy. A silicone catheter was placed into the proximal ureter and connected to a titanium injection port, which was placed subcutaneously at the level of costal margin. Two weeks later a saline antibiotic was injected in the port daily, limited by the pressure in the system. Within six weeks, the ureter was opened longitudinally on the anterior aspect, reconfigured into a U-shaped patch, anastomosed to the bladder and covered with an omental flap. A suprapubic tube was placed for 10 days after the procedure. After six months the animals were euthanized. The cystogram showed a mean increase of 260% in the bladder capacity. Urodynamic studies were compatible with a low-pressure, high-capacity bladder. In 1998, Ikeguchi and associates (32) performed chronic segmental ureteral expansion in eight pigs. A latex balloon was located in the distal ureter inserted through the renal parenchyma open surgically. A 10F Malecot nephrostomy was also placed. Daily ureteral dilation (150–1000 mL) was performed with 1–50 cm^3 daily over a period of 2–4 weeks, with no anesthesia required. After this, an open ureterocystoplasty and reconstruction of the ipsilateral ureter were performed. A transurethral catheter was maintained for one week. Cystograms revealed an increased bladder capacity. The animals were sacrificed after four weeks, and the histological sections showed preservation of ureteral architecture with ephitelial regeneration. In 2003, we initially reported a completely minimally invasive approach for chronic ureteral balloon expansion followed by laparoscopic augmentation ureterocystoplasty in a survival porcine model (30).

The methodology of visceral tissue expansion in the genitourinary system has yet to be refined to a place where it can have a real practical use by urologists, to the extent that skin expansion has become an accepted part of plastic reconstructive surgery.

Although the potential for ureteral tissue expansion in the context of urinary tract reconstruction has been preliminarily explored, none of the investigators have taken the

issue far enough to explore the cellular and molecular mechanism involved in visceral tissue expansion and remodeling.

Encouraged by the above principles and potential usefulness of expanded ureteral tissue, we have pursued development and proof of concept of a methodology that would enable us to obtain excess ureteral tissue with minimally invasive surgical techniques. The expanded ureteral tissue can be used in open or laparoscopic surgical techniques in a variety of reconstruction applications for the lower urinary tract. Further, our preliminary studies have provided stimulus for pursuit of biological markers possibly responsible for visceral tissue remodeling.

DESAI STUDY

The study was performed in 35 to 40 kg female farm pigs, after approval from the Animal Research Committee of our institution. The initial five animals were used to develop the prototype design and insertion technique of the ureteral expansion balloon, its inflation schedule, and the technique of laparoscopic ureterocystoplasty. Subsequently, five animals entered the survival study.

Percutaneous Insertion of Ureteral Expansion Balloon

All five chronic animals underwent unilateral (right three, left two) percutaneous insertion of the ureteral expansion balloon[a], a dual-channel balloon catheter: one for inflation, and the other for proximal nephrostomy drainage (Fig. 1). Initially, a 5F open-ended ureteral catheter was inserted cystoscopically into the ipsilateral renal collecting system. The animal was then positioned prone, and percutaneous renal access was obtained under fluoroscopic guidance. A 0.035 inch Glide-wire[a] was manipulated antegrade down the ureter and retrieved through the bladder, and the open-ended ureteral catheter was removed. Using an antegrade 5F ureteral catheter, the Glide-wire was replaced with a 0.035 in Amplatz Superstiff guidewire[a]. The percutaneous tract was dilated using a single-step dilator, and a 20F peel-away sheath was positioned in the renal pelvis. A 21F 10 cm ureteral

FIGURE 1 ■ Ureteral expansion was performed using a novel silicone balloon TUEC catheter having two channels: a smaller channel to inflate balloon (c1) and a larger fenestrated channel to drain kidney (c2). The 14F shaft has multiple holes to facilitate proximal urinary drainage. The balloon (b) has one radiopaque marker (m1 and m2) at its either end to facilitate fluoroscopic confirmation during placement. Additional radiopaque marker (m3) on shaft immediately proximal to last drainage hole should lie within kidney. Terminal end of catheter is fashioned into a pigtail to facilitate retention in bladder. Single-step dilator (d) is used to position 20F peel-away sheath (s) within renal collecting system.

FIGURE 2 ■ Procedures of percutaneous insertion of TUEC, and inflation of balloon. Balloon position. (A) Deflated balloon is positioned in juxtavesical ureter. [a]Microvasive, Natick, MA.

dilation balloon (Uromax[a]) was used to dilate the entire ureter in a stepwise fashion over a period of two minutes to facilitate subsequent passage of the novel expansion device. The adequately lubricated balloon expansion catheter was gradually manipulated antegrade into the ureter over the Superstiff guidewire (Fig. 2A). The balloon, flanked by radiopaque markers, was positioned in the juxtavesical ureter and distended with 2.5 to 3 mL of contrast medium to secure it in position (Fig. 2B). The excess proximal length of the catheter exiting the animal's back was tunneled subcutaneously so that only the inflation and drainage ports were visible outside the skin.

> The inflation could be carried out without anesthesia or analgesia while the overnight fasting animal was busily eating.

The inflation could be carried out without anesthesia or analgesia while the overnight fasting animal was busily eating.

Chronic Ureteral Expansion

Starting the day after placement of the ureteral expansion balloon, the ureter was gradually dilated by daily incremental instillation of a dilute (1:4) contrast solution. Ureteral expansion was monitored radiologically every 7 to 10 days (Fig. 3).

Laparoscopic Augmentation Ureterocystoplasty

Laparoscopic ureterocystoplasty was performed in all five animals after 3 to 4 weeks of ureteral expansion. All procedures were performed using a four-port transperitoneal approach with the pig under general anesthesia. Initially, the ureteral balloon was completely deflated, and the amount of fluid aspirated was measured. The balloon was subsequently refilled with the same amount of dilute antibiotic solution to facilitate intraoperative identification and to prevent intraoperative spillage of potentially infected fluid should inadvertent puncture of the balloon occur intraoperatively. After port placement, the pelvic organs were examined laparoscopically. The expanded ureter was identified as a readily visible bulge adjacent to the urinary bladder. The medial peritoneum overlying the expanded ureter was incised to expose the ureteral wall. The fallopian tube and ovary on the ipsilateral side were mobilized away from the ureter. The bladder was mobilized by dividing the medial umbilical ligament and the superior vesical pedicle and incised laterally in a longitudinal fashion from just above the ureteral orifice up to the dome. The ureteral orifice and intramural ureter were preserved. While in the initial two animals the bladder dome was not excised, in the latter three approximately 80% of the bladder was removed. The medial wall of the expanded ureteral segment was then incised using a J-hook monopolar cautery electrode, thus opening the expanded ureteral segment medially. Care was taken to minimize any mobilization of the ureter, thus maintaining intact the laterally based vascularity of the expanded ureter (Fig. 4). The length, site, and orientation of the ureteral incision were tailored to correspond to the bladder defect (Fig. 5). After the ureteral incision was completed, the balloon was deflated and the catheter removed. The in-line tissue-expanded ureteral patch was then anastomosed to the bladder in a running fashion using 2-0 Vicryl sutures on a computed tomography-1 needle with freehand intracorporeal laparoscopic suturing and knot-tying techniques (Fig. 6). After the posterior wall was sutured, an 18F red rubber urethral catheter was inserted antegrade into the urethra through the bladder neck. The anterior wall was then sutured to complete the augmentation ureterocystoplasty. A 22F Malecot suprapubic catheter was left indwelling and brought out through the suture line in the initial two animals only. A 22F

tube drain was positioned in the prevesical space in all five animals and brought out through a port site. The animals were returned to the chronic animal care facility.

Oral antibiotics were administered until urethral catheter was removed. The suprapubic catheter was removed after seven days, and the urethral catheter was removed after 14 days if not spontaneously expelled earlier. The drain, if not spontaneously expelled, was removed a day after the urethral catheter was removed. All animals underwent laboratory, radiologic, urodynamic, and histologic investigations (Table 1). Additionally, transmission electron microscopy of the expanded ureter and measurement of vascular endothelial growth factor and transforming growth factor-$\beta 2$ in expanded ureteral tissue were performed in selected animals. Animals were euthanized at 15 days ($N = 1$), one month ($N = 1$), two months ($N = 1$), and three months ($N = 2$).

RESULTS

Percutaneous Insertion of Ureteral Expansion Balloon
Percutaneous insertion was technically successful with satisfactory balloon placement in all five animals. The mean operative time required for balloon insertion was 52 ± 6 minutes, and there were no complications (Table 2).

TABLE 1 ■ Investigation Schedule

	Timing
Laboratory: Complete blood count, metabolic profile, urinalysis and culture	Prior to balloon insertion Prior to augmentation ureterocystoplasty Prior to euthanasia
Radiologic	
Plain film	Weekly during balloon inflation Prior to augmentation ureterocystoplasty
Cystogram	At 1-month follow-up Prior to euthanasia

Tissue cytokine assay (VEGF and TGF-β2)	During augmentation cystoplasty ($N=5$)[a]

[a]Seven tissue biopsies were obtained from the five animals at the time of augmentation ureterocystoplasty for cytokine assay.

Chronic Ureteral Expansion

All five animals underwent successful ureteral expansion over a mean of 25 ± 1.4 days (Table 3). The mean final volume of the ureter was 177.1 ± 41.3 mL. The mean volume of fluid instilled was 12.7 ± 0.9 mL in the first week, 38.4 ± 4.3 mL in the second week, 66.2 ± 17.4 mL in the third week, and 59.8 ± 28.4 mL in the fourth week. The mean daily inflation volume was 1.8 ± 0.1 mL in the first week, 5.5 ± 0.6 mL in the second week, 11.3 ± 2.5 mL in the third week, and 16.1 ± 1.8 mL in the fourth week. All five awake animals readily tolerated the daily incremental instillation of dilute contrast solution without apparent pain or discomfort.

> The inflation could be carried out without anesthesia or analgesia while the overnight fasting animal was busily eating.

The inflation could be carried out without anesthesia or analgesia while the overnight fasting animal was busily eating.

Radiologic volumetric assessment of the ureteral balloon during the phase of ureteral expansion was commensurate with the amount of fluid instilled. We did not note any complications during ureteral expansion. Proximal urinary drainage through the fenestrated channel of the ureteral expansion catheter was adequate in all five animals.

Laparoscopic Augmentation Ureterocystoplasty

Laparoscopic ureterocystoplasty was technically successful in all five animals without need for open conversion in any case. The mean operative time was 156 ± 41.1 minutes (range 115–210 minutes), and the mean estimated blood loss was 29 ± 16 mL (range 10–50 mL). One animal had a small-bowel serosal tear, which was readily suture repaired laparoscopically. Some periureteral adhesions were encountered in the vicinity of the expanded ureter, which could readily be lysed laparoscopically. Intraoperatively, at the time of ureterocystoplasty, the expanded ureter appeared thick and highly vascular, with areas of urothelial denudation. Intraoperative instillation of saline through the urethral catheter at the end of the ureterocystoplasty revealed a

[a]Total volume of fluid introduced into balloon in a week divided by number of days injected. Although inflation was performed daily, a few days were skipped for logistical reasons.

[b]Total volume of expansion achieved during week.

[c]Estimated amount of fluid in balloon at end of expansion process.

[d]Actual volume of fluid aspirated from ureteral expansion balloon immediately prior to augmentation ureterocystoplasty. This volume was slightly less than the anticipated volume. There are two possible explanations: (1) some immeasurable fluid loss may occur during balloon inflation because of sudden movement of the animal, and (2) some fluid may not be completely aspirated from balloon.

watertight anastomosis in all five cases. Postoperative complications were seen in two animals: lower ureteral obstruction and pyelonephritis with urosepsis.

Urodynamic, Cystography, and Cystoscopy Data

Over a follow-up ranging from 15 days to 3 months, the mean bladder capacity was 574 ± 221.3 mL (range 380–940 mL). The P_{ves} at maximum capacity was 14 ± 4.5 cmH$_2$O (range 8–20 cmH$_2$O), and bladder compliance was 71.7 mL/cmH$_2$O (range 35.3–188 mL/cmH$_2$O). Uninhibited detrusor contractions were not evident on urodynamic evaluation in any of the five animals (Table 4). Cystography revealed ipsilateral reflux in four renal units: grade II in one animal, grade IV in two animals, and grade V in one animal (Fig. 7). At autopsy, one renal unit demonstrated lower-ureteral obstruction and therefore showed no reflux on cystography. There was no contralateral reflux in any renal unit. In all four refluxing units, the refluxed contrast drained from the kidney immediately after the bladder was emptied, thereby ruling out any ureteral obstruction. Additionally, the cystogram did not reveal contrast extravasation in any case.

Cystoscopy was performed in all animals at one month and at autopsy. By one month, the bladder revealed a fully regenerated mucosa in four animals; one animal euthanized at 15 days still had patchy areas of denuded mucosa.

Laboratory Data

Laboratory examination revealed minimal metabolic alterations in four animals. One animal that developed pyelonephritis and urosepsis had evidence of azotemia,

TABLE 4 ■ Radiologic Data

[a]Cystographic examination was performed at one month ($N=3$) and at autopsy ($N=5$) by injecting contrast through a urethral catheter. In all refluxing renal units, obstruction was ruled out by documentation of prompt drainage of contrast from the collecting system.

[b]Urodynamics, in the form of filling cystometrogram, was performed in each animal immediately prior to autopsy. The animal was anesthetized and placed supine on the table. The bladder was filled through a 6F urethral catheter, and intravesical pressure was recorded through a separate 6F urethral catheter connected to manometer tubing. Parameters recorded included total bladder capacity, resting and end filling pressures, bladder compliance, and involuntary detrusor contractions.

[c]No animal developed contralateral reflux.

FIGURE 7 ■ Autopsy photographs. **(A)** Augmented bladder and both renal units. Healed suture line between expanded ureteral patch (u) and native bladder (b) is seen (*arrows*). **(B)** Interior of augmented bladder shows demarcation (*arrows*) between expanded ureter (u) and native bladder (b). hyponatremia, hyperkalemia, and acidosis (Table 5). The mean serum creatinine concentration was 1.3 ± 0.2 mg/dL at baseline, 0.9 ± 0.2 mg/dL at bladder augmentation, and 2.0 ± 0.9 mg/dL at euthanasia.

Autopsy Data

At autopsy, the ureteral patch appeared well vascularized, and the ureterocystoplasty suture line was healed in all five animals. The ipsilateral renal parenchyma appeared grossly normal in three cases, with pre-euthanasia intravenous urography revealing prompt opacification with mild hydronephrosis. One animal with a lower ureteral obstruction revealed thinning of parenchyma and poor function on intravenous urography. At autopsy, the obstruction was found to be the result of flimsy synechia formation at the junction where the upper, normal caliber ureter entered the expanded ureteral segment. The animal with pyelonephritis and urosepsis had a grossly scarred kidney that was nonfunctioning on intravenous urography.

Histologic Data

Histologic examination of the expanded ureter harvested at the time of autopsy revealed persistent muscle hypertrophy and hyperplasia, a fully regenerated transitional epithelium, and variable amount of fibrosis.

Light microscopic examination of biopsies of the expanded ureter obtained at the time of augmentation cystoplasty revealed muscle hypertrophy and hyperplasia, mucosal atrophy, and variable inflammatory infiltrate.

Histologic examination of the expanded ureter harvested at the time of autopsy revealed persistent muscle hypertrophy and hyperplasia, a fully regenerated transitional epithelium, and variable amount of fibrosis.

Electron Microscopic Data

Transmission electron microscopy performed on the ureteral tissue obtained at the time of laparoscopic augmentation revealed cellular evidence consistent with muscular hypertrophy and hyperplasia.

TABLE 5 ■ Serum Biochemical Data

	Prior to ureteral balloon expansion	Prior to augmentation cystoplasty	Prior to euthanasia
Mean serum cretinine (mg/dL)	1.3 ± 0.2 (1.1–1.4)	0.9 ± 0.2 (0.7–1.1)	2.0 ± 0.9 (1.4–3.4)
Mean serum potassium (mEq/L)	139.4 ± 3.3 (136–143)	135.5 ± 7.0 (127–144)	132.5 ± 9.7 (119–140)
Mean serum sodium (mEq/L)	4.3 ± 0.2 (4.1–4.5)	4.4 ± 0.2 (4.1–4.6)	4.7 ± 0.6 (4.1–5.4)

Mean hemoglobin (mg/dL)	11.6 ± 0.3 (11.3–12)	9.6 ± 1.0 (8.7–10.9)	10.3 ± 2.6 (8.8–14.1)
Mean hematocrit (%)	39.8 ± 2.0 (37.7–42.3)	32.0 ± 3.4 (29.1–35.8)	35.3 ± 8.1 (27.7–46.8)

Growth Factor Assay Data

Preliminary data on growth factor expression in expanded ureteral tissue obtained and snap frozen at the time of augmentation ureterocystoplasty revealed a two to threefold increase in transforming growth factor-β2 (median, 44 pg/mL; range, 27–49 pg/mL) over controls (normal ureter, 16 pg/mL). There was no increase in vascular endothelial growth factor expression in the expanded ureteral tissue compared with control samples.

CLINICAL STUDY [b]

After percutaneous placement of the balloon device, in-line expansion of the distal ureter was achieved on an outpatient basis over 23–38 days to a volume of upto 218 mL. Notably, all three patients did not require any analgesia during this entire expansion process.

Following our laboratory experiments and upon availability of the opportunity in two outside medical centers, we performed this procedure in three patients outside the United States, in India ($N=2$) and Brazil ($N=1$), with the approval of the ethical committee at each local institution. Clinical data from these patients have been encouraging, supporting our laboratory data. Specifically, we treated two women and one man, aged 14, 65, and 54 years, respectively. Each patient suffered from a noncompliant bladder with reduced capacity (range 15–150 mL).

Operative time for the laparoscopic augmentation ureterocystoplasty ranged from two to three hours, and blood loss was 25 to 50 mL. Each patient commenced oral intake on the same day and ambulated within 24 hours. Hospital stay ranged from six to eight days. There were no infections or other complications at any stage of this study. Postoperatively, bladder capacity increased significantly to 250 to 280 mL at two-month follow-up. The first patient has now completed two-year follow-up with durable success. All three patients have experienced significant, even dramatic, improvement in voiding symptoms, and the renal function is well preserved.

The availability of a urothelium-lined, muscle-backed, vascularized, autogenous, in-line tissue material for purposes of augmentation, and possibly even replacement, of the urinary bladder would indeed be a major advance.

CLINICAL IMPLICATIONS

This could potentially eliminate the use of bowel (and its attendant morbidity) in urinary tract reconstruction. Potentially, such a bladder substitute could have mucosal, myogenic, and neurogenic attributes that approximate those of a functionally intact urinary bladder. Our proposal represents a concerted effort at establishing and developing this novel field of visceral tissue expansion.

The search for the ideal tissue substitute for bladder augmentation is ongoing. Currently, intestinal segments remain most commonly used for bladder augmentation. Although the results of augmentation cystoplasty using various bowel segments have generally been acceptable, these tissues are associated with absorptive metabolic changes, mucus production, and stone formation, the magnitude of which is dependent on the length and segment of bowel used (34). Significant research in the past few decades has focused on alternative tissue substitutes for urinary tract reconstruction. These have included tissue-engineered materials, xenografts such as small-intestinal submucosa, and techniques such as autoaugmentation and de-epithelealized bowel (1–3). Some of these techniques, although promising, have either been insufficiently durable or require considerable refinement.

The ureter, with its transitional epithelium, is potentially an optimal tissue for bladder augmentation (5).

Augmentation ureterocystoplasty has been reported, with encouraging long-term urodynamic results, and limited, if any, metabolic changes. However, the amount of ureteral tissue needed to provide a urodynamically acceptable bladder augmentation can be obtained only in a patient with a large megaureter. Therefore, currently, augmentation ureterocystoplasty is limited to the occasional patient with a megaureter and a nonfunctioning kidney who requires bladder augmentation.

Thus, although the potential for ureteral tissue expansion for urinary tract reconstruction has been demonstrated, further characterization of the biology of ureteral expansion and refinement of technique are necessary prior to its clinical application. The Desai study was designed specifically to address the following crucial issues: (i) the

---

[b]Gill et al., unpublished data.

feasibility of percutaneous insertion of the ureteral expansion device; (ii) the efficacy of this novel balloon in expanding the ureter to the desired volume while simultaneously providing adequate drainage of the renal unit; (iii) a safe and reliable time line schedule and regimen for ureteral balloon expansion; (iv) the technical feasibility of performing laparoscopic augmentation ureterocystoplasty using the tissue-expanded ureter; and (v) the biologic nature of the expanded ureteral tissue and its efficacy in providing a urodynamically adequate bladder augmentation in a survival porcine model.

Postoperative complications occurred in two animals. One animal, whose ureter was unstented, developed lower-ureteral stenosis, hydroureteronephrosis, and poor ipsilateral renal function, and the other animal had pyelonephritis with urosepsis. At autopsy, the animal with lower-ureteral obstruction revealed flimsy adhesion formation at the junction of the expanded ureter with the proximal normal-caliber ureter. There was no transmural fibrosis on histologic examination of the stenotic area. This obstruction probably represents cross-healing of the opposite ureteral walls following mucosal denudation during the expansion process and can potentially be avoided by stenting at the time of augmentation ureterocystoplasty until re-epithelization is complete.

Our survival porcine study demonstrates that progressive, incremental ureteral tissue overexpansion can be carried out safely and reliably with a percutaneously placed expansion balloon. This ureteral expansion is well tolerated and can be performed over a 3- to 4-week period to create a sizeable reservoir for bladder augmentation. The expanded ureter is thick and vascular and reveals histologic and electron microscopic features of durable ureteral smooth-muscle hypertrophy and hyperplasia. This expanded tissue can be used laparoscopically to augment the bladder. Such augmented bladders possess good urodynamic properties over a three-month follow-up period.

> This approach has the potential to provide native, urothelium-lined tissue for augmentation or, possibly, replacement of the urinary bladder.

This approach has the potential to provide native, urothelium-lined tissue for augmentation or, possibly, replacement of the urinary bladder.

Concerted research in this arena will lead to further development of this novel field of visceral tissue expansion.

EXTRACORPOREAL TISSUE TRIPSY IN UROLOGY

M. Marberger and Y. K. Fong
Department of Urology, University of Vienna, Vienna, Austria

INTRODUCTION

An old dream of mankind foresees targeted tissue destruction within the body from an extracorporeal energy source with a no-touch technique, and no damage to surrounding structures. Rapidly developing technology now appears to be gradually moving this approach from science fiction to the doorsteps of clinical realm.

RADIOSURGERY

Radiation destroys sensitive dividing cells by mitosis-linked death. High-energy external beam radiation affects tissues surrounding the target area with wide margins and even with modern planning techniques can therefore not be applied for truly focal tissue ablation in radiosensitive organs. Brachytherapy permits sharply defined ablation, but requires placing of the radioactive material within the target, and therefore does not constitute an extracorporeal technique. These problems are in part overcome by using stereotactic techniques to apply highly focused radiation. Pioneered in neurosurgery for the treatment of intracranial tumors, they exceed the scope of this treatise. A frameless image-guided radiosurgical device (Cyberknife) has recently been evaluated for focal renal ablation in a porcine model (1). The system combines a lightweight 6 mV linear accelerator mounted on a robotic arm with an image-to-image algorithm for target localization. An adequate conformal radiation dose is delivered by focusing a multitude of radiation beams at the target zone, yet directing the individual beams along different pathways so that the surrounding tissues are not exposed to a harmful dose. With a targeted dose of up to 40 Gy, complete fibrosis of the target zone was achieved without any apparent damage to surrounding structures (1).

MECHANICAL TISSUE TRIPSY

By forcing water through a small nozzle under high pressure at $10–50 \, \text{kg/cm}^2$ parenchymatous tissue can be removed, whereas vessels >200 μm in diameter remain undamaged (2). This tissue skeletonization by water-jet facilitates subsequent hemostasis by electrocautery or suturing and is being utilized clinically, such as for partial hepatectomy or nephrectomy. Structures up to diameter of ~500 μm can be dissected by using probes generated to longitudinal and transverse oscillation of 200–300 μm by ultrasound in the 20–50 kHz range. By combining mechanical tissue fragmentation with thermal sealing of larger vessels with the heat generated during the tissue fragmentation process, ultrasound dissectors permit blood-free dissection of even heavily vascularized structures, and have become standard surgical equipment today (2–9). Both techniques, however, can only be utilized upon contact, and not by an extracorporeal approach.

The success with extracorporeal shock wave lithotripsy, and in particular analysis of its side effects on soft tissues (10), generated interest in using shock-wave energy

FIGURE 1 ■ Profile of extracorporeal shock wave as used for lithotripsy; the negative pressure phase results in cavitation bubble formation. *Source*: From Ref. 12.

for extracorporeal tissue ablation. The relatively weak acoustic shock waves used for lithotripsy exert both positive and negative pressures up to 100 and 10 Mpa, respectively (11). Especially, the latter are sufficient to cause cavitation from liquid failure at numerous sites near the focus. As the liquid fails, the vapor-filled cavities that are initially developed collapse with enormous force (Fig. 1). Asymmetric high-speed liquid microjets with velocities of 130–170 m/sec are generated at their surface, which are considered to be the primary mechanisms for stone disintegration and also for trauma to the soft tissue surrounding (3,13). Because of the high speed of the bubble breakdown there is virtually no temperature rise within the focus (14). Homolytic cleavage of molecules may also result in free radical formation, and this has been speculated to result in an additional focal tumoricidal effect (15,16).

A number of in vitro and in vivo experimental studies with the electromagnetic and electrohydraulic shock-wave sources used for lithotripsy have documented shock-wave–induced cellular damage in the focal area (17–19), but the microenvironments of the cells treated impact significantly on the shock-wave effect. If tumor cells in suspension are treated, the effect is significantly more pronounced than when the same type and number of cells are immobilized in gelatine (20–23).

Clearly, secondary physical effects such as microjet formations, blast effects, compressions, and tensile stress factors also play major roles in cellular damage. Similar studies have also shown a potentiating effect of shock waves on cytotoxic agents such as cisplatin, vinblastin, doxorubicin or 4-hydroperoxycyclosphoride and cytokines (24–28). The effect diminishes rapidly after shock-wave exposure, suggesting transient increases in cell membrane permeability as a result of direct mechanical damage of cellular structures being the main mechanism involved. Clearly, single cell suspension models are simply insufficient to study cytotoxic shock-wave effects.

In vivo studies on more complex in vivo models with implanted tumors have yet failed to define structured effects of shock waves as used in lithotripsy other than hemorrhage and signs of mechanical tissue dissipation (18,28–31).

Tissue cavitation within the focal zone can be augmented by increasing the negative pressure of the shock wave, but more effectively by increasing the frequency of shock waves generated to more than 10 exposures per second (i.e., >10 Hz) (Fig. 2). By using ultrasound shock waves generated from piezoceramic elements mounted on a concave disk and focused to a joint focus (Fig. 3), both high frequencies and site intensities can be obtained, which result in immediate cellular disruption within the focus. This technique has been defined as "high-energy shock wave" tissue tripsy or "pyrotherapy" and has received considerable experimental and phase II clinical attention (32–35).

Vallancien's group (32) described an extracorporeal apparatus for in-depth tissue ablation based on this mechanism. The system is an adaptation of a lithotripter (Pyrotech™ᵃ). The energy source consists of multiple transducer elements and has a focal length of 15 cm. The site intensity has been quoted to exceed 10,000 W/cm² , but precise data are not available. A 3.5 MHz sectorial imaging transducer with a focal length of 14 cm is positioned in the center of the therapy elements. The focal area is 10 mm high × 2 mm wide for 50% power at −6 dB. The energy source head is positioned in a large bag of cavitation-free water below a waterproof membrane in the middle of a treatment bed (Fig. 3). During high-energy shock wave, the bubble formation with the focal zone increases progressively; these bubbles subsequently collapse rapidly. This rapid collapse compresses the gas inside the bubble without heat exchange with the surrounding tissue and results in a local temperature increase. Therefore, high-energy shock wave is considered to make use of both the mechanical and more limited, the thermal effects of ultrasound. This extracorporeal device has been tested under numerous experimental conditions, and preliminary human trials involving prostate, kidney, and bladder pathology have been reported.

Sidebar (left margin):

A number of in vitro and in vivo experimental studies with the electromagnetic and electrohydraulic shock-wave sources used for lithotripsy have documented shock-wave–induced cellular damage in the focal area, but the microenvironments of the cells treated impact significantly on the shock-wave effect. If tumor cells in suspension are treated, the effect is significantly more pronounced than when the same type and number of cells are immobilized in gelatine.

In vivo studies on more complex in vivo models with implanted tumors have yet failed to define structured effects of shock waves as used in lithotripsy other than hemorrhage and signs of mechanical tissue dissipation.

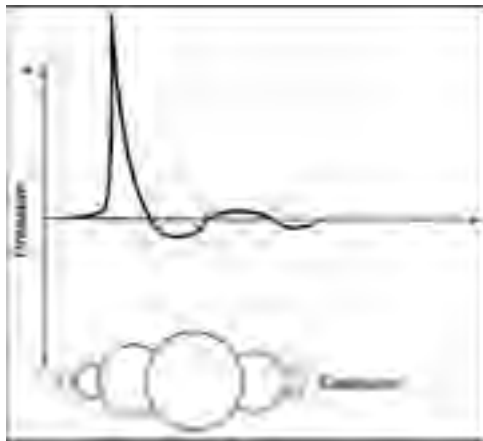

FIGURE 2 ■ Cavitation processes within the focal zone are augmented by increasing the negative pressure of the shock wave and by increasing shock wave generation beyond 10 HA, so that the next shock wave hits the focal zone before the cavitation bubbles generated by the previous shock wave have fully collapsed. *Source*: From Ref. 12.
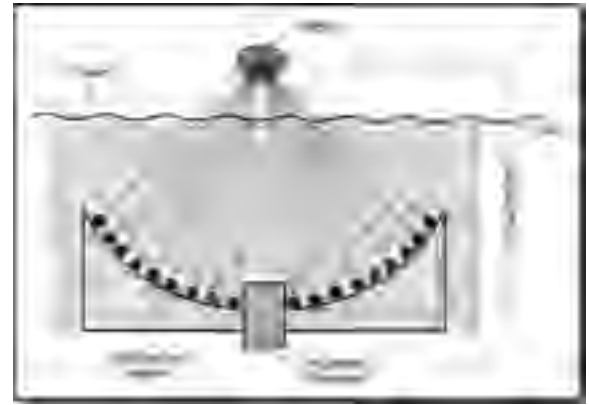

FIGURE 3 ■ Schematic depiction of system for extracorporeal high-energy tissue tripsy: ultrasound shock waves are generated at high frequency from multiple piezoceramic elements focused to a joint focus. A cushion filled with gas-free water serves for air-free coupling of the shock waves to the skin. *Source*: From Ref. 32.

Although the majority of these studies yielded encouraging data, high-energy shock wave has not been introduced into broader clinical use for oncologic indications to date. This is mainly attributable to insufficient tumor targeting and the fact that cell damage from high-energy shock wave is mediated primarily via the mechanical effects of ultrasound (i.e., tissue cavitation), which is difficult to target, control, and predict. Reliable destruction of deep lying tissues (a prerequisite for use in oncologic indications) is hard to achieve with current high-energy shock wave devices.

Vallancien and colleagues (32) studied sequential histologic effects of high-energy shock wave on 110 kidneys of white landrace pigs. Immediately after treatment, a high area of congestion with hemorrhage and exudation was present. After 24 hours, coagulative necrosis appeared. On day 7, the target area was completely necrotic, and at day 90, fibrotic scarring was seen in the treated area. In humans, the histologic impact of extracorporeal ultrasonic tissue tripsy on renal tissue was also studied (33). Patients with renal cancer ($n = 5$), renal atrophy ($n = 2$), or complex stones ($n = 1$) were subjected to extracorporeal ultrasonic tissue tripsy prior to nephrectomy. The treated volume averaged 4 cm^3, the mean number of shots was 195, and the skin–focal point distance averaged 68 mm. Immediately after the procedure, treated areas showed intense congestion with severe hyperemia and marked alterations of microcapillaries. The results were identical to those observed in the porcine kidney. After 48 hours, early signs of limited subcapsular necrosis with a persistent zone of hyperemia were detected. Side effects were moderate: two patients noticed skin burns, but otherwise, no significant adverse effects were seen. The high-energy shock wave method has also been applied to ablate prostatic tissue. Although intraprostatic coagulative necrosis was demonstrable, the transabdominal approach proved to be poorly suited because the bony pelvis shields the prostate. Vallancien and colleagues could target the prostate adequately in only 50% of cases.

The Pyrotech device has also been used to treat superficial bladder tumors. After an experimental study, a phase I/II clinical trial was initiated (34,35). In the first series, five patients with single recurrent superficial bladder tumor were treated immediately prior to transurethral resection. In all five cases, a change in the appearance of the tumor was noted. In two cases, the tumor was completely destroyed and histology showed coagulative necrosis. In a subsequent phase II trial, 20 patients with superficial bladder tumors were treated with this technique. Of these, 15 (75%) had normal urinary cytology results and cystoscopy at one month. In 67% of the patients with a primary tumor, there was no recurrence at one year; the remaining 33% developed recurrent tumors (35).

In phase II clinical studies with HESWL, no tumor progression or occurrence of metastases was observed during follow-up of 3–21 months (33,35). Nevertheless, the risk of cell dissemination appears to remain an inherent problem of tumor destruction based primarily on mechanical forces. Although some authors have specifically studied this aspect and observed no enhancement of tumor metastases (31,36,37), there remains a cause for concern for the clinical application of high-energy shock wave to treat malignant tumors. Moreover, systems with multiple transducers targeting a joint focal area have proven difficult to focus in clinical practice.

Although the majority of these studies yielded encouraging data, high-energy shock wave has not been introduced into broader clinical use for oncologic indications

to date. This is mainly attributable to insufficient tumor targeting and the fact that cell damage from high-energy shock wave is mediated primarily via the mechanical effects of ultrasound (i.e., tissue cavitation), which is difficult to target, control, and predict. Reliable destruction of deep lying tissues (a prerequisite for use in oncologic indications) is hard to achieve with current high-energy shock wave devices.

THERMAL TISSUE ABLATION

Heating above 47°C results in protein degradation of tissues, with the extent of damage depending on the time of heat exposure and, to a lesser degree, the type of tissue and its structure. With heating >60°C, protein degradation of all biologic tissues becomes instantaneous, and irreversible coagulation necrosis of the targeted structure occurs. Temperatures beyond this range can be achieved in vivo using extracorporeal high-intensity focused ultrasound.

High-Intensity Focused Ultrasound

As an ultrasound wave propagates though biologic tissues, or any medium that is not ideally viscoelastic, it is progressively absorbed and the energy is converted to heat. If the ultrasound beam is brought to a tight focus at a selected depth within the body, the high energy density produced in this region results in temperatures exceeding the threshold level of protein denaturation. As a consequence coagulative necrosis occurs.

> As an ultrasound wave propagates though biologic tissues, or any medium that is not ideally viscoelastic, it is progressively absorbed and the energy is converted to heat. If the ultrasound beam is brought to a tight focus at a selected depth within the body, the high energy density produced in this region results in temperatures exceeding the threshold level of protein denaturation. As a consequence coagulative necrosis occurs.

The energy drops sharply outside the focal zone so that overlying and surrounding tissues remain unchanged. This creates an extremely sharp border between ablated and undamaged tissues. The size and location of the ablated region depend on the shape of the piezoceramic element and its respective focusing system, the ultrasound frequency and duration of insonication, the absorption coefficient of the incident tissues, and the site intensity achieved (12,38,39). In a defined biologic environment, the size of the thermal lesion can be controlled by the power and duration of the ultrasound pulse (40). With higher in situ intensities ($>3500\,W/cm^3$), cavitation phenomena with bubble implosion and mechanical tissue disruption are added, which are more difficult to control (41,42).

The antineoplastic effect of high-intensity focused ultrasound has been clearly demonstrated in vivo in a number of experimental settings.

> The antineoplastic effect of high-intensity focused ultrasound has been clearly demonstrated in vivo in a number of experimental settings.

Kishi and coworkers (43) reported on a significant reduction of implanted glioma tumors following high-intensity focused ultrasound-treatment using $1000\,W/cm^2$ for two seconds at a frequency of 0.944 MHz. Fry and Johnson (44) implanted hamster medulloblastoma cells in rats, which were subsequently treated by high-intensity focused ultrasound ($900\,W/cm^2$, 1 MHz, seven seconds). The tumor cure rate was 29% in rats treated with high-intensity focused ultrasound and 40% in rats given a combination of high-intensity focused ultrasound and chemotherapy. Moore et al. (45) studied the effect of high-intensity focused ultrasound on the Morris 3924-A hepatoma implanted in rats. The tumor volumes in treated animals were subs-tantially smaller than those in the untreated control group. However, although the entire tumor was included in the target zone, no tumor was completely destroyed. Chapelon and associates (46) reported on the effect of high-intensity focused ultrasound on the Dunning R3327 prostatic adenocarcinoma implanted in Copenhagen rats. In Study 2 of this series, 25 rats with AT2 subline implants were treated with an acoustic intensity of $820\,W/cm^2$. Complete tumor necrosis was achieved with this acoustic intensity in 24 cases (96%), and 16 lesions (64%) appeared to be cured, whereas all rats in the control group died of progressive tumor growth within 60 days of tumor implantation.

These data demonstrate that high-intensity focused ultrasound applied extracorporeally is capable of inducing precise, well-controlled contact- and irradiation-free in-depth tissue destruc-tion. However, it needs to be empha-sized that none of these experimental studies were 100% successful.

> These data demonstrate that high-intensity focused ultrasound applied extracorporeally is capable of inducing precise, well-controlled contact- and irradiation-free in-depth tissue destruction. However, it needs to be emphasized that none of these experimental studies were 100% successful.

In all series, some local recurrences were seen or viable cells were identified within the target zone. The reason for this phenomenon is not fully understood; most likely, the efficacy of each high-intensity focused ultrasound shot might vary, and the penetration of the ultrasound beam into tissue could be reduced in certain circumstances, such as by tissue (micro)cavitation.

The potential use of high-intensity focused ultrasound for oncologic indications raises the important issue of whether such treatment hinders or accelerates the formation of distant metastases. In various studies, no evidence of increased rate of metastases has been reported (Table 1) (46–50). Chapelon and associates (46) determined the impact of high-intensity focused ultrasound on the development of metastases of

TABLE 1 ■ Rate of Metastases After in Vivo High-Intensity Focused Ultrasound of Experimental Tumors

Authors	Model	Rate of metastasis controls (%)	HIFU (%)
Goss and Fry (47)	Joshida sarcoma	43	26
Yang et al. (48)	Hepatoma 3924° in rats	21	4
Chapelon et al. (46)	Dunning R3327, prostate Ca, rats	28	16
Kaketa et al. (49)	Horie sarcoma rats	44	24
Oosterhof et al. (50)	T-6 Dunning R3327 prostate Ca, rats	25	23

Abbreviation: HIFU, high-intensity focused ultrasound.

experimental prostate cancer. In the control population 28% of the animals developed distant metastases, whereas in the high-intensity focused ultrasound-treated animals this percentage dropped to 16%. Similar findings were reported by Oosterhof and colleagues (50) using a T-6 Dunning R3327 rat prostate cancer subline, which was implanted in the hind limb of Fisher–Copenhagen rats. Metastases were seen in 23% of the high-intensity focused ultrasound-treated animals compared with 25% of the sham-treated animals. From these data, it can be concluded that high-intensity focused ultrasound applied to cancer tissues does not accelerate the development of distant metastases; indeed, numerous studies suggest that high-intensity focused ultrasound treatment reduces the rate of metastases (Table 1). As a result, high-intensity focused ultrasound has received considerable experimental and clinical attention.

Extracorporeal High-Intensity Focused Ultrasound Tissue Tripsy in Prostatic Disease

All systems presently used for therapeutic high-intensity focused ultrasound for urologic indications have a single transducer, which is focused either by having a concave shape or with acoustic lenses. The former are smaller and therefore have mainly been utilized for intracavitary use, such as transrectal high-intensity focused ultrasound of prostate cancer. As the focal lengths thus needed are smaller, frequencies in the 3–4 MHz range can be used. They produce small but very precisely defined lesions. Larger areas are ablated by moving the transducer electronically and adding one lesion to another (Fig. 4).

The approach was first used clinically to ablate the transition zone in obstructive benign prostatic enlargement. Although both experimental and phase II clinical studies showed high-intensity focused ultrasound for benign prostatic enlargement to be safe and minimally invasive, long-term results were disappointing (51–57). In spite of treatment times in spinal anesthesia of around 60 minutes, tissue ablation with larger median lobes or calcification was frequently insufficient. Obstruction at the bladder neck was often not permanently eliminated because of the development of scar tissue, and the treatment result was poorly predictable in the individual patient.

Gelet et al. (41) pioneered the use of transrectal high-intensity focused ultrasound for the treatment of localized prostate cancer.

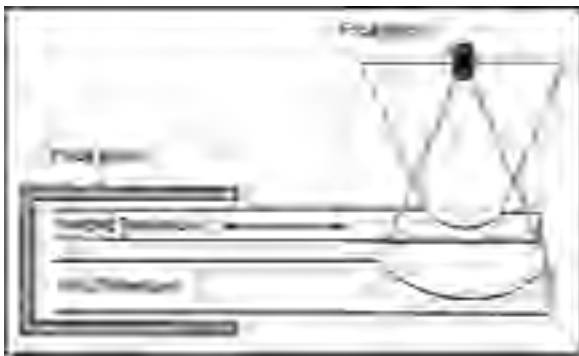
> Gelet et al. pioneered the use of transrectal high-intensity focused ultrasound for the treatment of localized prostate cancer.


FIGURE 4 ■ System for transrectal high-intensity focused ultrasound: separate transducers for imaging and therapy incorporated in a joint transrectal probe are used intermittently (Ablatherm™, EDAP, Paris, France). *Source*: From Ref. 12.
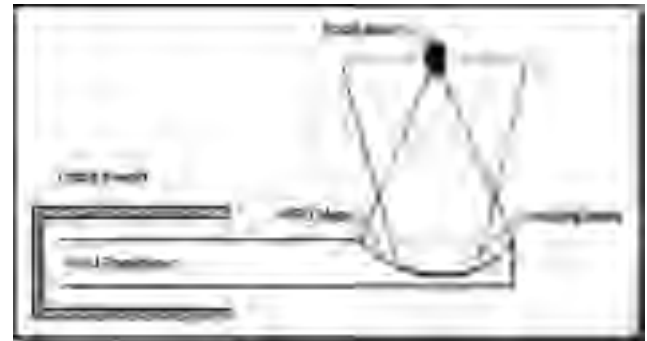

FIGURE 5 ■ System for transrectal HIFU: the same transducer operating at 4.0 MHz is used for imaging and therapy (Sonoblate™, Focus Surgery, Indianapolis, Indiana). *Source*: From Ref. 12.

Using a system that utilized a 2.25 MHz therapeutic transducer and a 7.5 MHz probe that was advanced intermittently for imaging (Fig. 4), Gelet et al. (58) treated patients in spinal or general anesthesia in the lateral decubital position. Rectal burns and unreliable tissue destruction in borderline target zones in early series could be overcome by raising the treatment frequency to 3.0 MHz (41,58–60). Therapeutic complete high-intensity focused ultrasound ablation of the entire prostate requires long treatment times in regional anesthesia, and is particularly difficult to achieve in the anterior segments of larger prostates. In a prospective study, Madersbacher et al. (40) attempted targeted ablation of localized cancers as defined by hypoechoic ultrasonographic appearance and selective biopsy. They used a system where the central zone of 4 MHz transducer used for high-intensity focused ultrasound therapy is also utilized for imaging (Fig. 5). In 10 patients whose prostates were removed prospectively after high-intensity focused ultrasound, residual cancers were demonstrated in seven patients in other areas, proving that complete ablation of the prostate is needed for curative treatment. The study also showed that the lesion grew towards the probe, i.e., towards the rectum, rendering it difficult to ablate tissue anterior to the urethra.

By restricting high-intensity focused ultrasound ablation to localized cancer in prostates <40 mL in volume and utilizing the intrarectal balloon to flatten the prostate by compression, the anterior segment is better reached. Four hundred and two patients were treated in this manner in a phase II/III study (62). Although 27.9% of patients required two treatment sessions, an overall 87.2% of 288 patients had negative biopsies at follow-up and a median prostate specific antigen nadir of 0.4 ng/mL was achieved with a minimum follow-up of six months (62). Thüroff and Chaussy (63) circumvent the problem of prolonged catheterization by combining high-intensity focused ultrasound with transurethral resection of the transition zone during the same session. In 232 patients with clinically organ-confined prostate cancer, follow-up biopsies were negative in 84% of patients and prostate specific antigen remained stable in 83% of patients with a median follow-up of 27 weeks. Nevertheless, the need to retreat in 7.7% of patients already with this short follow-up and treatment times in anesthesia of >2 hours clearly show the need for improvement of the technique before this can be considered standard treatment. Improved lesioning by more rapid study cycles, longer focal length ultrasound transducers, and ideally phased array transducers with variable focal length and monitoring of the treatment effect by on-line magnetic resonance imaging thermometry (64–66) may be feasible solutions to these problems in the near future. Better patient selection may likewise be a key for improving results. High-intensity focused ultrasound may be most beneficial in patients with local recurrence after radiation failure (67). Finally, experimental data suggest that high-intensity focused ultrasound may promote tumor immune response even with sublethal treatment and enhance other systemic treatment approaches, such as in vivo gene transfer (68,69).

Testis Tumors

The testicle appears as an ideal organ for extracorporeal high-intensity focused ultrasound as it is easily accessible, even for transducers with short focal lengths, with almost no interfering acoustical interphases, and because ultrasonography permits superb visualization of testicular tumors. Clearly, a unilateral testicular tumor in the presence of a normal contralateral testicle would always be treated by orchiectomy. About 2% of all malignant testicular tumors are bilateral, either synchronous or metachronous. To avoid anorchia organ sparing tumor excision and subsequent irradiation of the residual testis with 16–20 Gy to eradicate Ca in situ is usually considered the therapy of choice (70). Although the recurrence rate is <6% with this approach, ~20% of the patients ultimately loose the testis and need permanent androgen replacement therapy (70).

Using a high-intensity focused ultrasound system originally developed for transrectal high-intensity focused ultrasound, Madersbacher et al. exposed four patients with metastatic prostate cancer to transcutaneous high-intensity focused ultrasound prior to orchiectomy. The scrotum was submerged in saline, the testicle immobilized with a sling around the base of the scrotum, and target lesions within the testicle of 8×8 mm ablated at a frequency of 4.0 MHz and site intensity of 1680 W/cm^2. Histology showed definite signs of necrosis, with detachment of the germinal epithelium, shrinkage of nuclei and cell disintegration in the target zone, and targeted lesion and obtained lesion corresponding in size and location (71).

A clinical phase II study in patients with tumors in the solitary testis in whom the contralateral testis had been removed for a malignant tumor demonstrated the possibility of cure with high-intensity focused ultrasound and postoperative irradiation (71).

A clinical phase II study in patients with tumors in the solitary testis in whom the contralateral testis had been removed for a malignant tumor demonstrated the possibility of cure with high-intensity focused ultrasound and postoperative irradiation.

In the meantime, seven patients with tumors in a solitary testis were treated in this manner, with a mean follow-up of 42 months and follow-up over five years in four patients (61). The only patient to develop a recurrent tumor in the series refused postoperative irradiation. This testicle was removed and histology showed the recurrent tumor to be an embryonal carcinoma in a different location, with the high-intensity focused ultrasound-treated area tumor free. All other patients remain tumor free, with normal levels of serum testosterone and no need for androgen replacement (61).

Renal Tumors

Up to two-thirds of kidney tumors diagnosed today are detected incidentally in asymptomatic patients, and up to half have a diameter of <3 cm. Their tendency to grow is usually low and up to 14% may actually be benign (72–75). As they are also frequently detected in elderly patients with significant comorbidity, there is a material interest in less invasive treatment modalities than the standard surgical procedures. Well over a third of these are in a peripheral, exophytic location that render them well discernible by ultrasonography and accessible to an energy ablative approach.

Percutaneous techniques using either cryoablation or thermal coagulation are widely employed for this today but the need to puncture the tumor with the potential risk of hemorrhage and tumor spillage raises some caveats. Transrectal high-intensity focused ultrasound systems operating in the 4 MHz range have been modified for laparoscopic use.

In porcine kidneys they permit reproducible partial kidney ablation with no damage to surrounding structures (76), especially when fitted with an integrated 6.5 MHz imaging transducer. For extracorporeal high-intensity focused ultrasound ablation, however, penetration at this frequency is too short, even in small laboratory animals (77). In the 1–1.5 MHz frequency range, the penetration of the transducer increases and the focal zone becomes more cigar shaped. Chapelon et al. (78) and Watkin et al. (79) were able to obtain significant renal lesions with an extracorporeal approach in vitro and in vivo in large animals with experimental systems of this type, but targeting proved difficult and skin burns occurred frequently. Two recent developments seem to have overcome these problems and have revived clinical interest in extracorporeal high-intensity focused ultrasound of renal tumors: the Storz Medical and the Chongqing devices for extracorporeal high-intensity focused ultrasound.

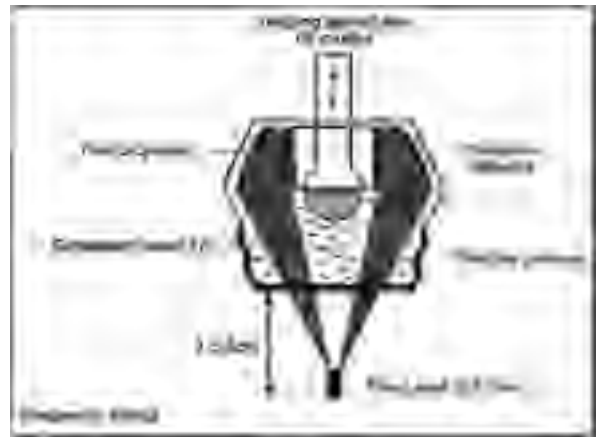
The Storz Medical extracorporeal high-intensity focused ultrasound system[b] consists of a cylindrical piezoceramic element generating ultrasound waves of 1 MHz, which are focused at a depth of 10 cm with a parabolic reflector (Fig. 6). A 3.5 MHz ultrasonic transducer is integrated centrally for in-line imaging of the focal area. Ultrasound waves are coupled into the body though a flexible polyurethane cushion filled with degassed water. Electrical power can be increased up to 1.8 kW. The focal zone ($p_{max}/2$) has an ellipsoidal shape of approximately 12×3 mm in biologic tissues. At 400 W power and penetration through 10 cm of porcine muscle in vitro, this provides calculated site intensities of 1430 W/cm². In porcine kidneys, insonicated ex vivo reproducible lesions of coagulative necrosis with central areas of liquefaction were obtained, with the size correlating to pulse duration and power (80). Köhrmann et al. (81) tested the system in vivo on the renal parenchyma of kidneys removed for nononcological reasons and observed similar lesions of irreversible tissue damage.

In a curative attempt in vivo in a patient with three tumors in a solitary kidney, two were completely ablated by extracorporeal high-intensity focused ultrasound, with a follow-up of six months (81).

This prototype has been available at the Department of Urology, University of Vienna, Medical School, for phase II clinical testing since April 2001 (89). 16 kidney tumors in 16 patients were insonicated extracorporeally. The procedure was always performed in general anesthesia, with attempts to reduce respiratory movement of the kidney by briefly stopping ventilation during insonication. As the treatment procedure is evolving, the treatment parameters varied over time, with electrical power being raised up to 1.8 kW, pulse durations of four or six seconds, and up to 70 pulses administered. The system was also changed technically by increasing the diameter of the reflector from 100–144 mm and changing its aperture from 64° to 84°, reducing its focal length from 10–8 cm, and most notably, by adding a mechanical arm directing the applicator.

In two elderly patients, each with a small tumor, the same procedure was performed with curative intent and the entire tumor was treated with 70 pulses of six

[b]Storz Medical System, Kreuzlingen, Switzerland.

FIGURE 6 ■ Schematic drawing of treatment arm of Storz^TM system for extracorporeal high-intensity focused ultrasound. A cylindrical transducer generating ultrasound at 1 MHz is focused with an acoustical lens to a focus 3 × 12 mm in situ; a flexible cushion filled with degassed water permits a variable focal length of 3.5–8 cm and an integrated B-mode transducer provides imaging of the target area. *Source*: From Ref. 80.


seconds duration at 1.8 kW. Follow-up magnetic resonance imagings showed some shrinkage of the tumor in one patient, but no complete radiological remission. In the other patients only a lesion of 10 ×10 mm was targeted in the tumor. The tumors were then removed in the same anesthesia with the standard surgical procedure. Some erythema of the skin were noted in the five patients subjected to the highest doses, but never skin burns. At surgery, all structures appeared normal and specifically no alterations were noted on the surface of the kidney. Macroscopically limited zones of bluish discoloration and focal hemorrhage were seen in the targeted zone in five kidneys. Histological changes suggestive of acute tissue necrosis (82) were detected in the nine tumors that had been subjected to the highest U.S. dose. They only comprised 15–35% of the area targeted, and were considerably smaller than lesions observed with similar energy settings in normal renal parenchyma or experimental studies (80). Nevertheless, the changes were only observed within the targeted area, and surrounding structures always appeared normal.

In the Chongqing "high-intensity focused ultrasound" extracorporeal device[c], exchangeable ellipsoidal therapeutic transducers of 12 or 15 cm diameter are mounted around a central 3.5 MHz diagnostic transducer and positioned within a basin filled with degassed water under the patient table. Depending on the transducer used, frequencies of 0.8, 1.2, and 1.6 MHz, and focal lengths of 100, 130, 135, 150, and 160 mm are available. The in vivo focal region for the 1.6 MHz transducer was calculated at 3.3 × 1.1 mm, with only minor differences for the other transducers. In situ intensities are estimated as ranging between 5.000–20.000 W/cm^2 (83). Ablation can be achieved by placing individual lesions side by side as with all other systems, but the device also has the capacity to achieve more rapid ablation through "painting out" the target area in sequential linear tracks. Smooth, three-dimensional movement of the activated transducer enables this process, and by exposing the same target area 2–6 times, the volume of ablated tissue increases in a linear fashion (Fig. 7) (83). At these energy levels cavitation processes are clearly also involved, but detailed experimental and clinical studies provided no evidence for tumor cell dissemination (88). Because of the high in situ intensities used, treated tissues become hyperechoic on ultrasonography and this effect is used for on-line targeting and feedback. Wu et al. (84) have employed this system for the treatment of 1038 patients with malignant tumors, mainly of the liver, breast, and soft tissues. In spite of large-volume ablations and reportedly good tumor control, side effects were low, and mainly consisted of fever in up to 20% and skin burns in 5% of the patients. The authors also mention treating 27 patients with renal tumors, and in a more recent report they give details of a subgroup of 13 patients with tumors 2–15 cm in diameter. Patients were treated in anesthesia with a 0.8 MHz transducer with a focal length of 135 mm, at a scanning speed of 2–5 mm and track length of 20–40 mm. At a median treatment time of 5.4 hours and a median 1.3 sessions per patient, the tumors were completely ablated in three patients and between 40% and 70% in the rest (85).

A similar system was installed at the Churchill Hospital, Oxford, United Kingdom in May 2002 and has been in use in phase II clinical trials since November 2002. Sixteen patients have been treated in phase II clinical trials, four with renal tumors, and the remaining 12 with liver tumors (88). All patients have been treated under general anesthesia, and respiratory movement is minimized by selective intubation, with ventilation of only the contralateral lung during ultrasound exposures. Acoustic powers of 180–300 W have been

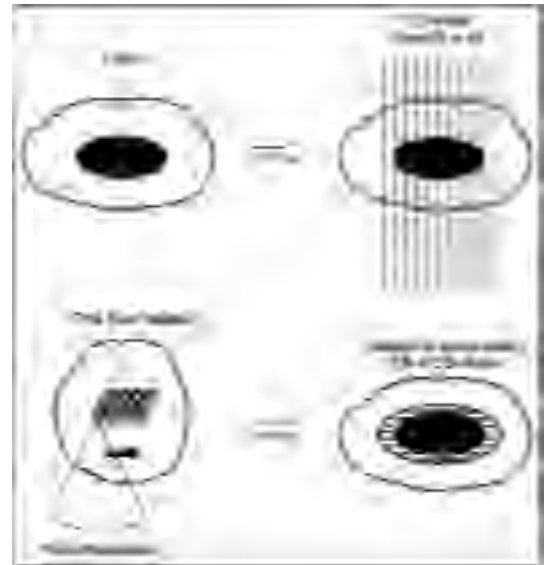
[c]Chongqing HAIFU, Chongqing, China.

FIGURE 7 ■ Schematic depiction of the treatment principle involved in the Chongqing HAIFU system: The target is dissolved into multiple two-dimensional ultrasound slices at 5–10 mm internal, which in sum establish a three-dimensional image of the target. With directional movement of the transducer, each slice is treated, and the effect is monitored by immediate reimaging thereafter. *Source*: From Ref. 83.


used, and the most common exposure regime has been the placement of single lesions adjacent to one another (with an overlap of half the transverse diameter of the focus). Maximum transverse diameters of the target renal tumors have ranged from 2.5–5.4 cm, and according to the trial protocol, only a proportion of each renal tumor was exposed to high-intensity focused ultrasound. Estimated treated volumes range from 4.0–8.0 cm^3. No skin burns were seen despite the high exposure powers, and the most significant adverse event reported has been a transient bruising sensation. Magnetic resonance and color Doppler imaging after two weeks provided an early indication of the treatment outcome, and following an interval of approximately six weeks post-high-intensity focused ultrasound, three of the four patients with renal tumors progressed to surgery.

At the time of high-intensity focused ultrasound treatment, the hyperechoic changes on ultrasonography, which are characteristic of successful ablation, were not seen in any of the treatments despite the very high acoustic powers used. A small region of reduced contrast uptake on magnetic resonance imaging in one patient, and reduced perfusion color Doppler sonography in another patient indicated a possible volume of ablation. Unfortunately, these regions could not be identified confidently on histological examination, and other than some adherent Gerota's fascia and fat necrosis in the perinephric fat, no conclusive evidence of successful ablation has been found in the other three excised renal tumors. However, the sample size is too small to draw meaningful conclusions and results have been considerably more encouraging in the treated liver tumors. Treatment parameters will be adjusted as the trial progresses, and if consistent ablation continues to prove difficult, the combination approach of embolization plus high-intensity focused ultrasound as employed in China (83) will be explored.

The process of developing a thermal lesion by high-intensity focused ultrasound in vivo, over sound propagation and absorption to heat generation, conduction and adequate temperature distribution, is subject to a multitude of variables. These are especially difficult to control with high-intensity focused ultrasound of renal tumors.

Respiratory movement has been proven a major problem. Even with controlled ventilation placing one small lesion precisely next to the other has proven virtually impossible. Automated coordination between insonication and ventilation and "painting" the lesion with continuous insonication rather than placing one lesion next to another may further improve this.

Acoustic interphases result in absorption and reflection phenomena and therefore significantly impact the site and size of the lesion. In high-intensity focused ultrasound of renal tumors overlying ribs present a major challenge. Although they only marginally influence focal position, high-intensity focused ultrasound beam and peak intensity are impacted significantly, and with direct insonication the rib may even be damaged. The use of wider apertures of the beam, directing it through the intercostal spaces, dose adjustments, and perhaps even shielding of sensitive areas with acoustic absorbers should solve the problem (86). More difficult to compensate for are acoustic interphases within the kidney, and specifically within the tumor. Structural inhomogeneity may be pronounced even in small tumors, yet is difficult to define at the time of treatment. This is obviously also the main reason for the less consistent lesioning in renal tumors than in normal renal

> The process of developing a thermal lesion by high-intensity focused ultrasound in vivo, over sound propagation and absorption to heat generation, conduction and adequate temperature distribution, is subject to a multitude of variables. These are especially difficult to control with high-intensity focused ultrasound of renal tumors.

parenchyma. This mainly impacts on lesion size (87, 88). Higher site intensities, obtained by either increasing power input, longer pulse duration, retreating the same area repeatedly or by combining these parameter modifications, appear as the most obvious solutions. Ideally, the problems could be overcome with the availability of a reliable method for assessing tissue necrosis at the time of high-intensity focused ultrasound application so that the dosage can be adapted individually. Hyperechogenic changes on gray-scale ultrasonography signalize a high-intensity focused ultrasound effect at this point, but not necessarily complete necrosis. Presently, this can only be monitored on-line by extremely complex rapid magnetic resonance imaging thermometry (88), which appears nonfeasible in a clinical setting at the time. Given current progress in ultrasound densitometry of microperfusion changes, new options may rapidly appear on the horizon. Until then the only practical solution lies in ongoing phase II clinical studies as reported herein.

SUMMARY

- Although the majority of the reported studies yielded encouraging data, high-intensity focused ultrasound has not been introduced into broader clinical use for oncologic indications to date. In fact, tumor targeting is insufficient and cell damage from high-intensity focused ultrasound is difficult to target, control, and predict with current high-intensity focused ultrasound devices.
- The antineoplastic effect of high-intensity focused ultrasound has been clearly demonstrated in vivo in a number of experimental settings. high-intensity focused ultrasound applied extracorporeally is capable of inducing precise, well-controlled contact- and irradiation-free in-depth tissue destruction. However, it needs to be emphasized that none of these experimental studies were 100% successful.
- Compared to high-intensity focused ultrasound ablation of lesions in the liver, breast, prostate, and testes extracorporeal high-intensity focused ultrasound ablation of renal tumors is certainly more challenging. Promising results from other centers in China using the Chongqing "HAIFU" device give cause for optimism, but our own results show that it must definitely be categorized as experimental at present. Nevertheless, as early clinical experience with ESWL of urolithiasis has shown, relatively minor technical improvements may suddenly bring the clinical breakthrough.

TELEMENTORING AND TELESURGERY

Mehran Anvari

Department of Surgery, McMaster University, St. Joseph's Healthcare, Hamilton, Ontario, Canada

INTRODUCTION

Advances in laparoscopic surgery in the past decade have been rapid and have impacted most surgical disciplines. However, in few instances has the approach become the standard of care. While its application to simple and increasingly complex surgeries has been shown to offer a number of benefits including shorter hospital stays and recovery times, lower complication rates, and superior cosmetic results, the primary factor preventing many surgeons from offering advanced laparoscopic surgery is lack of training.

The learning curve for such procedures may be long and many of the skills required simply cannot be acquired in a classroom setting. The complication rates encountered during the learning curve and the medicolegal concerns raised have caused many surgeons to shy away from unsupervised attempts at gaining experience, which was the hallmark of the early years of minimally invasive surgery revolution.

On-site mentorship (1) has been shown to be the most effective means of enhancing the training experience and reducing the learning curve mishaps.

However, for surgeons in smaller communities, access to the expertise of skilled laparoscopic surgeons concentrated in tertiary care teaching hospitals can be difficult. Thus, completing the supervised practice or mentoring recommended by the Society of American Gastrointestinal Endoscopic Surgeons (1) is a major impediment to many aspiring advanced laparoscopic surgeons. As a result, laparoscopic surgery for many procedures is not available to patients in rural communities without involving travel to a distant urban center and is completely unavailable in less technologically advanced parts of the world. However, recent advances in telecommunications and computer-aided surgical systems (robotic surgery) have the potential to revolutionize the field of surgery through the development of programs in telementoring and robot-assisted remote telepresence surgery, resulting in access to a complete range of minimally invasive techniques for patients in rural or remote areas.

Telementoring utilizes modern videoconferencing technology to allow an expert surgeon to observe a distant surgery in "real time" and provide interactive instruction and guidance throughout the procedure.

Utilizing Integrated Services Digital Network, Internet protocol, or satellite technology, telementoring provides a means for surgeons to acquire laparoscopic skills under the supervision of an experienced expert, ensuring high standards of surgical quality and patient care. However, it also has a number of significant limitations, mainly the fact that the expert surgeon is not physically present to assist and is unable to react and take over in case of complications or unexpected developments.

Robot-assisted remote telepresence surgery utilizes robotic surgical systems together with advanced telecommunications technology to allow a surgeon to operate

> On-site mentorship has been shown to be the most effective means of enhancing the training experience and reducing the learning curve mishaps.

> Telementoring utilizes modern videoconferencing technology to allow an expert surgeon to observe a distant surgery in "real time" and provide interactive instruction and guidance throughout the procedure.

from a remote location. The surgeon gains physical telepresence through the use of a master–slave telesurgical system with three robotic arms. One arm holds the scope and the camera and two perform surgical tasks. The surgeon's workstation provides a high-resolution view of the surgical field and the computer system transmits the movements of the surgeon's hands to the robotic arms.

Although such systems hold tremendous potential to transform the nature of surgical care, they have a number of obstacles that should be overcome, including prohibitively high start-up costs, safety concerns, and technical limitations of the existing systems. In addition to technology-related concerns, there are a number of issues concerning liability, confidentiality, and licensing, which will have to be addressed before telementoring and telerobotic surgery can gain widespread acceptance.

TELEMENTORING

History

The first reported case of interactive real-time surgical teaching from a distant location was in 1965 when DeBakey utilized broadband satellite to transmit guidance in cardiothoracic surgery to Europe from the United States (2). However, rapid communication developments during the 1990s have been, at least in part, behind the recently expanding body of literature reporting telementoring to be a safe and feasible option for surgical teaching.

In 1994, Kavoussi et al. (3) reported use of the AESOP® arm[a], a robotic arm capable of holding and manipulating the laparoscopic camera to perform three telementored surgeries in which the instructing surgeon was located in a separate room. Aside from the robotic arm repeatedly detaching from the camera, the procedures were performed successfully. In a series of 23 urologic procedures performed at the Baltimore Medical School, 22 were successfully completed laparoscopically by a junior surgeon with mentoring from an expert surgeon located in a separate building (4). Rosser et al. evaluated the role of telementoring in the teaching of advanced laparoscopic procedures. In a two-phase study, phase 1 involved four colonic resections during which the mentoring surgeon was present in the operating room and four colonic resections performed with the mentor located in a truck on the hospital grounds. Phase 2 involved two Nissen fundoplications mentored from within the operating room and two during which the mentor was located five miles away. In phase 1, audio and visual signals were transmitted via coaxial cable and in phase 2, coding and decoding algorithm-mediated compression technology and existing T-1 landlines were used. The authors reported no significant difference in mean operating times or surgical outcomes for the telementored procedures as compared to those in which the mentor was physically present (5). Early reports on the use of long-distance telementoring include an adrenalectomy performed in 1998 between Austria and the United States (6), and a series of five laparoscopic herniorrhaphies, completed on board an American aircraft carrier by the ship's surgeon while under the guidance of an experienced surgeon located in the United States. The surgeons were linked via the Battle Group Telemedicine System, which provided real-time audio and visual information (7).

Lee et al. reported results of transcontinental trial involving the United States and both Thailand and Austria in 1998 in which an electrocautery instrument could be controlled by the telementor. All surgeries, which included a nephrectomy, a varicocelectomy, and an adrenalectomy, were completed without complications (8). Since this time, numerous groups have reported successful telementoring of a wide range of procedures over substantial distances (9–13).

Center for Minimal Access Surgery Telementoring Program

In Canada, telementoring is currently in routine clinical use, providing community surgeons in two rural cities with access to the expertise of expert laparoscopic surgeons, without the need for extensive travel.

Surgeons at the Centre for Minimal Access Surgery (St. Joseph's Healthcare, McMaster University, Hamilton, Ontario, Canada) routinely mentor surgeons at two community hospitals, one in Northern Ontario and the other in Northern Quebec. Procedures performed to date include laparoscopic fundoplications, splenectomies, hernia repairs, and colonic resections (14). The telecommunications (two-way audio and visual connections) are conducted over either integrated services digital network lines or the Internet Protocol network, which connects most hospitals in Canada.

In Canada, telementoring is currently in routine clinical use, providing community surgeons in two rural cities with access to the expertise of expert laparoscopic surgeons, without the need for extensive travel.

TABLE 1 ■ Outcomes for 19 Telementored Procedures Involving Four Mentees

Procedure	No. of cases	Length of stay (day)[a]	No. of complications	Mentor's assessment of surgical quality[a]	Mentee's assessment of utility of mentoring[a]
Colon resection	10	5	1	4 out of 5	4 out of 5
Nissen fundoplication	5	3	1	4 out of 5	4 out of 5
Splenectomy	2	2	0	5 out of 5	4 out of 5
Ventral hernia	1	6	0	4 out of 5	4 out of 5
Reversal of Hartmann's	1	7	1	4 out of 5	3 out of 5

[a]Median values.

Detailed questionnaires administered to both the mentoring surgeon and the mentee following each telementoring procedure have been utilized to evaluate the success of each session. Details of 19 procedures performed between November 1992 and July 1993 are given in Table 1.

Telementoring has permitted the community surgeons involved to adopt advanced laparoscopic procedures while providing patients with the same standard of care as at tertiary care centers and has facilitated a reversal of the recent trend toward centralization of health care services. The Centre for Minimal Access Surgery plans to extend this service to include eight teaching hospitals and 32 rural communities within the next few years.

Technical Requirements and Considerations

Recent advances in telecommunications have encouraged the development and evaluation of surgical telementoring as equipment required becomes more readily available. Early telementoring occurred over short distances utilizing hard-wired connections. However, telecommunication currently utilizes integrated services digital network, a fully digital system readily available in many areas via commercial telephone line. These lines offer sufficient bandwidth to ensure adequate image quality. However, ultimately, internet protocol networks are likely to become the medium of choice due to reliability, safety, wide availability, and recent ability to offer quality of service (15). It should be noted that low-bandwidth connections can and have successfully been used in remote areas where telecommunications are limited. However, operators must minimize camera motion and slow movements in compensation (16).

Due to the reliance on technology, telementoring has raised significant concerns regarding patient safety. Loss of communications, poor image transmission, and equipment failure at either location are all possibilities that must be considered well in advance of any surgeries.

It is of utmost importance that a comprehensive plan exists to deal with all eventualities, including system failures and intraoperative complications. Because the mentor is not physically present to take over if required, such a plan must ensure that in case of a serious system failure or other complication, the local surgeon has the expertise and technical assistance necessary to complete an open procedure if required.

ROBOT-ASSISTED REMOTE TELEPRESENCE SURGERY

Robot-assisted remote telepresence surgery has the potential to address the deficiencies inherent in telementoring by offering true telepresence for the expert surgeon in the operating room of the learner, thus allowing the expert to assist or perform a part or all of the surgery as necessary and to slowly train the local surgeon in performing the advanced laparoscopic procedures safely. Robot-assisted remote telepresence surgery utilizes a multiple-arm robotic platform controlled by the surgical console located remotely hundreds or thousands of miles away and connected to each other via broad band telecommunication via either fiber-optic landlines or possibly satellite. Two-way audio and video connections facilitate communication between the remote surgeon and the local operative team, and views of the operating room in addition to those of the surgical field allow the remote surgeon to become immersed in the operative environment.

Current Applications of Robot-Assisted Remote Telepresence Surgery

In 2001, Marescaux et al. successfully utilized the Zeus TS system to perform the world's first transatlantic telerobotic surgery in which the remote surgeon, working from a

---

It is of utmost importance that a comprehensive plan exists to deal with all eventualities, including system failures and intraoperative complications. Because the mentor is not physically present to take over if required, such a plan must ensure that in case of a serious system failure or other complication, the local surgeon has the expertise and technical assistance necessary to complete an open procedure if required.

In 2001, Marescaux et al. successfully utilized the Zeus TS system to perform the world's first transatlantic telerobotic surgery in which the remote surgeon, working from a console located in New York City, performed a cholecystectomy on a patient located 3800 miles away in Strasbourg, France.

console located in New York City, performed a cholecystectomy on a patient located 3800 miles away in Strasbourg, France (17).

The procedure was completed without technical difficulties or complications in 54 minutes. Dissection of the cystic duct and artery and the dissection of the gallbladder off the liver were performed by the remote surgeons while the local operative team was responsible for exposure of structures and clip application in addition to robotic arm setup, induction of pneumoperitoneum, and trocar placement. Electrocoagulation was initiated by a local assistant upon voice command from the remote surgeon. The telecommunication link for this procedure was accomplished via a private dedicated asynchronous transfer mode. This terrestrial fiber optic network provided a bandwidth of 10 Mbps and resulted in a latency of only 155 msec. A duplicate backup line was also available in the event of disruption of the main line. However, such services are not available in many locales and are prohibitively expensive, further limiting their utility at the present point of time.

Routine Use of Robot-Assisted Remote Telepresence Surgery

In February 2003, the Centre for Minimal Access Surgery in Ontario, Canada established the first remote telerobotic surgical service (18,19). This unique service links a teaching hospital (St. Joseph's Healthcare) in Hamilton with a community hospital over 400 km away, providing patients with access to advanced laparoscopic surgery in a rural community setting. The service utilizes the Zeus-TS microjoint system, which provides telepresence for the experienced laparoscopic surgeon, and three robotic arms that are placed by the local surgeon. Telecommunication is via a virtual private network, which utilizes a public telecommunication infrastructure to provide remote hospitals with secure access to urban centers. The goal of a virtual private network is to provide the same capabilities as private dedicated networks, but at a much lower cost.

Since the inaugural surgery on February 28, 2003, 22 telerobotic surgeries have taken place with no major complications, no conversions to open procedures, and lengths of stay comparable to those seen in tertiary care centers.

Procedures completed to date include fundoplications, right hemicolectomies, anterior resections, sigmoid colon resections, and inguinal hernia repairs. The system allows the local and remote surgeon to interchange roles as necessary, thus permitting the remote surgeon to either act as the primary surgeon or demonstrate plains for dissection to the local surgeon, who had received partial training in advanced laparoscopic procedures through short courses and mentoring/telementoring.

Initial experience with robot-assisted remote telepresence surgery strongly suggests that this technology has the potential to revolutionize the delivery of healthcare, especially in rural or remote areas where access to advanced laparoscopic surgical procedures is limited or nonexistent. However, there are a number of financial, technical, ethical, and medicolegal issues that will have to be resolved before remote telepresence surgery becomes widely accepted.

Technical Considerations

Initial experiences with remote telepresence surgery have raised a number of technical issues. Firstly, development of robotic platforms to support remote telepresence surgery has been slow. To date, only the Zeus robotic system permits control of the robotic arms via a telecommunication link. However, the system is no longer commercially available following the recent merger of Computer Motion Inc. with Intuitive, manufacturer of the Da Vinci robotic system. Development of new robotic platforms that are more compact, portable, and easy to set up will be critical to the widespread adoption of this technology.

Rapid, accurate, and secure transmission of large quantities of data is critical to the success and safety of telerobotic surgery, and while Internet protocol-virtual private network and asynchronous transfer mode networks are available in many areas, they are not currently available in many remote or undeveloped areas. Currently, the use of satellite technology is not feasible due to excessive time delays (often in excess of 1 sec). Although surgeons can readily adapt to latency, there is varying evidence in the literature regarding the point at which latency leads to significant difficulty or increased errors.

Surgeons have been shown to have the capability to adapt to latencies of 500–700 msec but Fabrizio et al. (20) suggest that delays beyond 700 msec lead to decreased surgical performance.

Utilizing internet protocol/virtual private network networks, latencies of less than 200 msec are typical, of which the majority (more than 80%) is due to coding and decoding algorithm compression and decompression of the video signals. Current coding and decoding algorithm devices were designed for use in applications such as videoconferencing in which image quality is of primary concern and latency is not an important

issue. Development of new compression/decompression devices that are better suited to telepresence surgery could significantly reduce latency and shorten operating times.

Safety concerns surrounding telerobotic surgery are similar to those described for telementoring, because the remote surgeon is not physically present to take over in the event of a communication failure, robotic equipment failure, or operative complications. Use of a second redundant communication line provides an instantly available backup in case of a failure of the primary line. However, it is critical that the local and remote surgical teams outline in advance a plan of action and ensure that the local surgeon can successfully complete the procedure in the event of a system failure.

Nontechnical Issues Surrounding Telementoring and Robot-Assisted Remote Telepresence Surgery

As with the development of any new technology, telementoring and telepresence surgery have raised a number of issues related to confidentiality, liability, licensing across political borders, and assessment of the credentials of the parties involved.

Any transmission of data such as that used for telementoring or remote telesurgery via a telecommunication network poses the potential for a security breach. Encryption of the data minimizes this risk, but also adds an additional minimal time delay to transmission times. Because the data being transmitted includes medical images and identifying personal information, it is essential that all patients understand and accept that the potential still exists for inadvertent release of confidential information.

Due to the collaboration between distant institutions, telementoring and telerobotic surgery have also raised a number of legal concerns. There are no clear guidelines in existence to define the extent of liability of remote and local surgeons during telesurgical procedures. Traditionally, the party providing direct patient care has assumed liability; however, activities such as telementoring and telerobotics blur the lines that define direct care of a patient. During telementoring sessions, the mentoring surgeon has no ability to physically intervene in the case of unexpected events but nevertheless has the ability to influence the course of the procedure. The remote surgeon plays a substantially larger role during telepresence surgery, including functioning as the primary surgeon during some procedures. Thus, liability must ultimately be shared by both parties. The situation could be further complicated in the case of international collaborations in which jurisdictional conflicts may also exist. At present, no definitive solutions exist and any legal issues arising will have to be handled on a case-by-case basis. Before initiating any telementoring or telerobotic program, it is essential that both parties ensure that they are individually protected and that they reach a fundamental agreement regarding the identity of the "most responsible" physician.

Issues regarding licensing also arise when considering the establishment of a telementoring or telepresence surgery program. In cases involving mentoring or telesurgery across state or provincial boundaries, the remote surgeon must be licensed to practice in the jurisdiction in which the patient is receiving care. This requirement has the potential to impede the development of surgical support networks in which remote surgeons would potentially have to obtain licensure for a large number of jurisdictions, a costly and time-consuming endeavor. As the technology becomes more widespread, licensing bodies will most certainly need to develop new guidelines to address the unique requirements of telemedicine.

In both telementoring and telerobotic surgery, the quality of patient care is highly dependent on both the instructional and surgical skills of the remote surgeon. However, at the current time, there are no formal guidelines in place to assess these skills. As robotic assisted surgery gains in popularity, some institutions are adopting guidelines for credentialing (21). In general, these guidelines require clinical privileges for the equivalent open and laparoscopic procedures, a training course in the use of the surgical robotic system, and a step-wise progression from observation to assisting to supervised performance of the procedures. At the current time, no such guidelines exist for establishment of the credentials of telementoring surgeons. Furthermore, the success of telementored procedures is also dependent on the skills of the mentored surgeon. A minimum level of basic laparoscopic skills and thorough preparation specific to the procedure being performed are important prerequisites.

Benefits and Future Potential

Both telementoring and remote telepresence surgery offer tremendous potential to enhance the quality of surgical care offered to patients in rural or remote areas. At the current time, access to advanced laparoscopic procedures requires transfer to a distant

urban center. However, remote telesurgery enables these patients to remain in their community under the care of their local surgeon, yet have their procedure mentored or even performed by an expert surgeon at a distant teaching hospital. Creation of extensive remote telesurgery networks has the potential to reverse the recent trend toward centralization of advanced surgical care and to offer an improved level of care to patients in traditionally under serviced regions. As the technology develops further, it may be possible for an expert surgeon to guide a nonsurgeon through emergency surgical techniques in order to save the life of patients in remote areas with no immediate access to advanced medical care.

Telementoring and remote telepresence surgery also have the potential to provide novice laparoscopic surgeons with a convenient and efficient means of safely gaining experience in minimally invasive techniques.

At present, it is especially difficult for community surgeons to access the advice and instruction of expert surgeons, and this limitation has seriously impeded the widespread adoption of laparoscopic techniques. Utilizing remote telepresence technology, even surgeons in remote areas can benefit from the support of a distant expert surgeon and can confidently offer advanced laparoscopic procedures to their patients without the high complication rates that usually accompany the learning curve for such procedures. Telepresence surgery can also permit experienced surgeons to collaborate, thus encouraging the development of new surgical techniques and enhancing the quality of surgery during technically challenging procedures.

The speed with which these new technologies are adopted will depend on their demonstrated ability to address the needs of the surgical community. Also, a number of obstacles including medicolegal responsibilities and licensing issues need to be addressed before the majority of surgeons would be willing and able to utilize these services on a regular basis.

> Telementoring and remote telepresence surgery also have the potential to provide novice laparoscopic surgeons with a convenient and efficient means of safely gaining experience in minimally invasive techniques.

VIRTUAL REALITY AND SIMULATION IN UROLOGY

Robert M. Sweet
Department of Urologic Surgery, University of Minnesota, Minneapolis, Minnesota, U.S.A.

Jeffrey Berkley
Department of Industrial Engineering, University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

The focus of this chapter is virtual reality simulation and its role in urological applications. Virtual reality is one component of a true renaissance that is occurring in the surgical education curriculum. As hardware and software technology improve, it becomes possible to simulate a wider variety of surgical scenarios. Not only is it possible to prepare for such scenarios outside of the operating room but it is now possible to use the computer to automatically evaluate student performance and identify their specific training needs.

Every year at least 44,000 Americans die of medical errors. Medical errors are the seventh leading cause of death in the United States, greater than car accidents, breast cancer, or AIDS.

Pharmacy errors are no longer the leading cause of medical complications; procedural errors are. Indeed, there is an ever-increasing public scrutiny of medical training and the use of the operating room for teaching purposes.

Simulation is a promising alternative to training inside the operating room. Factors that support a shift toward simulation training include diminished resident work hours, increased operating room costs, the ACGME competency movement, and special training issues associated with the acquisition of minimally invasive surgical skills.

Many authors argue that the operating room is not the best environment for training (1,2). In fact, a recent survey of program directors demonstrated that 92% of respondents felt that there is a need for technical skills training outside of the operating room (3). However, the fact remains that to date there is a paucity of effective evaluation

> Every year at least 44,000 Americans die of medical errors. Medical errors are the seventh leading cause of death in the United States, greater than car accidents, breast cancer, or AIDS.

tools available that fully implement the power of simulation training as appropriate for a procedural skills training curriculum (4). Physical model simulators have been employed in many centers and have been shown to be effective in training some basic technical skills. Unfortunately, many of these training models do not convey a sense of "presence" to the student, and the models are not often coupled with objective metrics and training feedback. Virtual reality models represent an attractive solution to the above-mentioned shortcomings of physical model simulators. In particular, virtual reality simulation is very amenable to minimally invasive surgery and great strides have been made in select applications.

> When considering virtual reality in surgery, the key is to obtain "mimesis," or to trick the mind into believing that it is immersed in a real-life task.

It is important to acknowledge that even the most advanced simulators do not replicate the exact look and feel of a real procedure. However, for a simulator to be effective, the mind must set aside a sense of disbelief when encountering an artificial yet similar set of visual, tactile, auditory, and olfactory sensations. The student should feel that there are real consequences to mistakes made with a virtual patient, just as there would be with a real patient.

Professional athletes, musicians, actors, performers, and even surgeons have employed simulation training in a variety of fashions for decades.

> Training might focus on a subtask or an entire procedure in order for the student to achieve necessary technical skills.

On the simplest level, mental imagery techniques can be used to associate technical aspects of a procedure with cognitive rehearsal. This alone works well for relatively predictable activities, such as a 50 m swim or a gymnastic floor routine. The athlete commits to memory a list of steps required for performing a certain routine and then envisions performing each of those steps by the athlete. However, such training becomes difficult in situations where there is a reliance on multiple people, as they work with complex equipment while battling the physical forces of nature. For example, simulating scenarios on the battlefield or in outer space can be very complex and training errors can have serious repercussions. In these "less controlled environments," the aid of computer simulation to associate technical and cognitive learning can be very advantageous. Not only does simulation reinforce the learning of a particular technique but also how to deal with unexpected situations.

Simulation has been prevalent in industries such as aerospace, engineering, and the military since the 1950s. Complex tasks are evaluated not only to understand the overall problem but also to define individual components and how each part contributes to form the entire system. At the core of this process are information systems, which provide virtual prototyping of models. The tools include process and flow diagrams, interface requirement documents, and an overall design plan (5).

> Aerospace, military, industrial, and medical simulation applications all share the common pretense that for a trainee to interact with a complex system, there must be a thorough understanding of the overall system and the relevance of each subcomponent.

Aerospace, military, industrial, and medical simulation applications all share the common pretense that for a trainee to interact with a complex system, there must be a thorough understanding of the overall system and the relevance of each subcomponent. Such an understanding is necessary for a trainee to undertake the learning of many skill tasks that may involve life and death decisions.

A number of reasons for the limited role of simulation in the field of medicine compared to other industries have been postulated. One might blame the circumspect nature of medical professionals and their inability to see the "big picture" of technological advancements while trying to address patient demands with minor, incremental improvements (6). Another factor is the lack of a true funding source for efforts in surgical education. There is a significant shortfall in resources provided by government funding agency for supporting medical postgraduate education initiatives (7). The government does allocate money to residency programs. However, this money does not go to educational initiatives directly, but goes to the hospital to cover salaries and overhead assumed to exist because of the perceived inefficiencies associated with the training of residents. The end result is that medical institutions have little money allocated to buy surgery simulators and consequently the market for commercially developed simulators is quite small. Just the same, medical professionals expect the quality of surgical simulators to exceed that of common video games, even though the market for video games is many orders of magnitude greater than that of surgery simulators. Compounded by the reality that there are still a number of unsolved technical issues that prevent the creation of a truly accurate virtual prototype of the human body, there remains a large gap between expectations from the medical community and what industry is capable of delivering.

As compared to industrial and military applications, simulating the biological world includes additional complex layers of interactivity and unpredictability.

As compared to industrial and military applications, simulating the biological world includes additional complex layers of interactivity and unpredictability.

When considering the modeling of mechanical systems and how they interact with the physics of nature, we have a pretty thorough understanding of the overall system and the contribution of the individual components. Unfortunately, we have just barely scratched the surface of understanding on how genes and cells interact with each other and what this means from a physiological standpoint. Clearly, this becomes even more complex when considering and attempting to predict the output of important psychosocial factors and surgical manipulations on the "black box" organ of the human body: the brain. This is a critical thing to consider, which often frustrates our engineering colleagues who like to translate phenomenon into formulas. How then are we to simulate what we may not understand completely in the real world? Currently, the information systems for our model—the human patient—merely consist of the patient's chart (history, physical examination, and laboratory studies), and imaging modalities (the video monitor, magenatic resonance imaging, computed tomography, ultrasound, etc.) (5,8). Regrettably, these data are insufficient to create a true virtual prototype of our model. Such a human surrogate in cyberspace would be based on patient-specific data from historical, genetic, molecular, biochemical, physiological, and digital imaging sources (9). However, even without the complete data set necessary to create a truly accurate model, virtual reality still continues to aid us in the process of understanding the human body through virtual analysis that employs "block box" methodologies such as neural networks, genetic algorithms, and hidden Markov models (10).

HISTORY

In the mid-1970s, Myron Krueger coined the term "artificial reality" to describe the ability to simulate synthetic realities with the aid of computers. In 1987, a computer scientist named Jaron Lanier coined the term "virtual reality." It was during this period that a visionary general surgeon, Richard Satava, recognized that the concepts described by Krueger and Lanier could be applied to medical training. Dr. Satava has since led a crusade to apply this technology to medical procedures through countless lectures and multidisciplinary conferences like "Medicine Meets Virtual Reality" and by funding projects in this area through the Department of Defense.

Excited by the potential for virtual reality training, pioneering academic surgeons began widely promoting virtual reality technology. However, the initial hype led to false expectations and the surgical community became highly critical of early surgery simulation.

Excited by the potential for virtual reality training, pioneering academic surgeons began widely promoting virtual reality technology. However, the initial hype led to false expectations and the surgical community became highly critical of early surgery simulation.

At the time, virtual reality and medical simulation projects were limited by technological factors such as computing processing speed, graphical display hardware, data storage capacity, and data transmission bandwidth. Another significant problem was that computer scientists developed the initial surgery simulators without sufficient collaboration with surgeons. As a result, projects were often demonstrations of computer science and engineering principals that did not necessarily address the needs of the medical community. Applications demonstrated "proof of concept," but initially did not result in practical tools that could be used for medical education. As a result, the majority of the medical community considered surgical simulators impractical, expensive, unrealistic, and lacking of proper validation for use.

Successful simulation projects now involve not only collaborations between members of the medical and computer sciences but also the cognitive sciences.

Successful simulation projects now involve not only collaborations between members of the medical and computer sciences but also the cognitive sciences.

Cognitive scientists remind us that it is paramount that a simulator provide effective training, not perfect realism (11,12).

Simulation fidelity should be matched with training requirements because high fidelity simulators are not necessary for all tasks. It is the embedded instructional features in a simulator that make training effective.

Simulation fidelity should be matched with training requirements because high fidelity simulators are not necessary for all tasks. It is the embedded instructional features in a simulator that make training effective (13).

Repeatedly practicing something incorrectly without instructional feedback on the correct method will just reinforce bad behavior. It is also advantageous to embed carefully crafted scenarios with "triggers" that provide opportunities to practice and assess important behaviors. Such an example in urology would be to provide cues for the user to diagnose and manage a CO_2 embolism management during a laparoscopic radical nephrectomy. Salas and Burke (13) have stated, "Simulators should not only capture performance outcomes, but must also capture the moment-to-moment actions and behaviors." Such detailed moment-to-moment information is necessary in order to provide feedback as to how to improve performance. Salas and Burke stress that the education experience should be guided toward learning key competencies and that there is a reciprocal partnership between subject matter experts and learning/training specialists (13).

VIRTUAL REALITY ROLE IN PROCEDURAL TRAINING

While every simulator differs, in theory the primary advantage that virtual reality simulation of medical procedures has over inanimate synthetic models is its ability to track and log everything the user is doing during the task and provide useful feedback. This creates a safe and truly learner-centered environment that is comfortable and efficient, while not requiring the presence of mentor supervision. The option of adding mentored supervision, of course, is always possible and often desirable to enhance the learning experience (Table 1).

With current technology, patient-specific models can be imported into the simulation environment, allowing for the practice of specific cases prior to performing them in real life (14).

Berkley et al. (15) has begun work on this for urological applications with funding from the Defense Advanced Research Projects Agency. Many simulators have curricula built into their software, which train the cognitive aspects of the procedure as well as case scenarios and basic skills training modules. The user can focus on those subtasks, which cause the most difficulty and the proctor and the student can track progress over time and when the trainee reaches criterion levels set by experts on the simulator, they could then be given permission to "practice on patients" under supervision.

The use of virtual reality simulators to test new instruments is also a potential advantage for industry to develop cutting edge technology and train their sales staff.

In the United Kingdom, live animal operations are banned under the Cruelty to Animals Act of 1876, and there is some pressure in the United States to follow suit. While the current line of thinking in the United States is that the advantages of live animal surgery in training surgical skills seem to outweigh the pitfalls, it is always of great benefit to find alternatives to such a practice.

BUILDING A VIRTUAL REALITY SIMULATOR

A list of steps will be defined for constructing a simulator in order to promote discussion on various important issues related to surgery simulation. This list is intended to generalize so that it may be applied to a wide variety of surgical procedures rather than specific applications.

Step 1: Define a Desired Skill Set and Learning Objectives

Successful simulation projects require extensive input from the subject matter expert. When choosing physician collaborators, simulation developers need to look for physicians who are expert teachers/communicators first and technical experts second.

The first and arguably most important contribution the physician can make is defining the application or the procedure being simulated. Such a choice should be driven by training need first and apparent capability to simulate the skill set second, as

> **Sidebar (left margin):** With current technology, patient-specific models can be imported into the simulation environment, allowing for the practice of specific cases prior to performing them in real life.

> **Sidebar (left margin):** The use of virtual reality simulators to test new instruments is also a potential advantage for industry to develop cutting edge technology and train their sales staff.

TABLE 1 ■ Advantages/Disadvantages of Virtual Reality Simulators in 2004

Advantages	Disadvantages
Objective metrics	Expensive to develop
Learner centered	Expensive to purchase
Immediate user feedback	Lack of funding sources
Patient-specific data	Fidelity
Testing of new instruments	Validation lacking
Safe	Technology needs to recapitulate biology
Ability to break down complex tasks into modules	Need to define the metrics
Assessment capability	Need to define the standards
Does not require mentored supervision	Requires intense multi-disciplinary collaborations to build
Can build in curriculum	Lack of curriculum
Can discern cognitive versus technical errors	
Can track motion	
Animal welfare	

it is only with extensive discussion/bridging of the knowledge gap between computer scientists and physicians that the distinction between what can and a cannot be accomplished is defined.

Because the training need is the crux of the whole project, the physician needs to continuously supervise development to assure that the training needs are the focus and are properly being addressed. If training needs are not addressed, then the quality of graphics and model interaction become irrelevant.

There are essentially four learning domains that need to be considered:

- The affective domain (ability to manage a team, focus, attention, etc.)
- The cognitive domain (judgment, knowledge)
- The visual-spatial domain (ability to navigate in virtual space)
- The psychomotor domain (motor skills)

Some attempts have been made to measure the affective domain, but its abstract nature makes it more difficult to assess and quantify. Studies examining the effect of stress and lack of sleep in the operating room and subjective evaluation of interpersonal skills are examples of such studies (16–23).

Every urologic procedure is made up of several "skill sets," which can be thought of as building blocks. Performance of these isolated skill sets lies primarily in the visual-spatial and psychomotor domains. Thus, simulators created to simulate these basic tasks are only measuring and assessing these learning components.

The cognitive component of the procedure, or how and when these skill sets are put together, is the true backbone of the procedure. It has been approximated that 85% of what is learned for a given surgical procedure lies in the cognitive domain. The virtual reality simulator has the unique ability to dissect these domains allowing for critical and instructive analysis of causality of errors and techniques at a level much higher than inanimate simulators and even mentored instruction.

With this in mind, subject matter experts need to critically examine a given urological procedure for its cognitive, visual-spatial, and psychomotor components and look for the best opportunities by which simulation may help lessen the learning curve. The learning objectives can then be defined.

Step 2: Design a Curriculum and Analyze Where Simulation Would Be Most Useful

The next step is to design a curriculum targeted towards accomplishing those learning objectives. The design of your simulator will be such that it will hopefully be able to address the gaps in learning opportunities, which you have identified. Curriculum development is tedious and difficult work, but developers need to keep in mind that in the end it will be the "curriculum" and not the technical components of the simulator that will be validated and implemented.

Curriculum development and implementation is probably best done by a team of subject matter experts (urologists) in consultation with an expert in medical education.

Step 3: Justify the Application

The motivation to build a virtual reality simulator may include training, testing of new instrumentation, academic research, promotion of a new product, or simply financial. Regardless of the reason for building a simulator, the following guidelines are provided to help in choosing the appropriate procedures to simulate:

1. *The application should represent a commonly performed or required skill set and/or disease process:* Given the time, effort, and expense required to build a simulator, it is important that a simulator can be applied to a wide audience. For example, a simulator for training tasks such as laparoscopic port placement, Veress needle insertion, or full procedures for common diseases such as laparoscopic radical prostatectomy may be more widely used than a simulator that teaches laparoscopic excision of a urachal cyst.
2. *The skill sets embedded in the application should represent a prolonged learning curve:* If a skill set is not difficult to master, traditional training methodologies may be sufficient. Making a simulator or a module intended to train the bagging of a kidney specimen may be less useful than one for completing the urethral anastomosis during a laparoscopic radical prostatectomy.
3. *The application should address training issue that typically subject patients to risk. Patient safety should be a top priority and a driving force behind the creation of any surgical simulator:*

This issue is magnified in laparoscopic surgery, as it can be more difficult for the trainer to monitor and recover from an error performed by a trainee as compared to that which may occur in an open case. One example of a procedure that presents training risk for patients would be the hilar dissection during a laparoscopic nephrectomy.

4. *The application should address skill sets characterized by a significant training gap between preparation training and patient practice:* This issue is prevalent throughout laparoscopic urology since only the most recent graduates from select residency programs or laparoscopic fellowships received concentrated training in this arena. An entire generation of urologists is currently reliant on weekend courses, training videos, box trainers, and mentors to perform complex skills that many believe are the standard of care. It might be questioned that the skills gained from these training mechanisms adequately carry over to the operating room. With little or no objective assessment of skills prior to credentialing, it can be difficult to determine whether a trainee is ready to work with patients.

5. *Choose an application that is amenable to simulation:* It is important to choose a procedure that can be represented given the current level of technology. This used to be a significant limiting factor because the technology did not exist to address issues such as rendering complex tissue structures and their deformation. However, more recently, the consensus has been that most laparoscopic procedures could theoretically be simulated with acceptable accuracy. However, while we still lack an accurate model of the human body, it remains difficult to represent characteristics such as fluid flow and electrochemical reactions. Applications that are dependent on such intricate modeling, given current technology, may be doomed to failure.

Step 4: Define the Metrics

In order to objectively measure performance, developers need to choose what specific elements are important to track. Key metrics need to be chosen and calibrated by a consensus of subject matter experts (in this case physicians) (24). These include a taxonomy/definition of errors and a method by which results can be integrated and reported for individual users as well as groups of users (25,26).

In 2001, Satava et al. organized a surgical skills workshop attended by an assembly of representatives from surgical societies and boards responsible for the education, training, and certification of surgeons. The primary purpose was to begin standardizing nomenclature and assessment methods so that the entire surgical education, training, and evaluation community could communicate more effectively and have a common basis to compare statistical results (27). The product of such a consensus could provide critical information to the developers of simulation technology. A similar consensus publication examining medical errors has been held and the manuscript is in progress.

Table 2 shows only an initial baseline of possible metrics that may make it possible to assess and assign the degree of competency for a trainee. However, the debate over proper metrics continues and undoubtedly the list presented in Table 2 will grow with time. For example, recent simulation discussion has focused on efficient use of OR resources (preoperative planning, equipment, ancillary staff if appropriate, gas/fluid management, amount of energy delivery), which may prove important for evaluating training over a variety of medical procedures.

With the collection and classification of such data, criterion levels for each key metric can be established to define the levels of performance listed in Table 3.

Expert systems that rely on knowledge or reasoning that emulates the performance of human subject matter experts can also be created. Such expert systems might be based on encoded rule statements that reflect individual or gathered expertise in a field.

The expert system would then display "reasoning" via a rule interpreter in order to reach a decision, come to a conclusion, or give up on a particular problem.

Step 5: Recognize Which Sensory Modes Are Important and Should/Can Be Simulated

Surgeons rely on a variety of sensory feedback to execute complex hand–eye motor tasks and make important decisions. It is therefore important to determine which sensory feedback modalities are important to relay in a simulated environment. The types of feedback will vary form procedure to procedure.

In endoscopic procedures, the simulation of how objects appear and interact visually is the most dominate.

TABLE 2 ■ Suggested Specific Metrics that Can Be Used for Outcomes Analysis

Economy of motion
Purposefulness of motion
Absence of motion (indecision)
Path length
Time to completion
Sequence of steps
State analysis (still, moving)
Force measurements
Errors
    Missed target
    Tissue tearing
    Bleeding
    Organ perforation
    Burning of wrong tissue
Recovery from error
Response latency (time to recover from error)
Final product (e.g., leaking, inaccurate)
Global assessment of performance

Source: From Ref. 27.

In fact, in robotic laparoscopic applications, the only feedback to the surgeon is visual. It can be debated whether or not the addition of haptic feedback (force feedback and tactile feedback) would add a significant benefit. In contrast, the inclusion of haptic feedback is very relevant when simulating open procedures. If such feedback cannot be adequately represented, then a simulator may prove ineffective.

Glossary of sensory feedback in surgery simulation

- *Presence*: The sensation of actually being "there."
- *Immersion*: The state where the individual is absolutely focused on the task at hand.
- *Navigation*: The ability to move through the environment.
- *Interaction*: The ability to move and feel/touch objects in the environment.

The terms "presence" and "immersion" are often mistakenly interchanged, but they do have distinct meanings. For example, a child playing a video game may be immersed in the game and not realize what is going on around them. However, the child probably does not believe to be actually in the video game world. If the video game established a sense of presence, then the children would feel that they themselves are jumping over mushrooms and eating coins. As demonstrated, any video game (simulator) can create immersion, but as far as surgical simulation is concerned, a simulator must represent the multimodal senses of visual, tactile, auditory, and olfactory realism to enable the feeling of presence (28).

With new-generation tracking devices, navigation through virtual environments is possible as the trainee physically performs the hand/eye motor tasks used in real surgical procedures. However, in many cases, common tracking electronics may not fit within the construct of a variety of surgical instrument or there accuracy might be effected my metal, electric, and magnetic fields. This can impose limitations on a number of procedures that can be completely simulated to endoscopic procedures, laparoscopic procedures, procedures using Seldinger technique, and simple open procedures such as intubation, incisions, and simple suturing.

Another important factor to consider when addressing sensory feedback is the concept of clue conflict. Motion sickness can result when the body tries to interpret conflicting clues as they are received over multiple senses.

For example, when visual cues of physical orientation do not match vestibular feedback, an individual is likely to become sick. In simulation, this can occur when the frame refresh rate is too slow. The trainee can also become disoriented when visual cues do not match physical motion, such as when a trainee attempts to move an object in one plane but sees the object moving in a different plane. When one is first learning endoscopy, this may occur during actual procedures due to the fulcrum effect (Fig. 1), but with repeated patterned sensory stimuli (training), these senses adapt and this conflict resolves.

Auditory realism is important in surgical virtual reality applications.

The sounds of the operating room can provide very important cues that the surgeon needs to respond to, such as the sounds of electrocautery, verbal cues from the patient or other operating room personnel, and the pulse oximeter.

> Another important factor to consider when addressing sensory feedback is the concept of clue conflict. Motion sickness can result when the body tries to interpret conflicting clues as they are received over multiple senses.

> The sounds of the operating room can provide very important cues that the surgeon needs to respond to, such as the sounds of electrocautery, verbal cues from the patient or other operating room personnel, and the pulse oximeter.

FIGURE 1 ■ Laparoscopic simulators.

While such sounds are usually quite simple to represent in a virtual environment, they can add a significant degree of realism to a simulator. One concept, or technique, which allows for enhanced auditory realism, is known as convolving. Convolving involves filters and intertwines signals and renders them in three-dimensional space. These are used in virtual reality applications to recreate sounds that give directional cues. Such directional feedback can also prove quite valuable in simulation.

Haptics is the study of the psychomotor experience of tactile proprioception and force feedback.

Force feedback is the counterbalanced sense of a magnitude of force perceived when a force is applied to an object and is directional in nature. This needs to be discriminated from tactile feedback, which is nondirectional sensation. Some examples of tactile feedback are vibration, texture, and temperature. Such information is transmitted to the user through an "actuator" via mechanical and/or electric means.

Relatively speaking, simulation of haptics is very computationally expensive. When considering integrating haptics into a simulator, one must pay special attention to the magnitude and number of forces that must be applied. Basic physical principals dictate that all forces on an object must sum to zero or the object will be set in motion. Therefore, if a force feedback device is resisting the push from a trainee, the force feedback device must also push on a grounded object (such as the floor or a secure desk) in the exactly opposite direction so that all force vectors sum to zero. Otherwise, the force feedback device might fly right out of the simulator. Representing one point of force feedback is feasible, such as pushing/pulling on one point of a surgical instrument. A single robotic arm might be connected between the floor and the instrument to effectively render one vector of force by controlling motor torques in the joints of the robotic arm. However, force feedback becomes much more complicated as more points of interaction are added. Imagine what would be necessary to accurately render the appropriate sense of touch over the entire hand as might be required for some open surgical procedure. This would necessitate several different vectors of force applied over a number of contact points on the hand. It simply is not practical to attach a robotic arm to each of these points of force feedback.

Haptic fidelity refers to the rate at which haptic signals are updated. Different haptic phenomena require different degrees of fidelity to convince the trainee that a sensation is realistic. In general, directional force feedback requires less fidelity than tactile force feedback. The deformability of objects within the environment is also a factor to consider. The more deformable an object, the less fidelity is required. Accurate simulation of collision with rigid objects requires higher fidelity, as the degrees of change in force can be dramatic for small displacement. In other words, small, quick changes in motion can generate large forces, which are difficult to keep up with. While it may be possible to simulate contact of soft deformable objects at only 300 updates per second, rigid object contact may require well over 1000 updates for accurate feedback. In comparison, human vision only requires about 30 updates in order for animation to be perceived as smooth.

Another factor to consider is the complexity of the object surface being manipulated. If the instrument collides with more than one structure in a short amount of time, sampling update rate again needs to compensate.

Fidelity also depends upon the speed of movement of an object through the environment. Obviously, a fast moving object is more likely to collide with more surfaces and require higher fidelity than a slow moving object.

Force feedback can occur over multiple degrees of freedom. There may be directional forces along the x, y, and z coordinate planes. There may be torques resulting from rotations. Grip may need to be accommodated. The more the degrees of force feedback, the more difficult it is to accommodate a complex task in simulation.

Many applications do not require force feedback such as those designed to just assess cognitive decision-making skills. Others rely on physical models to provide force feed back such as the PercMentor (Simbionix). The UW transurethral resection of the prostate simulator utilizes a tension-based system,[a] while many of the laparoscopic force feedback device uses a linkage-based device such as the Laparoscopic Surgical Workstation by Immersion.

Open procedures require high-fidelity force feedback and tactile feedback. Unlike laparoscopic procedures, open surgery tools do not work through a fulcrum that diminishes the forces as well as tactile feedback.

Sidebar notes:

Haptics is the study of the psychomotor experience of tactile proprioception and force feedback.

Haptic fidelity refers to the rate at which haptic signals are updated.

Fidelity also depends upon the speed of movement of an object through the environment.

Open procedures require high-fidelity force feedback and tactile feedback. Unlike laparoscopic procedures, open surgery tools do not work through a fulcrum that diminishes the forces as well as tactile feedback.

The use of sense of smell is probably underappreciated during surgical procedures. Digiscents, Inc. is a company that has manufactured the ability to reproduce thousands of every day scents with a small cartridge that contains 128 primary odors. The combinations of these primary odors claim to effectively simulate virtually every smell. Some potential applications could include the smell associated with bowel injury and excessive cautery.

It is not always possible to represent all sources of sensory feedback in a virtual environment. In some cases, a possible alternative is cross-sensory substitution. In this case, one sensory stimulus is substituted for another. For example, speech might be converted into a visual display of text that can be read. It is important to be careful when employing cross-sensory substitution because the more you divert from standard sensory feedback, the greater the potential that simulation training will not carry over to the operating room.

In many applications, it is advantageous to incorporate additional sensory feedback that may not be found in the real procedure. Extra visual, audio, or haptics cues may help a beginner to initially learn a particularly difficult task. As the trainee becomes more comfortable with the task, this extra feedback is removed and the trainee is forced to rely on feedback that is actually found in the operating room. Sometime in the future, it may even be possible to add additional feedback to real procedures.

Augmented reality is the concept of superimposing transparent (not opaque) virtual images in real time over the real world as a frame of reference. Such a concept has already been demonstrated in an application that highlights the location of nerves during robotic radical prostatectomy.

Step 6: Computer Processing Needs

On an average, computation power doubles every 18 months—a trend that has become known as Moore's law. This translates to an annual 67% increase in computing power. Since 1990, the growth in storage capacity has been outpacing Moore's law by a wide margin, advancing 12 times faster than processing speed (29). Data transmission technology has developed at a more modest rate with a 50% annual increase in bandwidth (Nielsen's law). Enormous amounts of data can now be processed in milliseconds and graphical rendering is approaching photorealism. High-end graphical applications use to require expensive workstations with a price tag greater than $50,000. Now the same performance can be achieved on a personal computer that costs less than $2000. All of this has lead to remarkable advances in virtual reality and the improvements have not gone unnoticed by the medical community.

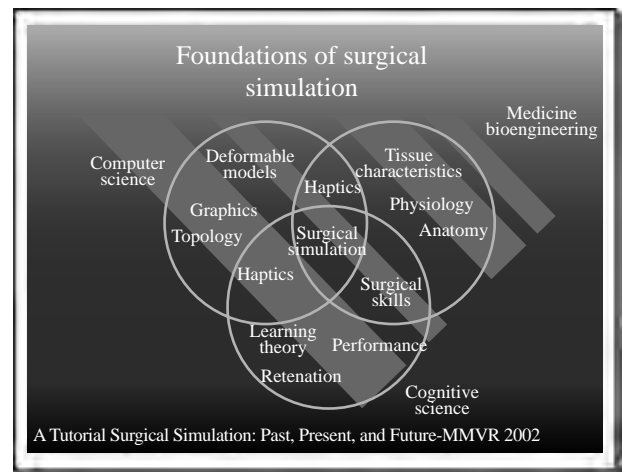
The processing power required for different simulators will vary because each simulated procedure will require different levels of graphical rendering, collision detection, deformation modeling, and haptic feedback. Processing power will directly affect latency and frame refresh rate.

Latency is a measure of the time between when a person moves a tracking device and when the computer displays the result of that tracking on the video screen. As latency exceeds 1/10th of a second, most people will become distracted by the disconnection between their actual movement and what they see moving graphically.

Frame refresh rate refers to the number of still images displayed per second. When the frame update rate is less than 20 frames per second, most people will perceive animation as jumpy or flickering. When displaying stereoscopic images (three-dimensional projections), the refresh rate needs to be at least twice as high to achieve smooth animation.

When considering processing power, one needs to consider not only the central processing unit but also the processing power of the graphics card. If the processing power of either is too low, the likely result will be extended latency and low refresh rates. The bus speed of a processor refers to the speed at which it can import and export data. Processing speed can become irrelevant if it takes too long to transfer data to and from the processor. Similarly, the speed of computer memory (or RAM) can create a performance bottleneck. To a lesser degree, the speed of hard drive storage can also affect performance. Finally, for computationally intensive applications, it can be very advantageous to use multiprocessor systems that divide processing labor between multiple processors and perform computations in parallel.

Step 7: Build Team Collaborations

All of the disciplines involved in creating medical virtual reality simulation applications are highly technical and they therefore require extensive collaborations. Tendick et al. presented a Venn diagram showing the complexity of such a process.


Conferences such as "Medicine Meets Virtual Reality" and programs sponsored by TATRC, which occur annually, have bridged this gap in understanding between healthcare workers, behavioral scientists, and engineers. As a result, numerous productive collaborations have been initiated. As in any complex new discipline, the leading investigators in the field have pushed their knowledge and understanding towards the center of the chart shown in Figure 2.

Key team contributors often include virtual world programmers, graphics animation/modeling artists, and hardware/interface experts. It also helps to have a behavioral scientist familiar with learning theory to help guide the design and metrics. Finally, a subject matter expert physician is necessary to guide the whole process, perform frequent usability studies, as well as provide the medical content.

Step 8: Build and Render the Model

There are many modeling software programs including Maya®,[b] Rhinoceros-three-dimensional®,[c] etc, that allow models to be constructed and then exported for use in virtual environments. Often, a number of applications are used to create a complete set of simulation models.

The simplest models are based on two-dimensional images or pictures. This is often employed when simulating fluoroscopic procedures.

For example, a single image, or series of images, captured during a real procedure may be augmented during simulation to give the impression that the image or images are being captured in real time. The movement of a guide wire may be rendered on top of a fluoroscopy picture by updating only the pixels that represent the guide wire.

Creating three-dimensional models of tissue structures can be quite challenging. Typically, a set of medical images is sectioned, where contours are extracted from a structure of interest (using applications such as NIH Image and ScanTool). These two-dimensional contours are then used to create a three-dimensional model. The contours might simply be used to guide the artistic creation of a three-dimensional model using freeform modeling software. Another option is to connecting the contours with polygons to form a surface. It is also possible to fit a set of equations to the contours in order to define a surface or solid model.

Polygonal models are the most common models used in three-dimensional visualization.

They form a computationally "cheap" representation and are very versatile. Hardware-accelerated rendering of polygons is common. The most general class of polygon models can be called a "polygon soup," which is a collection of polygons that are not geometrically connected and have no topology available. If the polygons form a closed manifold, then the model has well-defined inside and outside, which is very helpful when performing collision detection. If the manifold is convex, then this structure is even better suited for collision detection algorithms.

Parametric surface models are also popular. These surfaces are defined by equations, such as nonuniform rational B-splines. To render the geometries defined by these

---

[b]Alias Systems Corp, Toronto, Canada.
[c]Robert McNeel and Associates, Seattle, WA.

representations, the equations are used to find a set of polygons to represent the object surface. One big advantage of parameterized surfaces is that polygon resolution can be set to match the rendering capabilities of a particular computer. In addition, collision detection is very efficient with parametric surfaces.

Volumetric models can be constructed of voxels, elements or implicit primitives. Unlike surface models, volumetric models include information about the interior of the geometry. This can be very helpful for governing collision detection and deformation modeling.

If a model is to be used only for visualization, a voxel representation is likely the most appropriate. A voxel is essentially a small cube (like a three-dimensional pixel) that is uniform in color and shading. Voxelized models are three-dimensional representations created by stacking together a series of two-dimensional image slices (such as computer tomography, magenatic resonance imaging, or ultrasound images). The regions in-between the slices are filled in by interpolating, or morphing, from one image to the next. Most medical imaging systems are capable of generating three-dimensional voxel models. Unfortunately, voxel models lack a surface definable with normal vectors. This can make it difficult to apply lighting effects (such as shading and reflection) and to enable collision detection and force feedback. Voxel representations can also require a tremendous amount of computer memory and storage.

One example of a widely used database enabling the construction of volumetric models is the National Library of Medicine's Visible Human Project.

This database consists of detailed sets of scans taken of a deceased human subject. Not only does this data set include computer tomography and magenatic resonance images, the subject was also physically sectioned (frozen and then sliced into thin slabs) so that pictures could be taken of the slices.

A greater degree of interaction can be achieved with volumetric models based on elements. An element might take the shape of a tetrahedron or cube. The elements are then pieced together, like a set of logos to achieve a three-dimensional volumetric model. Each element may have its own color, shape, and specific behavior. Element models are ideally suited for deformation modeling.

An extension of element-based models is an implicit representation. Rather than using thousands of small elements to form a model, a small number of implicit primitives can be blended together to form complex geometric structures. Examples of implicit primitives are cubes, spheres, cones, cylinders, etc. These objects can be defined with simple equations that determine if a coordinate in three-dimensional space is inside, outside or on the surface of the object. A number of different implicit primitives can be used to create a complex shape using Boolean operations (union, difference, subtraction). The big advantage of implicit models is that collision detection is very efficient. A disadvantage is that the implicit equations must still be converted to a set of polygons that can be rendered. Finding these polygons can be very computationally intensive. It should be noted that implicit surfaces (a two-dimensional version of an implicit solid) sometimes have applications in simulation. Implicit surfaces are built from primitives such as triangles, squares, circles, etc. A closed manifold convex polygon model is essentially an implicit surface model.

A more detailed delineation of the types of volumetric models is illustrated in Figure 3.

Once the model has been created, it needs to be rendered. Rendering engines such as Open graphics library, Sun Systems, Direct X (Microsoft), etc. automatically determine three-dimensional perspective, lighting, shading, and allows the developer to apply texture images (Fig. 4).

Step 9: Texture Maps and Special Effects

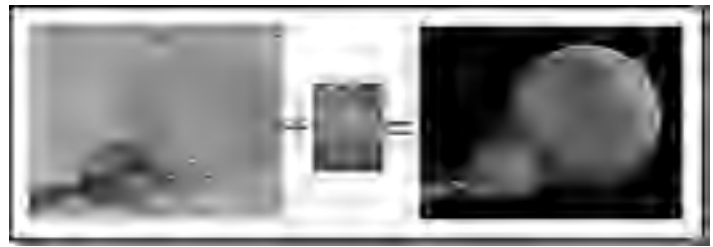
Texture maps can be applied to polygon models in order to make them look like a real tissue structure. A texture map is synonymous to a two-dimensional sticker that is

FIGURE 3 ■ Volumetric model types.

> One example of a widely used database enabling the construction of volumetric models is the National Library of Medicine's Visible Human Project.

> An extension of element-based models is an implicit representation.

FIGURE 4 ■ Three-dimensional rendering of volumetric model.

wrapped around the three-dimensional surface. A texture map might be a picture of the real anatomy or a set of pictures stitched together to form a visually appealing skin. It is also possible to use video clips to form a "live" texture map so that the look of the surface changes over time (30).


Developers can provide data derived from in vivo or in vitro experiments that can be used to create algorithms in the virtual environment.

The University of Washington did this when calibrating blood flow, irrigant, and prostate tissue resection algorithms, for their transurethral resection of the prostate simulator, as well as when obtaining information on the material properties of organs/tissues (30–32). Another possible use of texture mapping is for tissue blanching.

Special effects make models look more realistic. A technique known as bump mapping is commonly employed. This is a technique by which individual pixels on the two-dimensional texture map are illuminated to different degrees to give the impression that the surface is textured rather than flat (Fig. 5). Lighting sources can also be simulated in order to add ambient light, specular and diffuse light to a scene. Without lighting, it is very difficult to perceive an object as three-dimensional. Shadowing can also help to improve visual realism.

Other special effects such as bleeding across solid tissue surfaces, irrigation, smoke, electrocautery, fragmentation, and debris are frequently modeled using particle-flow methods (Fig. 6).

Step 10: Medical Instrumentation

Mock-ups or real instrumentation such as a blunt "needle" as in the PercMentor by Simbionix,[d] or a retrofitted resectoscope/foot pedal as in the case for the UW transurethral resection of the prostate simulator can be fabricated for a simulator (Figs. 7 and 8). Every application will call for different instrumentation requirements. Often the instruments need to be properly fitted with tracking devices, which track the relative components in space with respect to the virtual patient. Because these tracking devices are sometimes large and have connecting wires, it can be challenging to integrate them with a medical instrument without significantly changing the look and feel of the instrument.

FIGURE 5 ■ (A) Model of the urethra, prostate, and bladder rendered without lighting. (B) Model of the urethra, prostate, and bladder rendered with lighting. (C) Model of the urethra, prostate, and bladder rendered with lighting and a texture map. *Source*: From Ref. 33.

Step 11: Tracking Solutions

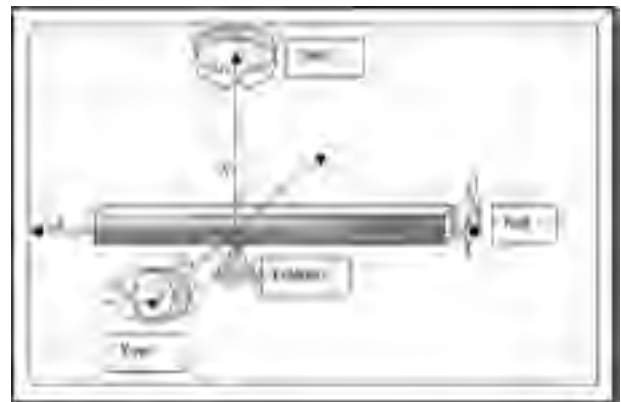
Tracking devices are electrical/ mechanical components attached to the surgical instruments and/or the simulator, which can track and locate where your instrument or model is in space.

Depending on the application, they can provide multiple degrees of freedom (Fig. 9). The most basic tracking device is an "on and off" switch that is one degree of freedom. A simple example of two degrees of freedom tracking device is the mouse. The mouse moves only in one plane and yields position coordinates in terms of X and Y.

In general, most spatial movement can be defined with six degrees of freedom. This includes spatial positioning in the horizontal (X), vertical (Y), and depth (Z) directions. In addition, three degrees of orientation (rotation, yaw, and pitch) can be defined.

In some cases, more than the standard six degrees of freedom will be required. For example, suturing involves seven degrees of freedom for each hand (translation in the X, Y, and Z direction, rotation about the X-, Y-, and Z-axis, and grip). Another example of a simulator requiring additional degrees of tracking freedom is transurethral resection of the prostate simulation. To track a resectoscope, it is necessary to include the rotation of the stopcocks, loop extension, camera rotation, foot pedals, etc.

In order to provide visual realism, tracking devices need at least 30–60 Hz (or updates per second). Most people will not perceive an upgrade in animation quality beyond this update level. Force feedback requirement are much higher. To simulate smooth force feedback with soft tissue, it is usually necessary to update position tracking at no less than 300 Hz. Requirements are even higher when modeling hard tissue

FIGURE 9 ■ Degrees of freedom defined for an instrument working on a fulcrum, is present with endoscopy. In many endoscopic applications, there is a fixed entry port into a body cavity, and therefore movement along the *X*- and *Y*-axes does not usually occur. Most endoscopic applications need at least four degrees of freedom (movement along the *Z* axis, pitch, roll, and yaw). In open procedures and laparoscopic simulations where port placement may vary, tracking along the *X*- and *Y*-axes would also be desirable.


structures, such as bone. Typically a tracking should be sampled at over 1000 Hz to accurately model the feel of hard objects.

A number of companies sell tracking hardware, such as Ascension and Polhemus®. Building your own tracking systems using optical encoders and fiduciary markers is also possible and can be much more affordable. Many force feedback systems include their own tracking capability, such as the Phantom[e] and the Mantis.[f]

Step 12: Orientation and Calibration of Metrics

Once the model has been created, it needs to be oriented properly with respect to the instrument/tracking devices. The metrics also need to be properly calibrated.

Orientation and calibration can be accomplished using in vivo or ex vivo techniques. One example of an in vivo technique involved the calibration of irrigation flow for the UW transurethral resection of the prostate simulator, in which flow rates in and out of the bladder under different stopcock settings and scope diameters were recorded with a uroflowmeter. An example of an ex vivo technique involved the calibration of blood loss with the UW transurethral resection of the prostate simulator, where bleeding movies were quantified and captured under different fluid flow states (30).

When at all possible, it is important to try and avoid relying on subjective calibration of metrics, even from the most experienced subject matter experts. Haptics calibration is notoriously unreliably consistent between subjects.

Step 13: Digital Acquisition Devices (Input/Output Boxes)

For the purposes of interactivity and data acquisition, any analog data (measured in terms of voltage) need to be converted into a digital format.

This is accomplished with the use of digital acquisition or interface devices or input/output boxes. These devices are fairly inexpensive and effectively translate actions made by the simulator's tools from electrical signals to meaningful code translated by the computer. They also integrate tracking input with display and haptic output through either a USB, firewire, or parallel port. Examples of devices that might require analog to digital conversion include dials and switches, optical encoders for tracking, and strain gauges that monitor applied forces.

Step 14: Collision Detection and Deformation

A crucial element of virtual reality simulation is determining when a surgical tool has collided with tissue structures or other tools.

In addition, tool contact can force one tissue structure into other tissue structures, which in turn could lead to even more collisions. Determining if and where collisions take place can be very computationally expensive. As discussed in step 8, models are typically rendered in terms of polygons. The objective is to determine if a point on the surface of one object has crossed the face of a polygon on another object. There can be tens of thousands of nodes (the corners of the surface polygons) on the tools and tissue structures in a scene that must be tested against tens of thousands of polygons.

A variety of techniques have been created to avoid the necessity to test every point against every polygon. The objective is to cull all the model polygons into smaller sets of "probable" collision polygons. Finding collisions with rigid objects is relatively straightforward. This is because all the polygons on an object stay in relative position to each other. For this reason, it is possible to sort surface polygons into a number of bounding volumes, such as a sphere, cube, or cylinder that can help collision algorithms zero in on polygons of probable collision. By first testing a point to see which bounding volume it is in, it becomes possible to reduce the total number of polygons that might come into collision. This is one reason why implicit solid models (as discussed in step 8) can offer tremendous performance advantages when it comes to collision detection. It is also possible to put bounding volumes within bounding volumes to further subdivide a model into probable collision polygons. This type of architecture is often referred to as a voxel tree.

Specific hardware is often added to the computer platform just to accommodate collision detection. As mentioned in step 6, multiprocessor computers are sometimes used in simulation. Often the reason is so that one of the processors can be dedicated to collision detection. Graphics cards can also be converted to collision detection systems.

The difficulty with surgery simulation is that there are usually a number of deformable object in the scene.

Sidebar annotations:

> Orientation and calibration can be accomplished using in vivo or ex vivo techniques.

> When at all possible, it is important to try and avoid relying on subjective calibration of metrics, even from the most experienced subject matter experts. Haptics calibration is notoriously unreliably consistent between subjects.

> For the purposes of interactivity and data acquisition, any analog data (measured in terms of voltage) need to be converted into a digital format.

> A crucial element of virtual reality simulation is determining when a surgical tool has collided with tissue structures or other tools.

> The difficulty with surgery simulation is that there are usually a number of deformable object in the scene.

---

[e]Sensable Technologies, Woburn, MA.
[f]Mimic Technologies, Seattle, WA.

Once an object deforms, techniques such as using a voxel tree, become ineffective because polygons are likely to stray out of their original bounding volumes. For this reason, a tremendous amount of research has been dedicated to methodologies for reducing the computational cost of collision detection when using deformable models. This is a complex issue that routinely receives a lot of focus at conferences such as MM virtual reality and SIGGRAPH.

After collision takes place, another difficult problem is determining how a model should deform. This often requires even more computation than collision detection.

Soft tissue is an extremely complex material and very difficult to accurately model. Not only does soft tissue contain three phases (solid, liquid, and gas) but also material properties vary significantly from person to person, tissue structure to tissue structure, and even within the same tissue body.

While continuum mechanical-based methods have been demonstrated to accurately model tissue structures such as cartilage, the majority of soft tissue types have yet to be modeled. More importantly, the methodologies that exist are so computationally intensive that it can take hours, or even days, just to model a single scenario for tissue deformation. This hardly applies to virtual reality where a new solution must sometimes be found a thousand times a second.

There is definitely a long way to go before modeling tissue deformation in surgery simulation becomes highly precise. However, as long as the deformation modeling is realistic enough to promote learning, it might be deemed "good enough." Most simulators actually employ "video game-like" techniques that completely ignore the tissue material properties. Spring models are most commonly used. Techniques vary, but many simply place a linear representation of a spring on the edge of every tetrahedron in a volumetric element model (step 8). Moving a node on a model compresses a set of springs that then in turn push into other nodes. Iterating through all the springs will result in a global deformation. One example of a spring-based model is the LapMentor simulator sold by Simbionix.

Beyond the problem of the inherent instability that often makes spring models appear to "flutter," spring models are also very difficult to calibrate. Determining an appropriate stiffness for every spring to approximate realistic deformation can be extremely difficult and labor intensive. Also, a spring model does not maintain its overall volume as is natural for most materials. Just the same, the trade-off is fast performance for limited accuracy.

A number of new techniques based on continuum mechanics have started to emerge. Finite element modeling is the industry standard for modeling stress, strain, and deformation in objects such as bridges, mechanical parts, car frames, cell phones, prosthetics, and more. Unfortunately, this methodology in its raw form does not lend itself to real-time applications. Fortunately, some versions of the technique have been recently adapted for application to surgery simulation. Now it is possible to measure a subject's soft tissue material properties and plug them in to a finite element model. Examples of finite element modeling-based simulators include the suturing simulator developed at the University of Washington and the robotic prostatectomy simulator currently under development at Mimic Technologies, Seattle, Washington, U.S.A.

While finite element models are more accurate than spring models in terms of stability, deformation, and force feedback, the method still has its limitations.

In particular, a lot of computation is required to build the mathematical representation of a finite element mesh. When the mesh is altered, such as when cutting through skin, the mathematical representation of the mesh must be updated. Significant mesh updates can be difficult to accommodate in real time. This limits the use of finite element models to certain surgery scenarios.

Step 15: Displays

Examples of common displays used in virtual reality include head-mounted displays, shutter glasses, autostereoscopic systems, CAVES, and video monitors. Current video monitors in surgery are a common interface for relaying images captured through a variety of scope designs. This interface is the easiest to recreate in simulation, since the standard PC uses a monitor interface anyway. However, as simulation and surgery progress, an understanding of other more immersive-type displays should be understood.

When people think of virtual reality, they often think of stereoscopic display or three-dimensional views that pop right out of the screen. The eye captures two-dimensional images on the retina and the human mind perceives distance or depth by using the many available depth cues. The physiological cues include accommodation, convergence, and binocular parallax. Accommodation is the eye muscle tension needed to change the focal

length of the eye lens in order to focus at a particular depth. Convergence refers to the muscle tension required to rotate each eye so that it is facing the focal point. Binocular parallax means that each eye sees a slightly different view. Psychological cues that contribute to seeing in three-dimensional including relative size, occlusion of far objects by close ones, linear per-spective, shading, texture gradients, atmospheric effects such as color and haze, and motion parallax.

Common run time graphics (such as Open GL) automatically calculate shading, occlusion, relative size, texture, atmospheric effects, etc. This allows the perception of distance in a two-dimensional display, but objects do not appear to pop out of the screen. To display a scene in stereo, it is necessary to address accommodation, convergence, and/or binocular parallax. Stereoscopic displays typically rely only on binocular parallax, where each object in a virtual scene is shown to each eye at a slightly different angle and view position (relative to each eye). Methods for displaying different views to each eye include color filters, polarizing filters (which requires a three-dimensional projection system), shuttered vision, and directional filters.

Stereoscopic display can be achieved with a simple cathode ray computer monitor and shutter glasses.

Shutter glasses alternately occluded each eye and this is synchronized with the computer screen. This makes it possible to show a different display to each eye. Because stereoscopic display requires two separate alternating views, the refresh rate must be doubled as compared to that required for standard animation. If the overall refresh rate is less than 60 Hz (30 Hz per eye), then many viewers will perceive a flicker in the display. Shutter glasses can also be coupled with large projection displays, such as found in theme parks or IMAX theaters.

It should be noted that using shutter glasses with a display screen is not considered a "true" three-dimensional display. This is because accommodation and convergence are ignored as the screen is always the same distance away. Many people will get a headache from extended viewing with these displays because there remains a conflict between the perceived distance of virtual objects and the actual focal distance of the display.

Autostereoscopic systems do not require glasses and divide two-dimensional displays into two sets of viewable pixels, which are displayed to each eye separately. The downside is that this display required a fixed viewing position.

At the sacrifice of display resolution, multiple sets of pixels can be utilized, which enables more stereo viewing positions and wider viewing freedom. Some advanced systems will track the viewer's eye positions and adjust the aim of each pixel set so that they follow the eyes.

Head-mounted displays consist of an image source with collimating optics (each eye sees a different display). The head-mounted display image may be a cathode ray tube (like a small TV), a liquid crystal display (like a laptop screen), or a virtual retinal display by which images are displayed directly on the retina (34).

A feature typically coupled with head-mounted displays is head tracking. This makes it possible to update the user's view based on where their head is relative to the virtual scene.

Volumetric displays are an emerging technology that allows for true three-dimensional display.

These systems show pixel information in a predefined volume of three-dimensional space, rather than just a flat two-dimensional surface. One application of a volumetric display uses a varifocal mirror that oscillates at a high rate enabling variable focal distances. By synchronizing the image shown on a reflecting screen with the optical power of the mirror, any point of a given volume can be illuminated. Another experimental display uses the concept of emissive volume. This display has given volume filled with a medium that can emit light from any part of its interior as a result of an external excitation (such as from different wavelength lasers). One key problem with this approach is finding the appropriate substrate to serve as the medium. Another approach is the rotating screen. A flat screen rotates at around 600 rpm. For every angular position of the screen, an optical system projects a scene corresponding to the perspective associated with the screen angle. The final result is the three-dimensional image of the object, viewable in 360°. Most volumetric displays are still in experimental development and it may be some time before they find a commercial market.

CAVE® is a room-sized advanced visualization solution that combines high-resolution DLP™ based stereoscopic projection technology and three-dimensional computer graphics to create the illusion of complete sense of presence in a virtual environment.

CAVE® is a room-sized advanced visualization solution that combines high-resolution DLP™ based stereoscopic projection technology and three-dimensional computer graphics to create the illusion of complete sense of presence in a virtual environment.

The CAVE was the first virtual reality technology in the world to allow multiple users to immerse themselves fully in the same virtual environment at the same time. This

is accomplished by using four, five, or six projection surfaces and numerous projectors that relay stereoscopic images when viewed with three-dimensional glasses (glasses based on either color filters, polarizing filters, or shuttered vision). CAVE systems are usually coupled with three-dimensional "pointer" tools that can be used to interact with the environment and each other.

CAVES are quite expensive and have not been widely utilized for medical simulation, but are beginning to be explored as a tool for medical team/disaster and immersive training.

Holograms are images made on high-resolution film that captures patterns of light waves emanating from an object when illuminated by a laser. When light shines through this special film, the light patterns are reproduced, giving a three-dimensional effect. Holograms usually involved fixed scenes with no animation.

> CAVES are quite expensive and have not been widely utilized for medical simulation, but are beginning to be explored as a tool for medical team/disaster and immersive training.

Step 16: Raw Data Collection Repositories

Virtual reality simulators can automatically collect enormous amounts of data relevant to a subject's performance. Not only should data collection and storage be considered per training institution, but all training institutions collectively that utilize simulation training. These data need to be organized in a useful and meaningful fashion. What may be meaningful to one may be useless to another. Therefore, efforts to create consolidated, centralized databases for simulators have been made. One such example of such a database was created at the University of Washington by Weghorst, Fried, and colleagues (Fig. 10).

Step 17: Graphics-User Interfaces

A user-friendly graphics user interface is usually present on all computer-based simulators. It is an interface that allows the user to navigate through training modules and select and adjust features of the simulator by pressing graphical buttons, pulling down menus, adjusting sliders and/or by entering data in designated fields.

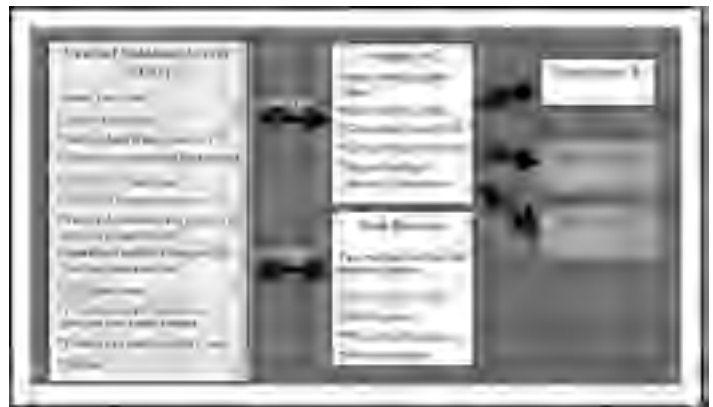
> An intuitive interface can be crucial for efficient utilization of a simulator.

An intuitive interface can be crucial for efficient utilization of a simulator. The graphics user interface should allow the user to easily access simulation didactics, and cognitive training for issues related to the psychomotor/visual-spatial tasks to be completed. (recommended at the Conference on Surgical Errors, Washington, D.C., 2003). This embeds a curriculum, allows the simulator to be used independent of a mentor, and allows for more accurate characteristic of the subject's performance. Some commonly used modalities for graphics user interface design include Microsoft Foundation Class, Redmond, Washington (MFC environment-typical windows buttons/menus) and HTML-based interaction common in most websites.

Step 18: Usability Studies

As each of the above major components of the simulator has been completed, informal usability studies with the subject matter expert should be done on a frequent basis. Developers intimately familiar with a simulator may not be able to fairly judge how easy a simulator will be to use and if the simulator is adequately addressing the learning objectives defined in step 1. Repetitive testing throughout development will help to insure that developers and subject matter experts are on the same page. Once the complete package is deemed realistic, accurately measures and logs metrics, is cutout user-friendly and adequately meets the training needs defined by the subject matter expert, the simulator is ready to undergo rigorous validation studies.

FIGURE 10 ■ AHRQ sponsored centralized database for simulators, University of Washington.

Step 19: Validity/Reliability Studies


Validation studies must be conducted before a simulator can be implemented in the curriculum of training programs and considered for use as an assessment tool. Validation results of a training simulator should be reproducible.

Validation protocols should be even more rigorous if the simulator is to be used as a tool for trainee assessment as the stakes are much higher for tools of assessment. In appropriate use of assessment, data could be used to discipline existing practitioners, prevent others from entering the field, or performing certain tasks.

Though the cognitive science community has a much more sophisticated grasp on validation measures, Litwin has provided translation for application of medical surveys while Gallagher et al. (35) has provided translation for use in surgical simulators.

When considering the validation of a simulator, a number of validity criteria should be considered:

1. *Face validity:* A type of validity assessed by having experts review the contents of a test to see if it seems appropriate. It is a very gross, subjective type of validation and usually only used when building the simulator.
2. *Content validity:* An estimate of the validity of a testing instrument based on a detailed examination of the contents of the test items. It is also subjective in nature. It is obtained when asking experts to review each item to determine whether it is appropriate to the task intended to be trained. The overall cohesiveness of the simulator is assessed, determining whether it contains the realism, steps, and skills that are used in a given procedure.
3. *Construct validity:* A set of procedures to evaluate a testing instrument based on the degree to which the test items identify the quality, ability, or trait it was designed to measure. This is a much more complex measure of validity and there are many constructs that can be examined. The most basic example is the ability of an assessment tool to differentiate experts and novices performing a given task.
4. *Concurrent validity:* An evaluation in which the relationship between the test scores and the scores on another instrument purporting to measure the same construct are related. It can be thought of as a subset of construct validity. It is achieved when testing a simulator versus gold standard methods of training. One problem with this method in surgical skills training is that very often no gold standard exists.
5. *Discriminate validity:* An evaluation that reflects the extent to which the scores generated by the assessment tool actually correlate with factors with which they should correlate. Another subset of construct validity, it is a sophisticated analysis looking at correlations. One example is a simulator's ability to differentiate ability levels within a group with similar experience, such as discriminating abilities of all the residents in postgraduate year 1.
6. *Predictive validity:* The extent to which the scores on a test are predictive of actual performance. Predictive validity is probably the most important validation measure to be considered given our training dilemma. It predicts who will and who will not perform actual surgical tasks well.

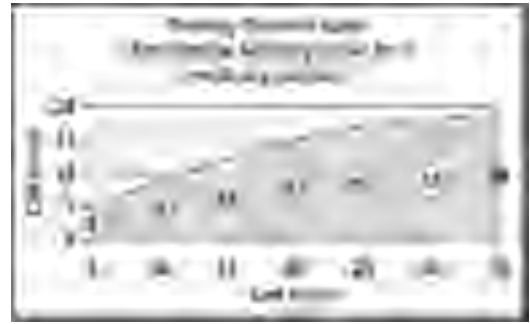
A reliable simulator measures something in a reproducible manner. Standards of acceptable reliability depend on the purpose of the test and the cost of misclassification. Usually expressed as a value between 0 and 1, it represents the proportion of the variability in scores attributable to true differences between subjects (36,37). Wanzel et al. (38) used a reliability of ≥ 0.8, as there was a high cost of misclassification because they were using their tool for assessment.

One of the common pitfalls for validation studies in the surgical sciences has been to use the same device that is being used for training (the intervention), as the very same tool used for evaluation pre- and post-training. Such a design merely shows that training on an instrument leads to improvement on that very instrument and lacks tangible evidence of translation to clinical skills.

For subjective evaluation, the agreement between two different observers is known as inter-rater reliability and agreement between observations on the same subject on two separate occasions is known as intra-rater reliability.

For virtual reality simulators that generate objective data, this is less of an issue, but validation of these instruments has and should continue to be correlated with reliable subjective evaluation.

One useful measurement to obtain once a simulation tool has been embedded in the curriculum for some time is what is called a training transfer ratio (Fig. 11). This is

FIGURE 11 ■ In this hypothetical example, the slope of the line at any point would represent the training transfer ratio (TTR). For a novice who has logged five simulation hours, this may be equivalent to five operating room hours (TTR = 1.0), as they may get more benefit from the simulator, while someone who has logged 15 operating room hours in this case would have a TTR = 0.40. Clearly, the value of simulation at different levels of training is unknown and this would need to be worked out for each skill task.


defined as the number of simulated case hours equivalent to one operative case hour. Such a ratio may not be quite so simple as simulated cases may be more useful for less experienced trainees than for those with experience. This ratio truly represents the derivative or slope of the learning curve at any given point during training, which is just that a "curve." In the aviation industry, this ratio has been estimated as half hour simulated time = one hour logged in a real plane.

Step 20: Commercialization

Once a simulator has achieved at least face and content validity, it may be considered for commercialization. A simulator may prove to be an extremely valuable training tool, but if it is too expensive for most training institutions to purchase, there is no chance that the simulator will be marketable. Effective implementation of step 2 will insure that there is a demand for a simulator and therefore justify development, manufacturing, and marketing expenses.

There are a variety of routes to take when commercializing a simulator. While a number of companies have been founded on new simulators, the most likely rout to commercialization is licensing the technology to an existing simulation company. There have been a number of academically developed simulators, which have been licensed to commercial entities.

Successful licensing depends on enlisting the help of an academic institution's department of technology transfer and licensing. A relationship between developers and technology transfer officials should be established at the onset of development so that plans can be made to protect future intellectual property.

Without proper legal documentation of the intellectual property, there is nothing to keep industry from reproducing what it sees discussed in publications and that which is demonstrated at conferences.

It is therefore important to follow university protocol when demonstrating the simulator to the public. Otherwise, commercialization potential might be forfeited.

Besides preparing legally for the licensing of a simulator, it is important to consider how a company might integrate a simulator into their current product line. Thorough documentation of methodology and software code is a must. Rarely will a simulator be used "as is" once a company licenses it. Typically, code and methods are adapted to fit within the architecture of a company's existing simulation platform and training protocol. The more difficult it is to decipher licensed code and methods, the more hours a company will have to invest in integration. The greater the integration effort required on behalf of a company, the less value they see in a license agreement.

Step 21: Implementation for Training

It is the author's belief that in order to be implemented into training programs, a simulator should at least achieve reliable face, content, and construct validity.

Predictive validity is probably not necessary for the purposes of training. Again the simu-lator must fit into a curriculum and it is that curriculum that must be supported. A plan for integration into curriculum should be discussed at the onset of development to insure that there is a place for the simulator after it is completed.

Step 22: Define the Learning Curve

As a virtual reality simulator is used at multiple institutions for the purposes of training, enormous amounts of data can be collected to show how a trainee learns a given procedure. After a simulator has been implemented into curriculum for a number of years,

> Successful licensing depends on enlisting the help of an academic institution's department of technology transfer and licensing. A relationship between developers and technology transfer officials should be established at the onset of development so that plans can be made to protect future intellectual property.

> It is therefore important to follow university protocol when demonstrating the simulator to the public. Otherwise, commercialization potential might be forfeited.

> It is the author's belief that in order to be implemented into training programs, a simulator should at least achieve reliable face, content, and construct validity.

true learning curves with associated outcomes and standard deviations can be established. This makes it possible for the learning curves of surgical procedures to be truly defined and targets for remediation can be validated and implemented.

Step 23: Implementation for Assessment/Credentialing

The use of virtual reality simulators for screening resident applicants, resident assessment, and physician credentialing should likely be reserved until after predictive validity and learning curves have been reliably established, since then and only then accurate projections as to a subject's performance can be made.

The stakes are otherwise too high in these situations to rely on less rigorous methods of validity and a lack of the establishment of a learning curve. The use of simulators for assessment and credentialing is destined to play an important role in medical education; however, it may take the better part of a decade before this becomes a reality.

SURVEY OF VIRTUAL REALITY UROLOGIC SIMULATORS

Surgical simulation modules have been classified according to whether they train the technical components of a procedure or strictly the cognitive components. Basic skills trainers train basic psychomotor and/or visual spatial skills that are proposed to translate into improved skills in clinical application. Simple task trainers focus on a specific construct within the context of a procedure like trocar insertion. Many of the existing box trainer physical models are examples of simple task simulators. Complex task trainers focus on a more complicated construct such as percutaneous access to the kidney or the renal hilar dissection and transection. Complete procedure modules allow the user to do cases from start to finish and may include simple and complex task trainers as submodules. The UW transurethral resection of the prostate simulator and the ureteroscopic module for UroMentor are examples of such trainers. Cognitive training modules are designed to provide for training and assessment of medical decision making and interactive mental surgical rehearsal and are less focused on the visual-spatial/psychomotor components. The following is a review of known current applications.

Digital Rectal Examination Simulators

Digital rectal examination for prostate cancer is an important basic skill for any urology training program. The gold standard method of teaching prostate cancer detection is either on patients with a repeat examination being done by the trainer or with a physical model simulator like the one provided by Merck, Heath Edco,[g] "prostate training kit." Unlike many of the other skill sets in urology where visual feedback dominates over tactile feedback, with digital rectal examination, the sense of touch is paramount. Using a silicon graphics inc. workstation, four prostates were modeled, which were similar to the Merck physical models, and a PHANToM haptic interface was used to provide force feedback.

Medical students had a 67% correct diagnosis rate of malignant versus nonmalignant cases compared with 56% for urology residents. Residents felt the content (force feedback) lacked realism and concurrent validity was not demonstrated, as residents were able to correctly identify malignancy on the Merck trainer (gold standard) 96% of the time (39).

Pugh et al. designed a pelvic examination simulator that also uses force feedback, which is now owned and distributed by Medical Education Technologies Inc. (METI).[h] It will soon include a digital rectal exam module.

Percutaneous Access

Percutaneous access is a skill set that requires excellent visual-spatial awareness and experience.

Simbionix designed a module on the UroMentor platform called PercMentor[i] that attempts to train these skills. It provides a mannequin and a needle that is tracked as it enters the virtual anatomy. The kidney exhibits respiratory variation and the trainee has

_____
[g]Waco, Texas, U.S.A.
[h]Sarasota, Florida, U.S.A.
[i]Simbionix, Lod, Israel.

to navigate the needle into the calyx and slip a wire past the virtual stone. The user learns c-arm manipulation and can either use the standard fluoroscopic view or the anatomical view as a teaching aid. Metrics include time to task, injury to blood vessels, perforation of the collecting system, amount of contrast used, and rib injuries. Matsumoto et al. presented data in abstract form showing that novice residents from two residency programs who train on the simulator have fewer attempts, use less fluoroscopy, and have fewer errors on the simulator than those who do not train between trials. Content, construct, concurrent and predictive validity studies are currently lacking but are underway. Training in ultrasound-guided access and percutaneous lithotripsy/nephrolithotomy currently are not features of this simulator, but would add substantially to this product.

COGNITIVE SIMULATION ENGINES

One of the oldest cognitive "simulators" is the surgical atlas. Frank Hinman Sr.'s *Atlas of Urological Surgery* has been an invaluable source and reference for physicians in practice as well as urology trainees to prepare them cognitively for the cases they were to encounter. The use of videotapes, though a less accessible media, added another level of presence. Both of these training tools are effective but passive in nature.

Computer-based simulators created to train the cognitive aspects of procedural training arguably provide "virtual reality," though they are less immersive in nature than those that also provide technical skills training. Considering that it has been argued that 85% of performing a surgical procedure involves the cognitive domain, cognitive simulators have probably been unrightfully de-emphasized and underutilized in surgical curriculum. A couple of examples with a potential role in urologic curriculum have been provided. Advanced cardiac life support is required of every new surgical intern. One of the first computer-based medical simulators was designed by Dr. Howard Schwid, an anesthesiologist in Seattle, Washington. The anesthesia simulator recorder to train management of critical events combined a graphic display of the operating room with mouse-driven input and uses an integrated set of physiological and pharmacological models to predict patient responses. It has undergone multi-institutional content, concurrent, construct and predictive validity for management of emergency situations in a population of anesthesiology trainees. Such a program has not been tested in residents of other specialties, but could be examined for its utility in surgical curriculum (40–48). Sweet et al. recently designed SimPraxis™, a software engine that provides interactive cognitive simulation and rehearsal of complex open surgical procedures. It has a DVD format and runs on a standard laptop and combines the simple format of an atlas with video as well as mentored instruction and provides objective feedback to the user. The prototype pelvic lymph node trainer begins with the indications, technical tips, and potential complications of the surgery from an expert author. It challenges the user to choose the actor (surgeon or assistant) and the appropriate instrument and then to apply the instrument in the correct position for each of the defined tasks of the operation. When performed correctly, the simulator plays the video clip of the subtask with commentary. Incorrect cognitive decisions are followed by instruction on the proper technique and the user is then allowed to try again. A "practice" mode provides mentorship in the form of hints from a "virtual" expert in the field. A "testing" mode is web-enabled and designed to monitor and log the user's selections including any requests for assistance. The software logs the frequency and types of errors. This record is then available for submission to residency directors, CME administrators, and/or later review by the user. Face and content validity have been established and construct, concurrent and predictive validity studies are underway (49).

The simplicity of such an approach circumvents some of the financial/technical roadblocks that virtual reality technical skills trainers have encountered.

When designed and studied in coordination with their technical skills trainer counterparts, cognitive trainers may actually be able to determine not only if an error has occurred but also dissect whether it was an error in cognition, psychomotor skills, or visual spatial orientation.

COMPLETE PROCEDURES

Transurethral Resection of the Prostate Skills: A Potential Training Crisis
Transurethral resection of the prostate remains the gold standard surgical procedure for successfully treating medically refractory lower-urinary tract symptoms of benign prostatic hyperplasia or benign enlargement of the prostate (50,51), a chronic and potentially

progressive condition that is symptomatic in approximately 5.6 million men in the United States alone.

The resection skills acquired during the performance of this procedure are also thought to translate to those used to resect benign and cancerous lesions in the bladder (TURBT) and in ablating posterior urethral valves in infants (TURPV). This set of skills remains a core skill set for a urologist in training (52).

TURP is challenging to teach and learn. Performing this procedure involves the ability to work in a small three-dimensional space while receiving two-dimensional visual feedback requiring the operator to have or develop unique visual-spatial abilities. It also requires that the operator have adept psychomotor abilities, as one has to continuously and simultaneously navigate the scope and the loop while managing the electrical current with the use of both hands and a foot pedal. Additionally, the procedure is performed in a fluid environment and the field is often visually obscured by tissue and blood, which can be disorienting to the training resectionist.

Transurethral resection of the prostate is potentially dangerous. Within this small amount of space, there are also many potential anatomical hazards, where an error in judgment, visual-spatial or psychomotor skill could potentially result in devastating consequences such as total urinary incontinence, rectal injury, ureteral injury, dorsal vein injury with profuse blood loss, erectile dysfunction, and life-threatening levels of hyponatremia. Historically, such a small margin of error coupled with the "disconnect" that exists between the operators and the patient that inherently exists with all endoscopic procedures has made training this skill set challenging.

Transurethral resection of the prostate outcomes vary widely in the community and are probably technically dependent.

Much like any procedural skill in medicine, when a urologist becomes board certified, the ability to perform technically challenging procedures such as transurethral resection of the prostate is not discriminated from the urologist's judgment and cognitive skills, which are measured via oral and written examinations. This fact as well as financial incentives has led many practicing urologists to pursue "alternative" or "minimally invasive" methods to deal with bladder outlet obstructive symptoms. While promising, and useful in many settings, none of these procedures has ever "outperformed" transurethral resection of the prostate in treating either the subjective symptoms of bladder outlet obstruction or objective measurements such as peak urinary flow rates and ability to empty one's bladder completely (51). In fact, depending on the series, transurethral resection of the prostate gives symptom relief anywhere from five to 20 years and the minimally invasive treatments follow-up data are only 3–5 years in evolution. Even within this period of time, 10% to 20% of patients undergoing an office bladder outlet reductive procedure go on to have a transurethral resection of the prostate anyway (51,53). The published morbidity of transurethral resection of the prostate is also quite variable. Average length of hospital stay ranges from 1.5 to 4 days, the incidence of urinary tract infections ranges from 4% to 20%, the reintervention rate (within 30 days after treatment) ranged from 0% to 14%, erectile dysfunction ranged from 0% to 21% and retrograde ejaculation ranged from 50% to 80% (53–61). Part of the discrepancy can be explained by different outcome measures, though many argue that this is due to a variable of surgical technique. Past studies have been unable to examine or quantify this, as we have lacked a standardized objective way of measuring transurethral resection of the prostate skills.

Historically, this training problem was addressed with shear case volume. A decade ago, residents performed 120 transurethral resection of the prostates on average prior to graduating from a residency program. This number has declined in the last decade (Fig. 12).

With the advance of medical management and less effective but lucrative "minimally invasive procedures," transurethral resection of the prostates are performed less frequently, but still remain the gold-standard therapy. The mean number of transurethral resection of the prostates a graduating resident had performed in 2002 has reached a plateau at 62 (ACGME). Without the benefits of a learning curve or objective data to reference, our group surveyed 72 board-certified urologists at the American Urological Association 2002 meeting and the perceived mean number of transurethral resection of the prostates they felt was necessary before entering independent practice was 66.8; a number well above the mean and encompassing a majority of the graduating residents in the United States (31).

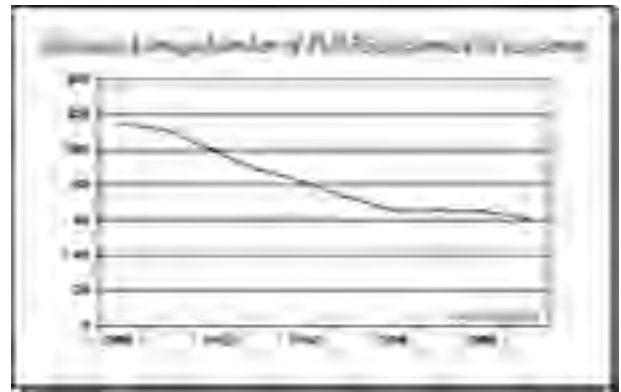
Given all the mentioned issues, simulation model training for transurethral resection of the prostate has been pursued. The first reported virtual reality transurethral resection of the prostate simulator was described by Lardennois et al. in 1990 (62) after having seen a colonoscopy simulator. Since 1999, Kumar et al. have

> TURP is challenging to teach and learn.

> TURP is potentially dangerous.

> Transurethral resection of the prostate outcomes vary widely in the community and are probably technically dependent.

> A decade ago, residents performed 120 TURPs on average prior to graduating from a residency program. This number has declined in the last decade.

FIGURE 12 ■ ACGME data on the mean number of TURPs done by U.S. urology residents. *Source*: From Ref. 30.


worked on a TUR simulator, which uses an optical tracking device and a hybrid/computer-generated and physical prostate model. The loop is tracked with a potentiometer and the scope is tracked in space. It was constructed as a virtual three-dimensional training aid to eventually be used in the operating room, but lacked features such as bleeding. Two urologists evaluated the content and felt that a poor frame refresh rate, a lack of bleeding and model movement and permanent deformation of the model as well as deformation secondary to absorbing fluid all contributed to made the trainer inaccurate in vitro. Validation studies are currently lacking but in vivo studies are in progress (63,64). Ballaro et al. (65) also created a virtual reality transurethral resection of the prostate simulator, but it lacked real-time interactivity and tactile feedback. Manyak et al. (66) also describe a simulator for lower urinary tract procedures, which adds haptics force feedback. No validation studies have been described in the literature for any of these trainers.

Sweet et al. began development of the UW virtual reality transurethral resection of the prostate trainer in 2000. Using Alias®, a virtual polygonal model of the urethra, prostate, bladder, and the loop was created de novo. Instrumentation and interaction was accomplished by securing two Polhemus tracking devices to an iglesias and a camera shell provided by ACMI®. A Bovie® foot pedal was used, and the electrical signal is transmitted to an SGI Octane® graphics computer through a TNG-3® interface box. A physical model of the penis and pelvis was created in collaboration with Simulab Corp®. using prosthetic materials. Computer graphics animation in Alias was used to recreate noninteractive portions of the simulation such as urine efflux and chip movement. Upon collision between the loop and the model, cutting was accomplished by "pushing" the anatomy of the model to accommodate the intersection between the loop and the tissue. Texture maps of prostatic urothelium, bladder urothelium, resection bed, and fat were obtained using digital footage from actual transurethral resection of the prostate procedures. Recognizing that dealing with hemostasis was a critical skill set to learn during transurethral resection of the prostate, an in vitro model for bleeding during transurethral resection of the prostate and a bleeding movie library taken from an in vitro model of the lower genitourinary tract under controlled fluid flow conditions were created. Fluid flow detection by the use of potentiometers attached to the stopcocks that trigger the changing of the blood flow movies is also employed. The result was a realistic interactive simulation of blood flow under fluid conditions. A force feedback device was then integrated using a custom Mantis device[j]; didactics and a graphics user interface have been put on the front end and subtask training modules have been added, which train orientation, cutting, and coagulation skills independently. The simulator can log motion and force data as well as operative errors, grams resected, blood loss, irrigant volume, foot pedal use, and differential time spent with orientation, cutting, or coagulation. The result is a complete transurethral resection of the prostate simulator that can provide objective feedback to the user. Version 1.0 was validated by 72 board-certified urologists and 19 novices at the AUA 2002 and face, content, and construct validity of the simulator was established (31). Based on these data, the simulator has been upgraded and the authors endorsed the simulator for training but cautioned its use for assessment and accreditation, though the simulator was also able to discriminate differences of skill within groups (unpublished data). Plans are underway to perform a multi-institutional predictive validity study examining the simulator's ability to improve performance in

---

[j]Mimic Technologies, Seattle, WA.

the operating room with residents and the ability of subtask training to improve performance in medical students. If strong predictive validity is established with this multi-institutional design, use for assessment accreditation could be considered. It is being distributed as a beta-prototype to select institutions and ideally it would be expanded to other transurethral procedures as well.

Virtual Reality Training for Ureteroscopic Skills

Currently, the most widely distributed virtual reality simulator in urology is UroMentor.[k] It runs on a personal computer and offers a high-level object-oriented application program interface available for use with either Microsoft Direct X or Open GL platforms (67). Simultaneous endoscopic and fluoroscopic views are displayed on the monitor and the user interacts with a mannequin with a multitude of virtual instruments including a flexible cystoscope, and rigid and flexible ureteroscopes. Tracking of the scopes with relation to the model is transmitted via a sensor on the endoscope and three sensors in the workstation. The model is volumetric in nature and created from data from digitized computer tomography and magenatic resonance imaging and the textures were obtained from endoscopic images during a real procedure. Like UW transurethral resection of the prostate, UroMentor provides a modular approach to train important subtasks for ureteroscopic and cystoscopic skills sets.

Shah and Darzi showed construct validity of a visual-spatial subtask cystoscopic module in UroMentor, which assesses the user's ability to find 10 flags in the bladder, which indicates that they have inspected the entire bladder. Seven experts outperformed 10 novices on the first trial both in the mean number of flags seen (9.57 vs. 8.0, $P = 0.01$) and the mean time to complete the task (2.33 vs. 4.89 minutes, $P = 0.03$). The experts did show improvement in speed between trials 1 and 2, but then remained the same up until trial 10. The medical students improved between the first and the 10th trial as far as speed ($P = 0.0005$) and approached significance with regards to seeing more flags ($P = 0.05$) (68). This study provided construct validity for the cystoscopy module, as experts outperformed novices presumably based on their prior experience on real cases. The authors also questioned the face validity, as finding flags did not accurately represent finding lesions in the bladder, though the fact that experts felt the simulator was realistic argues against this statement. Because the same instrument that was used for evaluation was also used for training and correlation with performance in the operating room was not examined, predictive validity was not established in this study (68).

Two other groups examined populations of novices (medical students) and UroMentor's ability to simulate and train ureteroscopic skills. Groups from the University of Texas Southwestern and Western Ontario University independently evaluated the acquisition of basic ureteroscopy skills using UroMentor using medical students ($N = 21$ and 20, respectively). The students were tested and randomized to training versus no training and retested on the simulator. Subjective assessment by a single subject matter expert (Western Ontario University) and two subject matter experts who were blinded to the randomization schedule was also performed. Significant improvements in performance were evident in multiple parameters within the trained groups in both studies. The authors believed the simulator to have face validity and convergent validity, as the subjective evaluation seemed to correlate with parameters tracked by the simulator. In a later study, the University of Texas Southwestern group confirmed construct validity by stratifying performance on UroMentor with clinical experience (69,70).

The group at University of Texas Southwestern also examined concurrent validity of the ureteroscopic module by examining whether training on UroMentor translated to improvement of performance on a cadaver. Sixteen medical students and 16 residents had baseline skills evaluation with UroMentor. Just the student group then underwent five hours of supervised training on the simulator and the two groups repeated the UroMentor ureteroscopic task and also performed diagnostic ureteroscopy in a male cadaver with subjective global assessment done by three faculty observers. The blinded status of these observers is unknown. Virtual reality and cadaver performances correlated closely in students but not in residents. Year of training correlated more on the cadaver performance than with the virtual reality performance. Medical students were unable to perform cadaver ureteroscopy comparable to residents despite the five hours of virtual reality training. The authors concluded that UroMentor may shorten the learning curve

---

[k]Simbionix, Lod, Israel.

early in training for ureteroscopic skills, but it was unable to over-ride the impact of clinical training (71).

The University of Texas Southwestern group examined UroMentor's ability to be used as an assessment tool. The authors examined the relationship between validated basic human performance testing and performance on UroMentor. Eighteen medical students underwent 13 validated tests and these skills were compared with performance of ureteroscopy on UroMentor. These performances were then used to create a model devised to predict performance on UroMentor rated by experts in a second group of 14 medical students after they completed the basic performance tests. They found that visual-spatial short-term memory capacity was the most prevalent limiting resource in the model building group and nondominant upper extremity steadiness was the most prevalent limiting resource in the model testing group. They also noted that the model was able to predict expert evaluation performance in some but not all instances (63% within ±10% agreement with expert rating on virtual reality performance) (72).

Virtual Reality Training for Laparoscopic Skills

The explosion of laparoscopic procedures in urology today led by such pioneers as Gill, Clayman, Guilloaneau, and Kavoussi are being associated with clear health benefits to Urology patients when compared to the open techniques. As laparoscopic approaches are validated as the standard of care, the dissemination, acquisition and certification of laparoscopic skills presents itself as a huge challenge. The American College of Surgeons recommends the granting of clinical privileges based upon evaluation of education, training, experience, and demonstrated current competence. The Society of American Gastrointestinal Endoscopic Surgeons expands this to include credentialing in diagnostic laparoscopy, hands-on experience either in a residency/fellowship or recognized didactic course, and observation of cases by a mentor proctor.

An additional problem is that urology lacked a procedure common enough to adequately maintain particular skills. Laparoscopic pelvic lymph node dissection in the 1990s paved the way for laparoscopic renal, prostate, and bladder procedures. Laparoscopic fellowships and mini-fellowships have been successful in the early adopters of this technology. Training courses with hands-on, porcine, cadaver, inanimate, and virtual reality simulators have emerged as attractive alternatives but must be associated with mentored learning opportunities for quality assurance. The summary of pertinent models and validation studies primarily revolves around laparoscopic cholecystectomy and may or may not be translatable to urological applications.

Inanimate Models (Box and Video Trainers)

For basic laparoscopic skills acquisition, inanimate trainers consisting of box and/or video trainers have been developed and utilized in urology programs and are usually relatively inexpensive, but all of them require mentored supervision for the purposes of data acquisition and assessment with its inherent cost. Some examples of inanimate trainers who have been validated include the "Rosser drills," which showed improvement in movements between the first and fourth trial (73,74). Reznick et al. (75,76) validated a "bench station" examination, which includes a global assessment scale that is widely used. The University of Kentucky established face and construct validity of their inanimate models for laparoscopic skills to perform laparoscopic appendectomy, cholecystectomy, and herniorrhaphy (77). The LTS 2000 (Hasson et al.) physical model simulator showed a positive correlation between the hours of practice on the simulator and basic gynecologic laparoscopic maneuvers and prospectively was able to reliably and reproducibly detect different levels of laparoscopic expertise in general surgery and OBGYN residents (78–80). A pilot study for laparoscopic urethrovesical anastomosis was performed by Katz et al., where they report a training program consisting of (1) passing a 30 cm polyglactin ligature between two needle holders, (2) intracorporeal knot tying, (3) intracorporeal suturing, (4) performing a linear anastomosis, and (5) performing a circular running anastomosis. Chicken skin and cardboard were used for this model. This is a very pertinent application, but validation studies are lacking. Other newer generation box video trainers include LapMan.[l]

In an objective scoring system for laparoscopic cholecystectomy done in a multi-institutional fashion by Eubanks et al. (81), the moves of a laparoscopic procedure were dissected into distinct goals associated with distinct deviations from the proper procedure (errors). This objectivity was based on reliable subjective assessment of videotaped

---

[l]Simulab, Seattle, WA.

procedures. Derossis et al. from McGill University and Coleman et al. at University of Texas Southwestern established construct validity for their training model as well.

Rosen et al. at the University of Washington designed a robot called the Blue Dragon that, when connected to the instruments, is able to track all motion and translate movements into signatures providing true objective assessment. Their objective was to develop a skill scale using statistical Markov models (10,32,82–84). Five novice surgeons and five expert surgeons performed two minimally invasive surgical procedures (cholecystectomy and Nissen fundoplication) in a porcine model. An instrumented laparoscopic grasper equipped with a three-axis force/torque sensor was used to measure the forces/torques at the hand/tool interface synchronized with endoscopic video of the operative maneuvers (Fig. 13). Three types of analysis were performed on the raw data: (1) video analysis encoding the type of tool-tip/tissue interaction, (2) vector quantization encoding the force/torque data into clusters (signatures), and (3) Markov modeling for evaluating surgical skill level. The video analysis was performed by two expert surgeons encoding the video of each step of the surgical procedure frame by frame (NTSC—30 frames per second). The expert encoding process used a taxonomy of 14 different tool maneuvers (Table 4). These 14 interactions encompass all the possible tool/tissue interactions identified during our previous video analysis of surgical procedures. Each identified surgical tool/tissue interaction had a unique F/T pattern. For example, in the laparoscopic cholecystectomy, isolation of the cystic duct and artery involves performing repeated pushing and spreading maneuvers (PS–SP—Table 4), which are accomplished by applying pushing forces mainly along the Z-axis (F_Z) and spreading forces (F_g) on the handle. These 14 tool/tissue interactions allowed us to encode each surgical procedure.

Virtual Reality Models For Laparoscopy

Schijven and Jakimowicz (85) did a thorough review of virtual reality laparoscopic simulators as of October, 2003. They surveyed eight of the main commercially active virtual reality companies regarding their laparoscopic products. There results are summarized in Table 5.

The minimally invasive surgical trainer-virtual reality (Mentice, Sweden) deserves special mention as it has undergone the most rigorous validation studies. Minimally invasive surgical trainer-virtual reality system runs on a desktop PC (400 MHz Pentium II, 64 Mb RAM) with tasks viewed on a 17 in cathode ray tube monitor. The frame rate is approximately 15 frames/sec. The laparoscopic instruments[m] provided six degrees of freedom and a foot pedal is provided to provide diathermy. Abstract targets appear within the operating space according to the specific skill task selected and can be grasped and manipulated with virtual instruments. Each task is objectively scored and quantified. Seymour, Gallagher, and Satava performed a series of validation studies reliably confirming face, content, construct, discriminate and predictive validity (86–89). Their "Virtual Reality to OR" predictive validity study whereby they prospectively randomized 16 residents to training versus no training and established baseline video performance metrics on laparoscopic cholecystectomy in the operating room both before and after the intervention is a landmark study in simulation validation (89). Grantcharov et al. (90) confirmed these findings in their Virtual Reality to OR study. Virtual Reality to OR of minimally invasive surgical trainer-virtual reality has been expanded to a multi-institutional predictive validity study. Gallagher et al. did use minimally invasive surgical trainer-virtual reality

to study controls versus urology trainees versus urology consultants with the intent to determine whether or not minimally invasive surgical trainer-virtual reality could be useful in aptitude testing. They found that minimally invasive surgical trainer-virtual reality, which is primarily a visual-spatial assessment tool, was not useful for this purpose (91). Various modules for the Procedicus, minimally invasive surgical trainer-virtual system are available. There is a KSA module which provides an abdominal environment for more advanced laparoscopic training such as scope and instrument navigation, pick and pass, cutting, suturing, needle passing, and diathermy. Arthroscopy, urology, gynecology, interventional cardiology, and radiology are available for the Procedicus platform. Force feedback is optional (www.mentice.com).

LapMentor[n] is an upper-end virtual reality laparoscopic trainer, which allows for the completion of entire general laparoscopic procedures. There are basic skills task modules such as instrument navigation, object manipulation, clipping, and cutting. Virtual patient cases are also present with accountability for different port placement sites. They acquired and employed Xitact's force feedback system to provide haptic feedback. Urologic applications are under development and validation studies are preliminary at this point (www.simbionix.com).

LapSim[o] offers nine basic laparoscopic skills training modules ranging from navigation to grasping, cutting, clip applying, and suturing. Force feedback is optional. Construct validity has been mixed. Duffy et al. (92) established construct validity for the simulator to distinguish between novices, trainees, and experts. Ro et al. (93) with a smaller number of subjects and only looking at one trial, actually showed that novices outperformed experts on instrumentation, suturing, and dissection modules. In a prospective design, however, naive subjects trained on the LapSim virtual-reality part-task trainer performed better on live surgical tasks in a porcine model as compared with those trained with a traditional box trainer (94). The software was recently upgraded and modules to include more advanced skill training and gynecologic procedures added (www.surgical-science.com).

The Haptica ProMis[p] trainer is a PC-based hybrid box and virtual reality trainer for laparoscopic skills. The Haptica trainer has undergone content and construct validity studies by Emory and the Imperial College of London. Significant differences between the performance of laparoscopic cholecystectomy subtasks were found between novices, trainees, and experts (95). Interestingly enough, Gallagher et al. found that older subjects (ages 60–69) performed significantly worse than younger subjects (ages 30–39, 40–49) on the box-trainer task for correct incisions (13.1 vs. 19.3, $p < 0.008$) and incorrect incisions (12.3 vs. 2.5, $p > 0.05$). They also performed worse on the virtual reality task for time (132 vs. 71, $p < 0.05$), error (99 vs. 41, $p < 0.05$) and economy of movement (22.8 vs. 11.7, $p < 0.05$) (www.haptica.com).

As laparoscopic skills become more widely disseminated, laparoscopic skills trainers representing complete procedures for laparoscopic urology procedures are desperately needed and are currently under development by numerous universities and simulation companies.

> As laparoscopic skills become more widely disseminated, laparoscopic skills trainers representing complete procedures for laparoscopic urology procedures are currently under development by numerous universities and simulation companies.

SUMMARY

- The ultimate goal of surgical education is to ensure competency, reduce error, and improve patient safety.
- The primary methods of assessment in medical education are based on testing factual knowledge.
- The ACGME core competencies and the OSATS and OSCE have provided a foundation for a paradigm shift in this concept. In the information age, factual knowledge may be less important.
- "The student should not be taught what to know, but rather where to find information (trusted sources), how to discriminate among the literally thousands of facts, and, once the correct information is found, how to make the correct decision."
- Virtual reality simulation is a promising tool that when built into such a dynamic curriculum will be used for objectively training and assessing procedural cognitive and technical skills.
- A mechanism of funding for postgraduate education skill acquisition, development, training validation, and assessment needs to be implemented before this goal becomes a reality.

MATHEMATICAL MODELING FOR PREDICTING OUTCOMES IN LAPAROSCOPIC UROLOGY

Sijo Joseph Parekattil

Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

In our current medical climate, the efficient use of medical resources is of prime importance. Unfortunately, this places the onus on medical care providers to develop measures to promote cost containment and reduce redundancy. This is a commonly shared theme in other fields such as engineering and business.

For example, let us look at the semiconductor chip design industry. Over the last 10 years, there has been an explosion in the ability to increase the complexity and density of semiconductor circuitry. This has driven the need to develop more cost effective and efficient methods to fabricate and test these chips.

Engineers have developed specialized fabrication and testing protocols to enhance the efficiency of these processes. The use of such protocols diminishes redundancy.

Similar techniques can also be applied to medicine. The use of clinical pathway protocols in the management of patients has been shown to provide significant cost containment and enhance efficiency in the use of medical resources (1,2).

Koch and Smith (2) presented some very elegant work in demonstrating cost containment by the use of a standardized clinical pathway protocol in the management of post–radical prostatectomy patients. This consolidated the use of such protocols at several institutions around the country. Flickinger et al. (1) demonstrated the beneficial use of clinical pathways in the management of pediatric ureteroneocystostomy patients.

This opens the door to a whole range of possibilities. The application of such protocols in patients that undergo laparoscopic or minimally invasive procedures is likely to have similar benefits. The design of current clinical protocols is usually based on the average or typical patient for that particular scenario. However, as we all know, not every patient is identical.

In the silicon chip fabrication process, not every wafer develops in an identical fashion. Thus, there are complex readjustment protocols that tailor the fabrication process to the specific requirements of that particular wafer.

Similarly, it only seems logical to design "smart" clinical pathway protocols that would readjust to a particular patient's needs to better suit the scenario.

Mathematical prediction modeling could be incorporated into such clinical pathways to provide this "intelligence."

> Engineers have developed specialized fabrication and testing protocols to enhance the efficiency of these processes. The use of such protocols diminishes redundancy.

> The use of clinical pathway protocols in the management of patients has been shown to provide significant cost containment and enhance efficiency in the use of medical resources.

> It only seems logical to design "smart" clinical pathway protocols that would readjust to a particular patient's needs to better suit the scenario.

This is but one example of the potential use of mathematical modeling in medicine. This chapter is dedicated to the discussion and presentation of mathematical modeling techniques and solutions in the field of laparoscopic or minimally invasive urology.

WHAT IS MATHEMATICAL MODELING?

The first person possibly documented to have used logic or mathematics in a device to create an outcome was the Spanish theologian Ramon Lull in 1274 A.D. (3). Lull's device was based on concentric disks of card, wood, or metal mounted on a central axis. Each disk would contain a number of different words or symbols, which would be combined in different ways by rotating the disks. By spinning the disks, you could achieve different sentences such as "This is an apple" or "That is a book."

We have come a long way from such humble beginnings to complex statistical methods of linear, logistic, nonlinear regression and artificial neural networks. Mathematical modeling is simply the use or equations or relationships (linear or non-linear) and logic to achieve some outcome, be it a prediction or a representation of the truth.

Some of the more commonly used methods will now be discussed.

Artificial Neural Networks

This is a computational method that strives to mimic the complex interconnections between neurons in a biologic system.

> Artificial neural network is a computational method that strives to mimic the complex interconnections between neurons in a biologic system.

Essentially there are three main components to the model; (i) specific inputs (input nodes), (ii) connections between these inputs and some intermediary data points (hidden nodes) that then lead to (iii) specific outputs (output nodes). Figure 1 illustrates this model.

Each level (input nodes, hidden nodes and output nodes) of the neural network is called a "layer." A simple linear model has inputs and an output—two layers. Neural networks have at a minimum three layers.

> When designing a neural network, the data to be analyzed in randomly distributed into three groups: a training data set, a testing data set and a validation data set.

When designing a neural network, the data to be analyzed in randomly distributed into three groups: a training data set, a testing data set and a validation data set.

The training data set is initially used to "train" the network. A set of inputs are entered, these inputs are multiplied by weights along each connection to produce hidden node values. These values are then multiplied by secondary weights along the next set of connections to finally produce an output. The error between the produced output and the desired output is then calculated and used to readjust the weights along the connection pathway from the first layer through the last. This process is repeated till the error between produced output and desired output is minimized. This is called the *perceptron learning rule.* More complex networks can be designed by utilizing more layers and designing feedback mechanisms that can adjust weighting values at any layer level without sequentially propagating through the system.

One must remember, though, that just because a model is designed as a neural network does not mean than it will perform better than a linear model. In fact, most neural networks must be compared to linear counterparts, if available, to assess if it is truly a benefit to utilize it.

Linear Regression Models

FIGURE 1 ■ Artificial neural network model.

These models are utilized to design models where a linear relationship exists between the input variables and output variables. The format of the model is represented as:

$$Y = ax_0 + bx_1 + cx_i + \cdots$$

Nonlinear Regression Models

These are utilized to design models where the relationship between input variables and output variable cannot be described by a simple linear model. The format of the model usually takes the form of:

$$Y = f(X, \beta) + \varepsilon$$

Here f is a function of X and β. X represents an input matrix, β a vector of weights and ε a vector of errors or disturbances from an expected outcome.

Logistic Regression Models

This type of model is used when the output parameter is not a continuous variable but takes an absolute value of 0 or 1. The relationship between input and output variables need not be linear in this case. The format of the model usually takes the form of:

$$\theta = \frac{e^{(\alpha+\beta_1 X_1+\beta_i X_i+\cdots)}}{1+e^{(\alpha+\beta_1 X_1+\beta_i X_i+\cdots)}}$$

All these models are simply attempts to associate or pattern a set outcome with specific inputs.

HOW GOOD IS A MODEL?

Deciding which model to use is the most difficult component of the modeling process. The type of variables utilized and the output parameters desired usually influence the type of model used.

Once a model is chosen, the question is how good is it?

There are a number of methods to assess the accuracy or effectiveness of models. One commonly employed method is to calculate the area under the receiver operating characteristic.

The receiver operating characteristic curve is the graphical representation of the True Positive Rate (sensitivity) versus the False Positive Rate (l-specificity). It essentially illustrates the trade-off between sensitivity and specificity for a model. The ideal model would have an receiver operating characteristic of l.

Table 1 illustrates a general guide to the meaning of area under the receiver operating characteristic values.

APPLICATION OF MODELING IN UROLOGY

Mathematical modeling has been utilized increasingly in the field of urology. Table 2 lists some of the models currently available for various urologic applications.

In order to facilitate the widespread development and free distribution of clinically applicable models, our group has created a web-based platform.(www.uroengineering.com). This is a noncommercial platform to further the use of mathematical and engineering techniques in urology. The hope is that this conduit would provide urologists easy access to urological models as they become available. This would allow for multi-institutional testing, refinement and validation of these models. The end result would be models that are actually widely clinically applicable.

APPLICATION OF MODELING IN LAPAROSCOPY

The use of mathematical modeling in laparoscopy is expanding. Gettman et al. (20) recently published an elegant study on the use of a nonlinear method to predict operative performance of laparoscopic surgery based on the assessment of surgeon performance in completing certain skill tasks. Lotan et al. have utilized decision tree models to perform cost effectiveness comparison between laparoscopic and open nephrectomy cases (21,22). These are but a sample of some of the potential applications in laparoscopic urology.

The use of mathematical modeling to predict hospital duration of stay after laparoscopic radical, simple, or partial nephrectomy by our group will now be presented.

Mathematical Models to Predict Duration of Stay After Laparoscopic Nephrectomy (Radical/Simple or Partial)

Laparoscopic nephrectomy (radical, simple or partial) is a minimally invasive procedure that is offered to patients for the treatment of renal malignancy or chronic renal disease. In our current medical climate, efficient use of resources in the postoperative care of patients undergoing these procedures is of prime importance.

Duration of hospital stay plays a critical role in determining the cost of individual surgical procedures (23).

Minimally invasive procedures offer significant cost savings in that they decrease duration of hospital stay (21,23). However, even within minimally invasive procedures, there may be differences in duration of hospital stay based on preoperative patient

---

Once a model is chosen, the question is how good is it?

The receiver operating characteristic curve is the graphical representation of the True Positive Rate (sensitivity) versus the False Positive Rate (l-specificity). The ideal model would have an receiver operating characteristic of l.

TABLE 1 ■ The Meaning of Receiver Operating Characteristic Values

Area under ROC	How good is the model?
1	Perfect
0.9–1	Excellent
0.8–0.9	Good
0.7–0.8	Fair
0.6–0.7	Average to poor
0.5–0.6	Not of value

Abbreviation: ROC, receiver operating characteristic.

Duration of hospital stay plays a critical role in determining the cost of individual surgical procedures.

parameters. The identification of patients who require a longer duration of hospital stay would better prepare ancillary staff for more efficient use of medical resources.

Preoperatively predicting duration of hospital stay for patients undergoing a laparoscopic nephrectomy (radical, simple or partial) would provide the hospital scheduling staff a planned approach to the recovery period. Such models could be incorporated into clinical pathways for postoperative management. The use of clinical pathways in postoperative management of patients after radical prostatectomy (2) and ureteroneocystostomy (1) has been shown to provide significant improvements in cost containment and medical resource utilization. The use of predictive models in clinical pathways may only further enhance these benefits.

> Our goal was to design algorithms to predict the duration of hospital stay after laparoscopic renal surgery based on preoperative patient parameters.

Our goal was to design algorithms to predict the duration of hospital stay after laparoscopic renal surgery based on preoperative patient parameters.

There are a number of confounding variables involved in determining duration of hospital stay, such as the patient's expectations, baseline patient coping ability, surgeon bias, and timing of the surgery (e.g., would the patient be discharged on a weekend day vs. a workday, etc.). However, our goal was to identify if there were any identifiable preoperative patient characteristics that predisposed the patient to a longer duration of hospital stay.

Retrospective review was performed on all 392 patients (July 1997–March 2004) who underwent laparoscopic nephrectomy (simple or radical) and all 334 patients (September 1999–April 2004) who underwent laparoscopic partial nephrectomy at our institution.

Prospective testing of models was performed on all 29 patients who underwent a laparoscopic nephrectomy and all 19 patients who underwent a laparoscopic partial nephrectomy from May 2004 to July 2004 at our institution. The protocol was approved by our Institutional Review Board. Age of the patients in the radical/simple nephrectomy group ranged from 24 to 89 years (mean, 61). Age in the partial nephrectomy group ranged from 17 to 87 years (mean, 60). Racial background was not recorded.

Laparoscopic Radical/Simple Nephrectomy Models

The following patient parameters were recorded during the retrospective chart review (392 patients): age, sex, surgeon, radical versus simple, unilateral versus bilateral,

planned adrenalectomy, planned lymph node dissection, gastro-esophageal reflux disease, hypertension, smoking, diabetes mellitus, hyperlipidemia, chronic obstructive pulmonary disease, coronary artery disease, hematuria (micro or gross), kidney stones, obstructive sleep apnea, congestive heart failure, cerebrovascular accident, polycystic kidney disease depression, fibromyalgia, liver cirrhosis, bleeding disorders, planned transperitoneal versus retroperitoneal approach, side of nephrectomy, tumor size, nodal involvement, renal vein involvement, body mass index, American Society of Anesthesiology grade, planned specimen extraction incision and duration of hospital stay (in days).

These "design group" data were used to create two duration of hospital stay prediction algorithms: to predict if the duration of hospital stay would be greater or lesser than two days, and to predict if the duration of hospital stay would be greater or lesser than one day.

The design group was initially divided into two groups: (i) patients with a duration of hospital stay less than or equal to two days (258 patients) and those with a duration of hospital stay greater than two days (134 patients). Univariate and multivariate logistic regression analysis comparing patient parameters between these groups identified significant predictors of duration of hospital stay. These results were used to generate a linear regression algorithm to predict duration of hospital stay (greater or lesser than two days) (24,25).

The same process was repeated for the greater or lesser than one day duration of hospital stay predictor. The design group in this case was divided into: (i) those patients that had a duration of hospital stay lesser than or equal to one day (123 patients) and those with a duration of hospital stay greater than one day (269 patients).

By combining the above two models, the algorithm would predict if the duration of hospital stay was lesser than or equal to one day, one to two days or greater than two days. These models were then prospectively tested on a separate 29 patient "test group" to assess the duration of hospital stay prediction accuracy. Testing was performed on this separate group to avoid any training bias.

Laparoscopic Partial Nephrectomy Models

The following patient parameters were recorded during the retrospective chart review (334 patients): age, sex, surgeon, body mass index, American society in anesthasiology grade, hypertension, prior pancreatitis, prior abdominal surgery, prior deep venous thrombus, peripheral vascular disease, smoking, coronary astery disease, gastic erophageal refull disease, anxiety, hyperlipidemia, depression, renal stone disease, constipation, liver cirrhosis, hepatitis C, hematuria (micro or gross), chronic obstructive pulmonary disease, alcohol use, hypothyroidism, diabetes mellitus, chronic renal insufficiency, cerebrovascular accident, gout, congestive heart failure, osteoarthritis, bleeding disorder, Crohn's disease or inflammatory bowel disease, obstructive sleep apnea, polycystic kidney disease, seizures, anemia, von Hippel-Lindau disease, simple or partial nephrectomy, planned retroperitoneal versus transperitoneal approach, tumor size (by computed tomography), solitary kidney, preoperative serum creatinine, tumor location–anterior, posterior, medial, lateral, mid, lower, upper, exophytic, parenchymal, up to renal sinus, central, peripheral, abuts the collecting system and duration of hospital stay (in days).

These "design group" data were used to create two duration of hospital stay prediction algorithms: to predict if the duration of hospital stay would be lesser or greater than two days, and to predict of the duration of hospital stay would be lesser or greater than one day.

The design group was initially divided into two groups: (i) patients with a duration of hospital stay less than or equal to two days (147 patients) and patients with a duration of hospital stay greater than two days (187 patients). Univariate and multivariate logistic regression analysis comparing the above patient parameters between these groups identified significant predictors of duration of hospital stay (lesser or greater than two days). These results were then used to generate a linear regression algorithm to predict the duration of hospital stay (lesser or greater than two days) (24,25).

The same process was repeated to design the lesser or greater than one day duration of hospital stay predictor. The design group in this case was divided into: (i) patients with a duration of hospital stay less than or equal to one day (28 patients) and patients with a duration of hospital stay greater than one day (306 patients).

These models were then prospectively tested on a separate 19 patient "test group" to assess duration of hospital stay prediction accuracy. Testing was performed on this separate group to avoid any training bias.

RESULTS

In the laparoscopic radical/simple nephrectomy group (392 patients), 123 patients (31.4%) had a duration of hospital stay of less than or equal to one day, 135 patients (34.4%) had a duration of hospital stay of one to two days and 134 patients (34.2%) had a duration of hospital stay of greater than two days.

In the laparoscopic partial nephrectomy group (334 patients), 28 patients (8%) had a duration of hospital stay of less than or equal to one day, 119 patients (36%) had a duration of hospital stay of one to two days and 187 patients (56%) had a duration of hospital stay of greater than two days.

Laparoscopic Radical/Simple Nephrectomy: Lesser or Greater Than Two Days Duration of Hospital Stay Predictor

Univariate logistic regression analysis in the design group for duration of hospital stay lesser or greater than two days (Table 3) identified that bilateral nephrectomy, hypertension, smoking, chronic obstructive pulmonary disease, polycystic kidney disease, planned transperitoneal approach, elevated preoperative serum creatinine, and extraction incision were significant predictors of a duration of hospital stay of greater than two days. Extraction incision, if a patient had morcellation, was significant in predicting a longer duration of hospital stay. This is plausible in patients, who underwent morcellation and had a small port extraction incision, likely to have had chronic renal disease and may be in poorer overall health. The patients who underwent simple nephrectomy were combined with those that had a radical nephrectomy because the type of nephrectomy on its own was not significant in predicting duration of hospital stay. The above-mentioned factors identified the patients within the simple nephrectomy group that would require a longer duration of hospital stay. Therefore, having a simple nephrectomy as a factor alone did not contribute in predicting duration of hospital stay.

Multiple logistic regression analysis (Table 3) identified chronic obstructive pulmonary disease, planned transperitoneal approach and elevated preoperative serum creatinine as independent significant predictors of a duration of hospital stay greater than two days.

This analysis identified the appropriate weighting for the above characteristics in the design of a linear regression prediction algorithm. All the above patient parameters were utilized to optimize model accuracy.

The equation for the lesser or greater than two day duration of hospital stay prediction model is:

> Multiple logistic regression analysis identified chronic obstructive pulmonary disease, planned transperitoneal approach and elevated preoperative serum creatinine as independent significant predictors of a duration of hospital stay greater than two days.

$$2 \text{ Day Score} = (\text{Unilateral/bilateral} \times 6) + (\text{Hypertension}) + (\text{Smoke} \times 4)$$
$$+ (\text{Chronic obstructive pulmonary disease} \times 4)$$
$$+ (\text{Polycystic kidney disease} \times 2) - (\text{Planned approach})$$
$$+ (\text{Serum Cr}) - (0.1 \times \text{incision type})$$

TABLE 3 ■ Laparoscopic Radical/Simple Nephrectomy Group: Analysis for Duration of Hospital Stay Less Than or Greater Than Two Days

Pre-op predictor of less than or greater than 2 days	Odds ratio	Univariate 95% CI	P^a val	Odds ratio	Multivariate 95% CI	P^a val
Unilateral vs. bilateral	5.2	2.2–12.1	<0.001	133K	0–∞	0.995
Hypertension	1.7	1–2.7	0.038	1.2	0.7–2.3	0.536
Smoking	2.9	1.1–7.8	0.035	2.4	0.8–7	0.120
COPD	3.4	1.2–9.5	0.021	3.3	1.1–10.3	0.036
Polycystic kidneys	20.7	2.64–63.7	0.004	2.9	0.2–34.8	0.404
Retro vs. trans-peritoneal	0.6	0.4–0.9	0.022	0.6	0.31–1	0.047
Pre-op serum creatinine	1.5	1.2–4.8	<0.001	1.3	1–1.6	0.016
Planned extraction incision	0.7	0.5–0.9	0.017	1	0.6–1.5	0.970

[a]P values in this table refer to the comparison of those patients that had a post-op duration of stay less than 2 day versus those greater than 2 day.
Abbreviations: COPD, chronic obstructive pulmonary disease; CI, confidence interval.

Key:
Type of nephrectomy: Unilateral = 0, bilateral = 1
Planned approach: Transperitoneal = 0, retroperitoneal = 1
Incision type: Morcellated = 0, Pfannenstiel, infraumbilical, McBurney's,
                      Gibson = 1, flank incision = 2

If the score is greater than 5, then a duration of hospital stay of greater than two days is predicted. If the score is lesser than 5, a duration of hospital stay of less than or equal to two days is predicted. Model accuracy in the design group was 74% (receiver operating characteristic 0.8) and in the test group was 66% (receiver operating characteristic 0.7) as shown in Table 7.

Laparoscopic Radical/Simple Nephrectomy: Lesser or Greater Than One Day Duration of Hospital Stay Predictor

Univariate logistic regression analysis in the design group for duration of hospital stay lesser or greater than one day (Table 4) identified simple nephrectomy, hypertension and planned morcellation extraction incision as significant predictors of a duration of hospital stay of greater than one day.

Multiple logistic regression analysis (Table 4) identified hypertension and planned extraction incision as independent significant predictors of a duration of hospital stay greater than one day. This analysis identified the appropriate weighting for parameters in the design of a linear regression prediction algorithm. Simple nephrectomy and planned extraction incision were utilized in the final model to optimize accuracy. The addition of hypertension did not increase model accuracy and, thus, was not used. This may be due to the fact that patients with hypertension that stayed greater than one day had one of the other factors concurrently.

The equation for the lesser or greater than one day duration of hospital stay prediction model is:

1 Day score = (Simple or radical × 6) − (0.5 × Incision type)

Key:
Type of nephrectomy: Simple = 2, radical = 1
Incision type: Morcellated = 0, Pfannenstiel, infraumbilical, McBurney's,
                      Gibson = 1; flank incision = 2

If the score is greater than 5, then a duration of hospital stay of greater than one day is predicted. If the score is lesser than 5, a duration of hospital stay of less than one day is predicted. The model accuracy in the design group was 73% (receiver operating characteristic 0.7) and in the test group was 97% (receiver operating characteristic 0.8) as shown in Table 7.

Laparoscopic Partial Nephrectomy: Greater or Lesser Than Two Days Duration of Hospital Stay Predictor

Univariate logistic regression analysis in the design group for duration of hospital stay greater or lesser than two days (Table 5) identified increased age, diabetes mellitus, planned transperitoneal approach, increased tumor size, parenchymal tumor, tumor extending up to renal sinus and tumor abutting the collecting system as significant predictors of a duration of hospital stay of greater than two days.

TABLE 4 ■ Laparoscopic Radical/Simple Nephrectomy Group: Analysis for Duration of Hospital Stay Less Than or Greater Than One Day

Pre-op predictor of less than or greater than 1 day	Odds ratio	Univariate 95% CI	*P*[a] val	Odds ratio	Multivariate 95% CI	*P*[a] val
Simple vs. radical	2.9	1.1–7.6	*0.035*	4.1	0.5–33.4	0.188
Hypertension[b]	4.2	2.2–8.3	*<0.001*	2.6	1.2–5.8	*0.016*
Planned extraction incision	0.5	0.3–0.6	*<0.001*	0.6	0.4–0.8	*0.002*

Note: Factors in italic were used to create the model.
[a]*P* values in this table refer to the comparison of those patients that had a post-op duration of stay less than 1 day versus those greater than 1 day.
Abbreviation: CI, confidence interval.

TABLE 5 ■ Laparoscopic Partial Nephrectomy Group: Analysis for Duration of Hospital Stay Less Than or Greater Than Two Days

Predictor of less than or greater than 2 days	Odds ratio	Univariate 95% CI	P^a val	Odds ratio	Multivariate 95% CI	P^a val
Age	1	1–1.04	*0.006*	1	1–1.04	*0.013*
Diabetes	5.4	1.6–18.7	*0.007*	7.5	2–28	*0.003*
Approach (trans vs. retro)	2.2	1.4–3.4	*<0.001*	1.5	0.9–2.5	0.157
Size of tumor (by CT)	1.5	1.2–1.8	*<0.001*	1.3	1.1–1.6	*0.004*
Exophytic tumor	0.3	0.2–0.5	*<0.001*	0.3	0.2–0.6	*<0.001*
Tumor extends up to renal sinus	4.2	2.3–7.5	*<0.001*	1.9	0.9–3.8	0.089
Tumor abuts collecting system	3.5	2.2–5.8	*<0.001*	1.8	1–3.3	0.065

Note: Predictors in italics were used to create the model.
[a]*P* values in this table refer to the comparison of those patients that had a post-op duration of stay less than 2 day vs. those greater than 2 day.
Abbreviations: CT, computed tomography; CI, confidence interval.

Multiple logistic regression analysis identified increased patient age, diabetes meelitus, increased tumor size and parenchymal tumor to be independent significant predictors of a DOS greater than two days.

Multiple logistic regression analysis (Table 5) identified increased patient age, diabetes mellitus, increased tumor size and parenchymal tumor to be independent significant predictors of a duration of hospital stay greater than two days.

This analysis identified the appropriate weighting for the characteristics in the design of a linear regression prediction algorithm. All the above patient parameters except tumor extending up to the renal sinus were utilized to optimize model accuracy. The addition of this particular parameter did not enhance the model accuracy. This may be explained by the fact that all the patients with tumor extending up to the renal sinus had tumors that were more parenchymal, tended to be larger, and were more likely to abut the collecting system. Thus, these other factors identified patients with a duration of hospital stay greater than two days without any further added contribution from the characteristic of tumor extending up to the renal sinus.

The equation for the greater or lesser than two day duration of hospital stay prediction model is:

$$\text{2 Day score} = (\text{Patient age}/59 \times 7) + (\text{Diabetes mellitus} \times 8) + (\text{Planned approach})$$
$$+ (\text{Tumor size by CT in cm}) - (\text{Exophytic tumor} \times 5)$$
$$+ (\text{Abuts collecting system} \times 4)$$

Key:
Planned approach: Transperitoneal = 1, retroperitoneal = 0
Exophytic tumor: Yes = 1, no = 0
Abuts collecting system: Yes = 1, no = 0

If the score is greater than 10, then a duration of hospital stay of greater than two days is predicted. If the score is less than 10, a duration of hospital stay of less than or equal to two days is predicted. The model accuracy in the design group was 73% (receiver operating characteristic 0.7) and in the test group was 68% (receiver operating characteristic 0.6) as shown on Table 7.

Laparoscopic Partial Nephrectomy: Greater or Lesser Than One Day Duration of Hospital Stay Predictor

Univariate logistic regression analysis in the design group for duration of hospital stay greater or lesser than one day identified 24 patient characteristics as significant predictors for a duration of hospital stay of greater than one day as listed in Table 6. As there were only 28 patients in the design group who had a duration of hospital stay of less than or equal to one day, the statistical significance of some of these parameters may be overstated.

Multiple logistic regression analysis (Table 6) identified congeorine heart failure, parenchymal tumor, and tumor abutting the collecting system to be independent significant predictors of a duration of hospital stay greater than one day. This analysis identified the appropriate weighting for characteristics in the design of a linear regression prediction algorithm. The following parameters were utilized in the model: hypertension, gastic esophageal reflux disease, anxiety, hematuria (micro or gross), diabetes mellitus, CRI, gout, congestive heart failure, Crohn's disease, transabdominal approach, solitary kidney,

TABLE 6 ■ Laparoscopic Partial Nephrectomy Group: Analysis for Duration of Hospital Stay Less Than or Greater Than One Day

Predictor of less than or greater than 1 day	Odds ratio	Univariate 95% CI	P^a val	Odds ratio	Multivariate 95% CI	P^a val
Hypertension	0	0	<0.001	0.8	0.2–4.1	0.793

Renal insufficiency	∞	∞	<0.001	24M	0–∞	0.996
Stroke/TIA	∞	∞	<0.001	0.08	0–∞	1.000
Gout	∞	∞	<0.001	37B	0–∞	0.999
Congestive heart failure	0	0	<0.001	0.002	0–0.06	<0.001
Osteoarthritis	∞	∞	<0.001	77K	0–∞	0.997
Thrombocytopenia	∞	∞	<0.001	2M	0–∞	0.996
Crohn's disease	0	0	<0.001	0.2	0–325	0.657
Obstructive sleep apnea	0	0	<0.001	0.4	0–89	0.755
Anemia	∞	∞	<0.001	382K	0–∞	0.999
Transabdominal approach	∞	∞	<0.001	2.9	0.8–10.3	0.093
Solitary kidney	∞	∞	<0.001	72M	0–∞	0.997
Exophytic tumor	0	0	<0.001	0.06	0.01–0.3	<0.001
Tumor extends up to renal sinus	∞	∞	<0.001	1.5	0.3–8.4	0.648
Tumor abuts collecting system	0	0	<0.001	0.02	0–0.1	<0.001

Note: Predictors in italics were used to create the model.
[a]*P* values in this table refer to the comparison of those patients that had a post-op duration of stay less than 1 day versus those greater than 1 day.
Abbreviations: COPD, chronic obstructive pulmonary disease; CI, confidence interval; TIA, transient ischemic attack.

exophytic tumor, tumor extending up to the renal sinus and tumor abutting the collecting system. The combination of these factors provided the optimal accuracy. The addition of the other factors listed in Table 4 did not enhance model accuracy, and thus they were not utilized.

The equation for the lesser or greater than one day duration of hospital stay prediction model is:

$$\text{1 Day score} = \text{Hypertension} + \text{Gastic erophageal reflux disease}$$
$$+ \text{Anxiety} + \text{Hematuria} + \text{Diabetes mellitus}$$
$$+ \text{CRI} + \text{Gout} + \text{Congestive heart failure} + \text{Crohn's}$$
$$+ \text{Transabdominal approach} + \text{Solitary kidney}$$
$$- \text{Exophytic tumor} + \text{Up to sinus} + \text{Abuts collecting system}$$

Key:
Presence of any of the above conditions: Yes = 1, no = 0.

If the score is greater than 0.5, then a duration of hospital stay of greater than one day is predicted. If the score is lesser than 0.5, a duration of hospital stay of less than or equal to one day is predicted. The model accuracy in the design group was 83% (receiver operating characteristic 0.8) and in the test group was 84% (receiver operating characteristic 0.8) as shown in Table 7.

In order to simplify the use of these four models Palm™- and Windows™-based versions were created.

TABLE 7 ■ Accuracy Profiles for the Duration of Hospital Stay Prediction Models

DOS model	Greater or lesser than 2 day		Greater or lesser than 1 day	
	Accuracy (%)	ROC	Accuracy (%)	ROC
Laparoscopic radical/simple nephrectomy				
Design group (393 pts)	74	0.8	73	0.7
Test group (29)	66	0.7	97	0.8
Laparoscopic partial nephrectomy				
Design group (344 pts)	73	0.7	83	0.8
Test group (19)	68	0.6	84	0.8

Abbreviations: ROC, receiver operating characteristic; DOS, duration of hospital stay.

> The results illustrate that there are certain preoperative patient parameters that may predict a longer DOS in patients undergoing laparoscopic radical/simple or partial nephrectomy.

Comment: The results illustrate that there are certain preoperative patient parameters that may predict a longer duration of hospital stay in patients undergoing laparoscopic radical/simple or partial nephrectomy.

These parameters may help guide physicians when counseling patients considering these procedures. The models are a user-friendly tool to provide predictions as to the expected duration of hospital stay. These models may be implemented in clinical care pathways to provide efficient use of medical resources during the hospital stay. Two completely separate sets of models (using separate patient groups) were designed for the radical/simple nephrectomy patients and the partial nephrectomy patients, as these are two very different procedures.

The problem with such models is that they tend to be biased to the patient population at the design institution. Therefore, multi-institutional external validation and refinement of the models would enhance their utility. We are currently performing this phase of development.

There are some confounding variables that may be decreasing the predictive accuracy of the models: subjective, but important factors such as baseline patient coping capacity, motivational level of the patient and level of surgeon optimism. However, these factors are difficult to objectively quantify into modeling parameters. Despite these caveats, the models do provide fair predictions based on the patient parameters that were evaluated in this study.

> Our design was based on strict statistical methods of univariate and multivariate analysis and logistic regression.

Our design was based on strict statistical methods of univariate and multivariate analysis and logistic regression (24,25).

The accuracy of the models and the receiver operating characteristic values did vary in the test groups compared to the design groups. This may be in part due to the small sample size of the testing groups.

In order to facilitate free exchange and testing of the model, Hand-held and Windows-based computer versions of the model were created. A web-based distribution platform was designed and the programs can be downloaded as free shareware. (from www.uroengineering.com). This allows physicians to use the models in their practice and to validate the effectiveness of the models at their institution.

Conclusions: These models provide 66% to 97% accuracy in predicting the postlaparoscopic nephrectomy duration of hospital stay. These models may allow the urologist to preoperatively counsel patients and to optimize the delivery of care during the hospital stay.

Our group is currently in the process of performing a multi-institutional prospective testing, refinement and validation study for these models. This will assess and develop the model's true widespread clinical utility.

THE FUTURE

> Mathematical modeling in laparoscopy and urology will only open more opportunities to further optimize the delivery of care to our patients.

Mathematical modeling in laparoscopy and urology will only open more opportunities to further optimize the delivery of care to our patients.

These techniques are merely tools to help better the quality of care provided. However, without multi-institutional collaborative testing, refinement and validation of these models, these tools are unlikely to be widely accepted or utilized. Therefore, the creation of open, noncommercial, freely accessible website platforms (e.g., www.uroengineering.com) for the exchange and development of urology models and concepts is of prime value.

INTRODUCTION

Is it science fiction, or is it reality, when a miniscule chip, smaller than what is currently available, is used in the molecular genetics laboratory to considerably accelerate research and to help identify markers of diagnostic, prognostic and therapeutic value? Is it science fiction, or is it reality, when specific drugs are delivered selectively to individual cells in the human body and thus treat potentially incurable diseases, with no side effects? Is it science fiction, or is it reality, when molecular robots are sent into the circulation with the mission of detecting cancer cells, disabling them, and then causing their selective destruction. This apparent science fiction is actually fast becoming reality, in the world of Nanotechnology.

Nanotechnology refers to the creation of functional material devices and systems through the control of matter on an atomic or molecular scale–the nanometer scale $(1\,nm = 1 \times 10^{-9}\,m)$. It is at this size scale that most biologic molecules inside living cells operate.

The prefix "nano" actually originates from the greek word nanos, meaning "little old man" or "dwarf" and the strict definition of nanotechnology is the study, design, creation, synthesis, manipulation, and application of functional materials, devices, and systems through control of matter at the nanometer scale. Nanomedicine, an offshoot of nanotechnology, refers to the highly specific monitoring, repair, construction, and control of human biological systems at the molecular level, using engineered nanodevices and nanostructures (1,2). Over the next decade, it is widely expected that nanotechnology and nanomedicine will have important and innovative applications in clinical research and medicine, as well as contributing $1 trillion to the global economy (3).

Preliminary designs of nanoparticles, such as artificial red blood cells, white cells, and killer cells that can identify a particular bacteria, or cancer cells, have already been developed, and it is anticipated that nanotechnology will allow urologists to intervene at the cellular and molecular level of any disease process in the future. In this chapter, we introduce important concepts of nanotechnology and discuss published data in the urological literature, which shows the potential for nanotechnology to link molecular signatures to urological cancer behavior and clinical outcome, develop nanoparticle probes for molecular and cellular imaging of urological disease, and for the novel use of nanoparticles for the delivery of drug therapy.

POTENTIAL APPLICATIONS OF NANOTECHNOLOGY IN UROLOGY

There are a wide range of potential applications of nanotechnology in the field of urology, as virtually every use of nanomaterials and nanotechnology in biology and medicine can be applied to urology. This ranges from prevention of disease, to early detection and improvement in diagnosis. In addition, treatment, prognosis, symptom management, and drug delivery of many urological conditions can be accelerated with nanotechnological devices.

> Nanotechnology refers to the creation of functional material devices and systems through the control of matter on an atomic or molecular scale–the nanometer scale $(1\,nm = 1 \times 10^{-9}\,m)$. It is at this size scale that most biological molecules inside living cells operate.

DELIVERY SYSTEMS FOR DRUG AND GENE THERAPY

Delivery systems for drug and gene therapy are particularly attractive targets in urological practice.

Novel drug delivery for prostate cancer using ceramic nanoparticles, carbon magnetic nanoparticles, protospheres and nanogold particles has been investigated in prostate cancer. Paclitaxel loaded biodegradable nanoparticles have been shown to be effective inhibitors of human prostate cancer cell lines in a murine model (4). In addition, enhanced cellular uptake of a triplex-forming oligonucleotide by nanoparticle formation in the presence of polypropylenimine dendrimers has also been found in metatstatic prostate cancer cell lines, indicating their potential use for delivering therapeutic oligonucleotides in cancer cells in vivo (5). Furthermore, Thomas et al. (6) have shown in vitro targeting of synthesized antibody against prostate-specific membrane antigen with conjugated dendrimer nanoparticles as a suitable platform for targeted molecule delivery into appropriate antigen-expressing cells. Studies investigating gene therapy in prostate cancer, have also shown enhanced in vitro DNA transfection efficiency by novel folate-linked nanoparticles (7), and similarly a human transferrin-targeted cationic liposome-DNA complex, Transferrin-lipoplex, has shown enhanced stability, improved in vivo gene transfer efficiency, and long-term efficacy for systemic p53 gene therapy when used in combination with conventional radiotherapy (8). Anderson et al. (9) have recently demonstrated that a polymer, termed C32, is capable of delivering genes to cancer cells more efficiently and with less toxicity than other polymers that have been tested in the field to date. Therapeutic genes delivered to cells in this manner are able to drive cellular production of a gene-encoded protein through normal processes. By genetically engineering the normal diphtheria toxin gene, a toxin was created that would be produced only in prostate cells. When injected into prostate tumors in animals with C32 nanoparticles, tumour growth was suppressed or reversed, relative to untreated tumors. Research is also being carried out to explore whether nanoparticles can be delivered intravenously to attack metastatic tumor cells, which are found throughout the body in advanced stages of cancer (10).

With the obvious financial potential of a drug delivery system, this particular aspect of nanotechnology is receiving considerable attraction from the commercial sector, specifically the pharmaceutical industry.

IMAGING AND LABELING WITH NANOSTRUCTURED MATERIALS

Body or organ imaging and labeling with nanostructure materials are also being used for adjuncts to uroradiological diagnosis.

Recently, Harisinghani et al. (11) have demonstrated that highly lymphotropic super-paramagnetic nanoparticles, which gain access to lymph nodes by means of interstitial lymphatic fluid transport, allow the high-resolution magnetic resonance imaging of clinically occult lymph node metastases in patients with prostate cancer, which previously have not been detectable by any other non-invasive approach.

Using nanocantilevers, which are flexible beams, resembling a row of diving boards that can be coated with molecules, capable of binding to biomarkers, Wu et al. (12) demonstrated the quantification of prostate-specific antigen at clinically significant concentrations. In addition, a novel reagent for low-level detection in immunoadsorbent assays has been described by Grubisha et al. (13). The reagent consists of gold nanoparticles modified to integrate bioselective species, such as antibodies, with molecular labels for the generation of intense, biolyte-selective surface-enhanced Raman scattering responses in immunoassays and other bioanalytical applications. In this study they demonstrated free prostate-specific antigen levels of approximately 1 pg/mL in human serum. It has to be appreciated that current research in its infancy at present, and the specificities and sensitivities of such methodology do not yet offer substantial advantages over conventional detection methods. However, it is inevitable that imaging and labeling with nanostructures will be clinically useful in the future in uro-oncology, as well as in non cancer cases (urinary tract stones).

MOLECULAR RECOGNITION

Basic science urological research has undoubtedly benefited from the advantages of nanotechnology, and in the future it is expected that not only will ongoing pre-clinical work be accelerated, but meaningful clinical studies using nanotechnology devices will

be performed rapidly, with results and outcomes useful for clinical practice available as early as the next decade. Particular tools available for performing research include nanowires and nanotubes. Nanowires are sensing wires that can be coated with molecules to bind to proteins of interest and transmit their information through electrodes to computers, whereas nanotubes are cylinder-like assemblies of carbon atoms, with cross sectional dimensions in the nanometre range, and lengths that can extend over a thousand times their diameter. Using such devices, several thousand sensors can be placed on a single chip, offering even greater multiplexing advantages. A variety of novel devices are emerging, such as microarrays with their high precision patterning of biological molecules useful for molecular diagnostics, genotyping and biomarker guided therapeutic targeting (14).

NANOSURGICAL TOOLS

Nanoshells, which are gold shell nanoparticles surrounded by a semiconductor, which can be heated resulting in irradiation of the target cell have been recently used to eradicate transmissible venreal tumours in mice (15). It is widely anticipated that nanoshells will be of widespread use in many urological cancers in the future.

Although further applications of nanotechnology in urology are less well advanced, arguably, they have potentially significant implications. Surgical tools, such as nanotweezers are already in development, and it is anticipated that their everyday use in microsurgical procedures such as vasectomy reversal and varicocoele repair are only a few years away. In addition, nanoprobes aiding diagnostic procedures, for example "nanourobots" being used for cystoscopy, ureteroscopy and fulguration of tumours, as well as searching the inferior vena cava and renal vein to detect venous involvement of renal cell cancer, may be just round the corner.

SYNTHETIC THERAPEUTIC DEVICES

The attraction of providing minimally invasive therapies with high functionality is immediately appealing.

Recently, a human nephron filter has been introduced, utilizing nanotechnology, that would eventually make possible a continuously functioning, wearable or implantable artificial kidney (16).

The human nephron filter has been computer-modeled, and operating 12 hr/day, seven days/wk the human nephron filter provides the equivalent of 30 mL/min glomerular filtration rate (compared to half that amount for conventional thrice-weekly hemodialysis). Animal studies should begin in the next one to two years, and clinical trials would follow. The enhanced solute removal and wearable design should substantially improve patient outcomes and quality of life.

Smart nanosensors with communication capability and synthetic therapeutic devices to provide minimally invasive therapies will undoubtedly be developed, with particular interest in urological tissue engineering for urinary tract reconstruction (1).

NANOTECHNOLOGY AND LIMITATIONS

There are potential problems associated with nanotechnology which will have to be fully addressed prior to universal acceptance. The time required for ascertaining their suitability for clinical use might therefore be quite substantial, but it appears that the establishment of faster, safe regulatory approval protocols would ameliorate concerns about the length of time it takes for agents to be assessed (14). Ethical, socioeconomic, political and environmental concerns are real, and in addition, there will a requirement for stringent regulations to prevent potential misuse, such as for terrorist activities.

NANOTECHNOLOGY AND THE FUTURE

The growing importance of nanotechnology is reflected by the increased U.S. Federal Nanotechnology budget from $270 million in the financial year 2000 to $738 million in financial year 2003 (17).

The National Institutes of Health has awarded researchers grants totaling nearly $10 million, to establish a multidisciplinary research program in cancer nanotechnology

Recently, a human nephron filter has been introduced, utilizing nanotechnology, that would eventually make possible a continuously functioning, wearable or implantable artificial kidney.

and to develop a new class of nanoparticles for molecular and cellular imaging. Working at the sub-atomic level, these scientists will be seeking data that will link molecular signatures to patient's clinical outcomes, so that cancers can be predicted, detected earlier, and treated more effectively. The primary focus of the new program will be prostate cancer.

CONCLUSION

Nanotechnology is expected to have a significant impact on urological research and clinical practice and will allow urologists to intervene at the cellular and molecular level, with diagnostic and therapeutic clinical benefit.

Concepts such as nanovectors for the targeted drug delivery, nanowires and nanocantilever arrays for the early detection of precancerous and malignant lesions, nanopores for DNA sequencing, and nanotubes and nanosensors for advanced delivery of theraputic agents are quickly moving from imagination to a reality, with significant applications relevant to the diagnosis, management, and treatment of all urological conditions.

> Nanotechnology is expected to have a significant impact on urological research and clinical practice and will allow urologists to intervene at the cellular and molecular level, with diagnostic and therapeutic clinical benefit.

INTRODUCTION

Technology has become a major driver of the future direction of healthcare and surgery. Likewise, the speed of change has accelerated beyond comprehension, with a number of revolutions occurring during a surgeon's career. Being an agent of change or rapidly adapting to change has become the hallmark of the gifted surgeon. The fundamental challenges to a future surgeon are addressed from a technological viewpoint, with emphasis on the impact upon the practice of surgery.

Everything occurs in cycles: revolution, change, adaptation to change, acceptance of the new standard, codifying the new establishment, resistance to further change, revolution, and the cycle begins again. In healthcare and surgery, this cycle had been occurring about every 100 years, but recently there has been a perceptible acceleration of this cycle. The first revolution for surgery came during the Industrial Age in the mid-1800s simultaneously with the introduction of anesthesia, asepsis, pathology, new instrumentation, and so on. Nearly a 100 years later, in the mid-20th century, as the Information Age was about to begin, surgery was advancing with antibiotics, intravenous fluid and hyperalimentation, radical surgery resections, and chemotherapy to name but a few. By the 1990s, laparoscopic (or minimally invasive) surgery emerged and became the standard for many procedures. Information Age technologies, such as video cameras and monitors, continued the evolution. But technology is accelerating faster than ever, and we are on the threshold of yet another revolution. This is referred to as the Biointelligence Age (1), an age of multidisciplinary medicine that can achieve much more than a single researcher or clinician can. The complexities of nature are yielding to interdisciplinary teams performing multidisciplinary research—genomics as a combination of biology and information sciences or robotics as a combination for physical (engineering) and information sciences. Much as previous revolutions, this current transformation is occurring because many different technologies are converging to fundamentally change surgery. There is a veritable explosion of new discoveries, such as genomics, micro-electro-mechanical systems, robotics, intelligent systems, molecular biology, etc. The entire surgical environment and culture is changing at an unprecedented rate of innovation that challenges the practicing surgeon every day. The change is occurring because of "disruptive technologies" that seemingly overnight completely reverse the fundamental approaches that have been standard for decades. In addition to technology, the surgical environment includes clinical practice, reimbursement, regulatory (such as Health Information Portability and Privacy Act), education and training, certification, research, and clinical trials. Because it is not possible to do justice to all those competing forces, the focus shall be upon the impact of technology, while fully admitting that at any one time, any of the factors play a dominant role in the life of a surgeon.

The opinions or assertions contained herein are the private views of the author and are not to be construed as official, or as reflecting the views of the Department of the Army, the Department of the Navy, the Defense Advanced Research Projects Agency, or the Department of Defense.

CLINICAL PRACTICE

Most practicing surgeons have already seen at least one significant revolution during their careers, the radical changes brought by the many discoveries of the Information Age. The most dramatic has been the shift to minimal access surgery (laparoscopic, endoscopic, etc). The surgeon of the near future will be trying to decide (just as was the case with the introduction of laparoscopic surgery) whether it will be necessary to train and practice with robotic surgical systems. Surgeons already have multiple options—open surgery, laparoscopic, endoluminal, endovascular, percutaneous, and so on. The answer to robotic surgery is an unequivocal yes.

Current view of robotic surgery is that the robot is used to enhance the performance of the surgeon—either through more precise motions or through providing access to very restricted places. While this is true, the real value of robotics is that it brings surgery completely into the Information Age. Open surgery is Industrial Age, with directly looking and feeling the organs and directly moving the tips of the instruments. Laparoscopic surgery is a transition: half in the Industrial Age—still directly moving instrument tips—and half in the Information Age—looking at the monitor with the electronic image (information) of the organs, not looking at the organs themselves. Robotics makes the transition to the Information Age complete by looking at information (the monitor) and manipulating information (hand motions send electronic signals that control the tip of the instruments). It is not longer blood and guts, it is bits and bytes.

This is a profound revolution, because it is now possible to integrate the entire surgical care of a patient with information science right at the surgical console of a robotic surgery system (Fig. 1). From the console, the surgeon can perform open surgery or laparoscopic surgery, can remotely operate with telesurgery, can rehearse a specific surgical procedure on a patient-specific three-dimensional image derived from the patient's computed tomography scan, can integrate the image during surgery with image-guided surgery to give the surgeon "X-ray vision," and can practice and train on the console using virtual reality surgical simulation. Thus from preoperative planning to specific surgical procedure rehearsal, to open or laparoscopic or interventional procedure, to training (for new procedures) all components become a single, seamless continuity for patient care. Although not yet implemented, the surgeon's hand motions can be recorded and archived as proof of proficiency on a continual basis (instead of periodic recertification).

Next generation robotic systems will also incorporate automatic tool changers (instead of scrub nurse to change the instruments) (Fig. 2) and automatic supply dispensers (instead of the circulating nurse) for suture, gauze, etc. Soon the surgeon will become a solo-surgeon in the truest sense of the word, controlling the entire operation from the console. Because there will be no people assisting the robot (the three systems together are called a "robotic cell"), the surgeon can sit at the console just outside of the operating room (looking through a glass window), and there will be no people in the operating room. Every time a tool is changed or a supply is dispensed, three actions immediately occur: The patient is billed, the tool or supply is restocked, and an order is

sent to inventory control to order a new tool or supply—all within 50 msec with 99.99% accuracy (which is the current industry standard). The result is clearly a dramatic improvement in performance and efficiency, as well as cost saving.

Another change in robotic systems is that they are incorporating new types of tools. By using micro-electro-mechanical system technology, tiny sensors can be inserted into the instruments to measure pressure, forces, etc. (Fig. 3) to provide for the surgeon the sense of touch (2), not only mimicking what the surgeon would actually feel, but also providing delicate touch beyond what is possible with the human fingertip.

There will also be an entire new tool-set for the surgeon of the future. Although the scalpel will still be required, many other modalities will be used. The trend is from mechanical instruments (of the Industrial Age) to energy-directed instruments (of the Information Age). Surgeons have begun using lasers, and next generation systems will employ high intensity focused ultrasound, thermal-directed systems (brachytherapy and cryotherapy), microwave instruments, and femtosecond lasers. These systems will require a complete rethinking of what it means to be a surgeon. The high intensity focussed ultrasound concentrates two beams of ultrasound at a distance, in this case inside the body. Early clinical trials are being conducted in breast, prostate, and liver tumors to completely coagulate or vaporize them from external high intensity focussed ultrasound system. In addition, animal trials have been successful in stopping bleeding from the liver and spleen transcutaneously (3). Thus surgeons will have to begin thinking about performing surgical procedures without entering the body or using a scalpel. There is also significant progress with femtosecond lasers. These new lasers are totally different from those used today—they release their energy in 10^{-15} seconds. The result is that it is possible to create a hole in the cell membrane without injury to the cell. This allows optical tweezers (another form of laser) to enter the cell and manipulate individual organelles, such as Golgi bodies or mitochondria. Additional progress is being made on entering the nucleus and directly manipulating the DNA. The significance is that the surgeon of the future may not be removing organs or tissues but rather using a microscope and laser rearrange the DNA inside the cell to change the fundamental biology—this is referred to as biosurgery (4).

EMERGING TECHNOLOGIES

The craft of surgery has revolved around correcting the structural and anatomic consequences of diseases. Malignant growths require the removal of entire organs or tissues and even radical resection of adjacent areas. However, there is always the conflict of goals, between removing enough tissue and conserving enough organ function. Transplantation has been a growing discipline because of the opportunity to remove entire organs and then replace their function with a donated organ. However, the supply is limited, and rejection is a constant problem. Tissue engineering artificial organs has progressed to a level where small amounts of organs are being synthetically grown. Vacanti and coworkers at Massachusetts General Hospital have been able to grow an artificial blood vessel system from endothelial stem cells, and are now using that vascular tree with

hepatic stem cells to grow artificial livers (5). These, and other approaches by different researchers, point to a time in the near future when it will be possible to grow a new organ from a patient's own stem cells. If this becomes the case, then it is theoretically possible that for nearly every disease, the surgeon will simply remove the patient's diseased organ and replace it with a new one (grown from the patient's own stem cells), without the fear of rejection. Therefore it may be that the future surgeon will perform only one operation for each organ system, no matter what the disease—remove the old one and replace it with a new one. This will dramatically impact the way the surgeon will practice, either by having a single operation for all patients in a practice (in the case of specialists) or a return of preeminence of general surgery, where every practice will consist a few operations to take care of all the major organ systems.

The replacement of human organs or functions has also been addressed by the use of prostheses; however, with the exception of the cardiac pacemaker, all prostheses have been inert and "dumb," that is, they do not respond the changing conditions in the body. Once implanted, artificial hips keep their position, and over time either wear out or cause problems such as loosening or damage to surrounding structures. Now prostheses are becoming "smart," with micro-electro-mechanical system sensors to detect changes and actuators to adjust the prostheses. This same feedback is being programmed into implantable devices, such as an insulin pump for diabetes (6). Ophthalmologists are implanting the first generation of artificial retinas into patients (7). This implies a future where surgeons will be asked to implant more and more artificial "parts," to either replace or enhance human function.

EDUCATION AND TRAINING

Until the beginning of the 20th century, nearly all training of surgeons was by passing down the conventional knowledge from previous surgeons—this was not based upon any scientific principles, but rather by ritual and tradition. In 1908, Senn was the first surgeon to criticize this practice (8), and bring forward the scientific principles of using observation and experience for education and training. Although this mentoring process continued, it was strict scientific principles, gained through experimentation and evidence, that formed the basis for surgical education and training. The Halstedian method of apprenticeship has become the model for surgical training, based upon rigorously applied scientific principles. However, this model is somewhat capricious, with the determination of competency of the resident being at the discretion of the supervising faculty and department chairman. With the exception of the written examination of the resident's knowledge, there are no objective measures of performance.

There is a new paradigm emerging in the field of surgical education. Objective measures are the new basis for training and assessing residents. Some of this change is being driven by new training methods, such as the Objective Structured Clinical Exam and the Objective Structured Assessment of Technical Skills (9). Other pressure is coming from the need for objective demonstration of competency. One technology that is fueling this change is the use of surgical simulators that can accurately measure hand motions and quantitatively report psychomotor skills. This ability to measure is driving the most fundamental change of all—that of training for a given period of time to the new paradigm of setting of criteria which the resident must achieve before progressing to the next level—so called criterion- or proficiency-based training. In 2002, Seymour et al. demonstrated unequivocally that residents that train on a simulator perform better in the operating room, taking less time and making less errors (10). Thus, the time is near when every resident will have to train on a simulator to reach a certain level; those who have better skills will achieve it faster, those who are slower will take longer. However no resident will operate on a patient until they have passed the simulator by achieving a high level of technical proficiency. No longer will residents be permitted to "practice" on patients. This will eventually spread to all surgeons, especially in learning new procedures such as laparoscopy. A week-end course may or may not be long enough—for the gifted surgeon may be able to demonstrate proficiency in that short period of time, while others may need further training. For the long-term maintenance of surgical privileges, it will be required to be recertified, including technical skills on a simulator. Eventually, each surgical procedure will be objectively assessed, as a method to continuously assure maintenance of surgical skills. This is not unlike the requirement for airline pilots today. Thus, surgical simulation and continuous assessment of performance to an objective level of proficiency will become the new standard for training, assessment, credentialing, and practice.

RESEARCH FOR CLINICAL TRIALS

Many practicing clinical surgeons engage in clinical research, either for a new medication, a new surgical procedure, or other innovation. The simple reporting of a series of cases to the literature has yielded to the randomized, double-blind clinical trial, adding a new level of scientific rigor to the research and reporting of new therapies. This requirement for "evidence-based medicine" is significantly increasing the quality of research and improving overall patient care; however, the time and cost involved in conducting such rigorous trials are enormous and have delayed many new therapeutic options. In addition, it is not possible to know the final outcomes in many instances, such as cancer, where it takes 20 years or longer until the long-term results (including possible complications) are known. However, other industries have been using modeling and simulation to predict outcomes into the future. Theoretically, the day will come when a virtual clinical trial will use predictive simulation of a therapy on a million patients over 50 years—on one week of supercomputer time. The accuracy of such predictions will be determined by how accurate the models of humans can become, from the genetic and cellular all the way to the organ and whole body level. Today drug companies are using "rational drug design" by computer programs and then doing virtual testing and evaluation of the products based upon the pharmacologic properties. This is the first step toward doing "predictive simulation" for clinical trials. The advantage for surgeons is that it will be possible to provide much more accurate information on the efficacy of drugs or surgical procedures that is available today as well as to customize the therapy for each patient.

MORAL AND ETHICAL CHALLENGES

A number of these new technologies will be raising moral and ethical questions that have never been considered before. Success with nanotechnology will be forthcoming rather soon, with a significant amount of speculation on the role of "nanomachines"—tiny systems that are injected into the blood stream or other areas of the body, for diagnostic or therapeutic purposes. The long-term effect of such systems will not be known for decades to come, however, there will be pressure to begin inserting them. Should surgeons comply with their patients' requests, even in the fact of unconvincing evidence of efficacy, or if efficacy is shown but long-term results are not known? Robotics is moving forward deliberately, but a new dimension will likely be soon available—femtosecond lasers to operate within the cell and even upon the nucleus and DNA. Although, it seems reasonable to remove a gene that leads to a congenital defect, should surgeons be tinkering with genes directly, and leading to the purposeful genetic design of children for characteristics such as eye or hair color? Or perhaps provide genetic material, such as the sequence that allows the pit viper snake to use infrared vision to see in the dark, to have characteristics that humans do not naturally have? With smart prostheses and artificial organs, it may be possible to extend life beyond the average life span for humans—to 150 or 200 years. What would the consequences to society be of such a prolonged lifespan, and will a person retire at age 65 with 90 to 100 years of "retirement?" The results of the research in today's laboratories are providing potential not only to change an individual or even society, but also to define what it means to be human. If 90% of our body parts are replaced with artificial organs or prostheses, will we still be human—is it the flesh and blood that we were born with determine whether we are "human?" While these have previously been mere speculations of fantasy, the scientific underpinnings are being created in the laboratory today, and the students we are training today will have to answer the above questions, and more. How can we prepare for such a future challenge?

CONCLUSION

This is a time in the history of medicine when truly revolutionary change is occurring, and at a rate that has never been seen before. While it is a historic fact that each generation of surgeons greatly surpasses the accomplishments of the preceding generation, the order of magnitude of change that is occurring now is unprecedented. The surgeon of the future will need to adapt, to be able to learn a wider range of the new technologies, and quicker than ever before. And the amount of information that needs to be learned will increase. The paradigm of training is changing from simple mentor ship to proficiency-based, quantifiable assessment, and the surgeon will be held to even higher

standards than today. Yet, the extra amount of work required to achieve these new standards is essential to be worthy of the enormous responsibilities that the changes of the coming generation will bring—the surgeons of the future will not only hold the lives of their individual patients in their hands, but may be responsible for the future of what it means to be human.

INDEX

Textbook of
LAPAROSCOPIC
UROLOGY

about the book ...

Divided into eleven detailed sections, this reference displays the expertise and research of specialists from leading urology centers around the world and offers authoritative chapters on the entire spectrum of urologic laparoscopy. The chapters cover methods in patient selection, peri-operative management, and complication avoidance; step-by-step descriptions of specific techniques; and the pros and cons of each procedure for a clear grasp of the many principles and practices currently utilized in the field.

Placed alongside the *Atlas of Laparoscopic Urology with DVDs*, this set will likely become the standard reference text in the field of urologic laparoscopic surgery.

This wide-ranging and reader-friendly guide covers all the essential strategies, techniques, and equipment required for successful laparoscopic surgeries...every laparoscopic procedure for benign and malignant disease...specific issues related to pediatric procedures...and developing issues in laparoscopy, as well as future advances that may impact the field in forthcoming years.

about the editor ....

INDERBIR S. GILL is Professor of Surgery, and Head, Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio. He has authored or coauthored more than 280 peer-reviewed scientific publications, 50 book chapters, and 4 books. Dr. Gill has been a visiting professor and invited speaker at more than 200 academic institutions and scientific meetings worldwide, and has mentored more than 50 post-graduate clinical and research fellows. He is President, 24th World Congress of Endourology, 2006. Widely recognized as a leader at the forefront of minimally invasive urology, he specializes in laparoscopic surgery of the adrenal gland, kidney, prostate, and bladder.
