To the loving memories of my father, my mother, and my younger brother
and
to my family (Tania, Karan, and Neeti) and my "team" at work
for the love, inspiration, and strength.

PREFACE

Laparoscopy is now a major domain in urologic surgery. The past decade has witnessed a literally logarithmic increase in the application and appropriateness of minimally invasive techniques for an entire spectrum of urologic surgical conditions. These advances have been fueled by many factors. Foremost is the natural order of change and progress. Change must not be adopted just because it is new or different. The reference standard, the tried and trusted open surgery, must not be cast aside until its novel, minimally invasive alternative has undergone a thorough, due-diligence evaluation. As such, laparoscopy is being incorporated into main-stream urology with appropriate caution and constructive critique. Second, the explosion of technological advances and novel imaging modalities have made possible minimally invasive techniques hitherto considered in the realm of science fiction. Finally, the surgical patient at the dawn of the 21st century, awash with information gleaned from the cyber-media, now has a better understanding of the available therapeutic options, rightfully leading to heightened expectations. This is only as it should be. The result is the emergence of a new surgical mentality, wherein the "big surgeons make big incisions" mindset is now aptly giving way to "the minimally invasive, maximally effective" mindset.

For minimally invasive oncologic surgeons, our work has only just begun. For laparoscopy to conclusively supplant open surgery where appropriate, stringent comparative analyses and joint research efforts need to occur in a spirit of healthy cooperation. These are ongoing. In this regard, combining the strengths of the two respected societies, the Society of Urologic Oncology and the Endourology Society, will go a long way towards advancing both fields. Our future is together.

This textbook aims to provide comprehensive, state-of-the-art information about the field of urologic laparoscopic surgery. Encyclopedic in scope, its 101 chapters have been organized into eleven distinct sections: Basic Considerations; Equipment; Laparoscopy: General Techniques; Adult Laparoscopy: Benign Disease; Laparoscopic Urologic Oncology; Pediatric Laparoscopy; Hand-Assisted Laparoscopy; Laparoscopy: Developing Techniques; Laparoscopic Complications: Etiology, Prevention, Management; Laparoscopy: Select Aspects; and The Future. Depending on the individual topic, emphasis has been placed on basic concepts, patient selection, laparoscopic technique and caveats, published outcomes, controversies, and future horizons. To enhance readability, important information has been graphically represented in a stand-alone manner in the left-hand column of the page. For certain chapters, invited commentaries have been solicited to stimulate debate, providing a broader perspective. Schematic figures, multiple tables, and thorough bibliographies combine to provide the reader a complete picture within one cover. This will benefit the novice as well as the experienced urologist.

Leading authorities have provided their opinions and thoughts herein. Collectively, these distinguished authors, each selected for recognized expertise and pre-eminence, comprise the *Who's Who* in the discipline.

It is our hope that the *Textbook of Laparoscopic Urology* will mature into the standard reference text in the field. Future editions will keep pace with the rapidly changing landscape of minimally invasive urology. Personally, it has been a true privilege to be able to edit the textbook. I am deeply grateful.

Inderbir S. Gill

ACKNOWLEDGMENTS

CONTENTS

CHAPTER 23: LAPAROSCOPIC PYELOPLASTY: TECHNIQUE ■ 295
George K. Chow

CHAPTER 24: ROBOTIC-ASSISTED ADULT AND PEDIATRIC PYELOPLASTY ■ 303
Joseph J. Del Pizzo, Michael A. Palese, Ravi Munver, and Dix P. Poppas

CHAPTER 25: LAPAROSCOPIC PYELOPLASTY: CURRENT STATUS ■ 313
Ioannis M. Varkarakis and Thomas W. Jarrett

CHAPTER 26: LAPAROSCOPY FOR THE CALYCEAL DIVERTICULUM: TECHNIQUE AND RESULTS ■ 325
Christopher S. Ng

SECTION X: LAPAROSCOPY: SELECT ASPECTS

CHAPTER 85: IMMUNOLOGIC ASPECTS OF LAPAROSCOPY ■ 953
Prokar Dasgupta and Ben Challacombe

CHAPTER 86: LAPAROSCOPIC SURGERY IN THE HIGH RISK PATIENT ■ 971
Assaad El-Hakim and Benjamin R. Lee

CHAPTER 87: LAPAROSCOPIC SURGERY DURING PREGNANCY ■ 983
Michael D. Rollins and Raymond R. Price

CHAPTER 88: LAPAROSCOPY AND TRAUMA ■ 997
Abraham A. Nisim and Daniel R. Margulies

CHAPTER 89: LAPAROSCOPIC ULTRASONOGRAPHY ■ 1001
Osamu Ukimura

BASIC CONSIDERATIONS

HISTORY OF LAPAROSCOPY: AN ODYSSEY OF INNOVATIONS

Sergio G. Moreira, Jr. and Raul C. Ordorica

"The principal mark of genius is not perfection but originality, the opening of new frontiers."
—*Arthur Koestler*

At the time of this writing, interest in laparoscopic urology continues to rise at an unprecedented rate. This interest is currently evident in both urologic practice and training. The wide range and availability of information has led the patient population to demand laparoscopic knowledge and skills from the urologic community. Thus, residency programs are increasingly emphasizing laparoscopic training, and graduates should have enhanced familiarity with laparoscopic technique once delegated to specialty training. Laparoscopic fellowship programs continue to thrive, producing tomorrow's academic leaders. Courses in advanced laparoscopic urology are available both nationally and internationally for established urologists.

Urologists once only peered into the "new frontier" of laparoscopy. Today we are now embracing it and thriving within it, bringing its benefits to our patients. Even as we witness its growth and realize its potential, it is instructive to peer into the past.

Laparoscopic surgery owes much of its history to the development of endoscopic technique in the beginning of the 19th century. Initial methods to examine body orifices were developed in 1805 by the German physician Phillip Bozzini (Fig. 1) (1), who constructed a thin silver funnel illuminated by reflected candlelight held within its stand (Fig. 2). After several modifications, the instrument was demonstrated at a scientific gathering in Frankfurt in July of 1806 and was indeed considered remarkable for the examination of the pharynx and nasal cavities. The "Lichtleiter" was purchased by order of the Emperor, and given to the Josephinum for testing its utility with unbiased studies. A set of tests on actual patients conducted by the faculties at the University of Vienna showed unfavorable results. The use of the instrument was considered an

unnatural act and there is no evidence that Bozzini had used the instrument again. Although the instrument would have proven cumbersome, inefficient, and painful for both the operator and the patient, it is considered the first major foray into endoscopy. The original Lichtleiter of Bozzini is now enshrined in the Josephinum in Vienna (2).

Throughout the mid 1800s, several scientists attempted to construct endoscope-like instruments. Pierre Segalas from France refined the urethroscope in 1826 adding an introduction cannula and mirrors for light reflection. Antonin Desormeaux, Segalas' fellow countryman, presented the first serviceable endoscope to the Academy of Paris in 1853 (Fig. 3) (1,3). He performed and reported several investigations of the urethra and bladder using such instrument, of which major development consisted of an illumination source of increased intensity obtained utilizing the reflected light from an alcohol lamp. A clear intellectual milestone had been reached, and Desormeaux was awarded a portion of the Argenteuil Prize for such an achievement (4).

The development of a light source that could be transported into the body cavity was the next, awaited major innovation. Using a platinum wire loop heated by an electric current, Julius Bruck, a dentist of Breslau, heralded the development of internal illumination in 1867 (5). Despite great success in the exploration of the oral cavity, Bruck's technique of water-cooled, diaphanoscopic bladder transillumination by a rectally placed coil was still dangerous, and rather ineffective. Apparently unaware of Bruck's earlier attempts, Max Nitze from Germany successfully applied this kind of illumination source to his cystoscope in the late 1800s (Fig. 4).

Compelled by the concept of an internal light source, Nitze succinctly stated: "in order to light up a room, one must carry a lamp into it" (5). Applying these concepts, Nitze and Diecke, an instrument maker in Dresden, were able to manufacture their first cystoscope in 1877 (6). This instrument was still rather bulky and unreliable. Teaming up with Joseph Leiter, a renowned instrument maker in Vienna, Nitze developed the necessary further improvements consisting of an electrically-heated platinum wire light source placed behind a quartz shield. The Nitze–Leiter cystoscope was presented in 1879 (Fig. 5).

Despite these advances, the heat generated within the bladder required a bulky water-cooling device, and the electrical apparatus that created the necessary current for the platinum wire was difficult to maintain (Fig. 6). Further progress awaited Thomas Edison's invention of the incandescent lamp in 1880. This landmark development provided increased illumination and alleviated the need for the water-cooling system. A larger part of the scope could be dedicated to the optical lens system, resulting in better visualization with improved light delivery (1). Multiple endoscopists, including David Newman (1883), Nitze (1887), Leiter (1887), and Dittel (1887) employed the incandescent bulb (6).

Refining the mignon lamp in 1898, Charles Preston provided a more dependable illumination source consisting of a bright light produced with low-amperage current (Fig. 7) (7). This became the standard light source for endoscopy until an adequate external systems of light delivery was developed 50 years later when Dimitri O. Ott, a famous Petrograd gynecologist, introduced "ventroscopy" for the inspection of the

abdominal cavity (8). He employed a head mirror to reflect light into a speculum introduced through a small anterior abdominal wall incision (9,10). Although technically primitive, the idea of closed diagnostic inspection of intraperitoneal contents was conceived. However, the concept of distending the peritoneal cavity with air to aid in visual inspection was not realized even though in 1870 Simons from Bonn had already reported safe air pumping into animal abdomen. Wegner from Berlin corroborated Simon's studies in 1877, and in 1882, Mosetit-Moorhof from Vienna successfully created pneumoperitoneum to treat tubercular peritonitis in a child (11). George Kelling from Germany (Fig. 8) had the pioneering idea of employing the Nitze cystoscope for the inspection of abdominal viscera. During the 73rd Congress of German Naturalists in 1901, he performed a so-called "celioscopy" on a dog. After insufflating the peritoneal cavity with air flowing through a needle, Kelling observed changes to the intra-abdominal organs at pneumoperitoneum pressures sufficient to stop intra-abdominal hemorrhage (i.e., up to 50–60 mmHg) (12). Kelling's advanced work was particularly notable for the use of a separate needle to produce the pneumoperitoneum. However, he failed to publish in a timely fashion his work on humans, and the

FIGURE 7 ■ Light source developed by preston in 1898 for the mignon lamp.

FIGURE 8 ■ George Kelling.

FIGURE 9 ■ Hans Christian Jacobaeus.

FIGURE 10 ■ B. M. Bernheim.

technical refinements he developed. Hans Christian Jacobaeus of Sweden (an internist in Stockholm) published on both human laparoscopy and thoracoscopy in 1910, high-lighting the low morbidity of such procedure despite the use of a single trocar to both produce the pneumoperitoneum and provide endoscopic access (Fig. 9) (13). By 1912, his reported series included a total of 115 patients (13–16). At Johns Hopkins University in 1911, Bernheim performed an *organoscopy* using a proctoscope to visually inspect the peritoneal cavity (Fig. 10) (17).

Minor variations in equipment and technique were described in subsequent reports from both Europe and the United States (18). In 1920, Orndoff devised a trocar with a pyramidal point and an automatic cannula valve to prevent the escape of gas from the pneumoperitoneum (19). He published his experience with laparoscopy per-formed using such devices and a roentgen screen. To prevent the leakage of gas, Stone from the United States described the fitting of the outer portion of the trocar with a rub-ber gasket in 1924 (20). At the same time, Zollikofer from Switzerland introduced the use of CO_2 for insufflation and observed its ease of absorption (21). The primary medium was previously filtered air, with its intrinsic risk of air embolism. To minimize the risks related to initial abdominal puncture, Goetze from Germany developed an automatic insufflation needle in 1918 (22). Initially, the insufflating medium for this instrument was oxygen, a gas with lower incidence emboli formation when compared to air. However, it soon became obsolete with the advent of electrocautery. In 1938, Veress from Hungary further refined the automatic needle initially used for the creation of pneumothorax in the treatment of tuberculosis (Fig. 11) (23). The Veress needle is now routinely used to create pneumoperitoneum.

Besides for developing technical advances, many physicians are renowned and responsible for the instruction of laparoscopy as an accepted method. H. Kalk from Germany exemplified this as an outstanding proponent of "peritoneoscopy" throughout Europe (Fig. 12) (24–26). In fact, in addition to devising a 135°, fore oblique viewing system, his teachings led to the widespread adoption of his methods. With some 21 papers on the management of liver and gallbladder disease published between 1929 and 1959, he is referred to as the "Father of Modern Laparoscopy" (10), a title oftentimes shared with Kurt Semm (Fig. 13), a German gynecologist who developed many laparoscopic operative techniques and instruments including intracorporeal suturing techniques, a controlled insufflation apparatus, and safe endocautery devices. Semm first performed a laparoscopic appendectomy, which

FIGURE 11 ■ Vepress's automatic needle (ca. 1938).

FIGURE 12 ■ H. Kalk.

FIGURE 13 ■ Kurt Semm.

was a considerable task, given the limited ability to convey the otherwise "closed" world of laparoscopy.

Although multiple devices had been designed for photographing laparoscopic detail, the majority of description was by illustration alone. These limitations continued until a single lens reflex camera for endophotography was introduced by Henning in 1931 (27). The first black and white and color photographic atlas was published by Kalk in 1935 (27). Later on Caroli, Ricordeau, and Foures from France first used an electronic flash intra-abdominally (28). Further major advances in visual reproduction awaited the development of improved light transmission, lens systems, cinephotography, and eventual video technology.

Meanwhile, laparoscopy made its initial forays into the interventional realm. Due to advances and modifications in high frequency unipolar electrocautery, in 1933, Fervers from Germany burned abdominal adhesions and performed excisional biopsy (29). In the United States, Ruddock further perfected his own peritoneoscope, pneumoperitoneum needle, trocar, and ancillary instruments for biopsy (30–34). He published his initial series of 200 cases in 1934, followed by his entire experience with more than 2500 cases. Laparoscopic tubal sterilization using electrocautery was first described in the porcine model by the Swiss Boesch in 1935 (35). Power and Barnes from the United States performed this on a patient in 1941; their report included an interim published discussion of the technique by Anderson (36,37). The American Donaldson used the Ruddock peritoneoscope to perform a uterine suspension in 1942 (38). Further progress in laparoscopic abdominal surgery had to await the better provisions for safe hemostasis achieved by improved electrocautery.

During World War II, culdoscopy, as described by Albert Decker in 1944, gained the attention of the American surgical community and became a standard gynecologic procedure in the United States for many years (39–41). Contemporarily, the French Raoul Palmer greatly furthered gynecologic laparoscopy throughout Europe (9,42). Interest was not rekindled in the United States until the publication, in 1967, of the first English laparoscopic textbook by the British gynecologist Steptoe, who was influenced by his European colleagues (43). The resurrection of American laparoscopy occurred through the dissemination of contemporary experience and by the accompanying advances in optics, light transmission, insufflators, and ancillary materials. These largely European developments broadened the field's utility and better ensured patient safety.

In 1952, the French Fourestier, Gladu, and Valmiere developed a method for light transmission along a quartz rod that greatly improved the quality of light produced, and removed the risk of electrical and heat injury plaguing previous systems (44). The same year Hopkins and Kapany from England first employed fiber optics similar to those used into the fiber optic gastroscope (45). Hopkins was also developed a quartz rod lens, which replaced prior lens systems of rigid endoscopes (46). Frangenheim

incorporated many of these advances in laparoscopy, using diathermy for tubal sterilization in 1963, and fiber optics in 1965 (46). His extensive publications regarding anesthetic methods, pneumoperitoneum, tissue emphysema, air embolism, intestinal perforation, hemorrhage, burns, and cardiopulmonary problems furthered the course of safe laparoscopic procedure (47).

In the United States, Cohen, followed by Hulka, were at the forefront of laparoscopy through the late 1960s and early 1970s, disseminating and popularizing laparoscopy within the gynecologic community (47,48). After initially diagnostic application, the major indication was voluntary sterilization. These methods were so widespread, that Jordan M. Phillips founded the American Association of Gynecologic Laparoscopists in 1972 (48). Its second annual meeting was held in 1973 in conjunction with the First International Congress of Gynecologic Laparoscopy, and counted 600 attendees. At that time, approximately 500,000 laparoscopic procedures were performed annually in the United States, and laparoscopy became a requirement of residency training in obstetrics–gynecology programs by 1981 (48).

Meanwhile, substantial pioneering work by Kurt Semm advanced the safety and scope of laparoscopy (4,35,49–53). Automatic control systems were developed for induction and maintenance of the pneumoperitoneum using CO_2. Through the 1970s, further Semm's work in conjunction with WISAP (Sauerlach, West Germany) led to the development of electronically controlled units. The development of the open trocar technique of Hasson expanded the indications for laparoscopy including patients with a history of prior laparotomy and adhesions, considered a contraindication to laparoscopy so far (46,54).

Semm takes great note regarding the lack of safe hemostasis as additional impediment in the advancement of laparoscopic surgery (35). The use of high frequency monopolar cautery within the abdominal cavity had been historically fraught with the serious sequelae of bowel injury. Indeed, the second most frequent cause for lawsuits against obstetrician–gynecologists in the early 1970s was for laparoscopic bowel burns (7). Therefore, a great deal of investigation was devoted to eliminate these dangers, particularly, with the growing popularity of laparoscopic tubal disruption. The electrical shielding of instruments and current reduction were introduced to obviate these problems, along with the subsequent development of the 100°C endocoagulator. Hemostatic methods also included the use of "endoloop" and suturing devices for large blood vessel control (4,50,53).

Laparoscopy, initially performed to diagnose liver and gallbladder diseases, was employed progressively less frequently as radiographic imaging developed and moved to the forefront. After performing the first laparoscopic cholecystectomy in Germany in 1985, Muhe suffered the indignities of collegial criticism and ostracism like Semm did before after performing the first laparoscopic appendicectomy. In 1987, Philippe Mouret, a French gynecologist, performed laparoscopic cholecystectomy during a routine pelvic procedure (45), and presented his experience during a meeting. The first clinical series of laparoscopic cholecystectomy were performed by Francois Dubois in France in 1988, and McKernan and Saye (1988) and Reddick (1989) in the United States (45,55). Reddick's and Dubois' documented the capability of laparoscopic cholecystectomy to duplicate open surgical principles (56). Based on these pioneering experiences, interest on laparoscopic cholecystectomy raised tremendously resulting in rapid widespread of the procedure to the point of almost replacing elective open cholecystectomy in many centers over a three-year period (45). While this may be startling when viewed as an isolated event, it is predictable when perceived within a broader framework.

The performance of complex intra-corporeal procedures in a safe and reliable manner required more than the simple development of advanced mechanical instrumentation. It was also the result of the coordinate efforts of many operators. During standard laparoscopic practice, only the primary could actually see the operative field, while the ability of the assistant to substantially participate was limited blind involvement. Additional eyepiece attachments were incorporated for learning purposes to allow the novice to gain the necessary skills to subsequently operate alone. Although closed circuit television was manufactured since 1959, portable systems were not available until 1970 (48). The term "portable" should be applied sparingly, because the initial cameras weighed some 10 pounds and were equipped with an attachable ceiling harness. Their size, image quality, and cost relegated them to the rare and cumbersome teaching aid. Only the advent of microchip technology allowed practical real-time video monitoring of the operative field. Widespread and extensive use of such technology throughout all areas of endoscopy marked the groundwork for major laparoscopic intervention. With the entire surgical team watching at the surgical field, more complex procedures could be undertaken.

Laparoscopy in urology paralleled, to a large extent, the changes in general surgery. Up to the late 1980s, urologic laparoscopy had limited applications. In 1976, Cortesi reported laparoscopic abdominal exploration in an 18-year old patient with bilateral abdominal testes (57). Since then, cumulative experience by multiple authors has substantiated laparoscopic management of cryptorchidism (58–61). Another anecdotal application was reported by Wickham, who, in 1979, performed laparoscopic ureterolithotomy by a retroperitoneal approach (62). Additional stone manipulation was performed by Eshghi, who, in 1985, laparoscopically monitored the percutaneous transperitoneal removal of staghorn calculi from a pelvic kidney (63).

However, apart from its use in the pediatric population for cryptorchidism, urologic laparoscopy lacked a broad application when compared to the large population of patients with cholelithiasis treated laparoscopically by general surgeons. In fact, in many urologic procedures the benefits of laparoscopy were initially outweighed by the technically challenging anatomy that greatly limited access and compromised control. Varicocelectomy and bladder neck suspension were deemed feasible but showed little benefit over open surgery. Laparoscopic pelvic lymphadenectomy performed to overtake inaccuracy of imaging techniques for staging of patients with prostate carcinoma was deemed both feasible and effective (64). Laparoscopic pelvic lymphadenectomy in a porcine model was described by Howard Winfield in 1989 (65). Schuessler and associates first performed this procedure in a series of patients with prostate cancer. Nevertheless, interest in laparoscopic pelvic lymph node dissection dropped precipitously in mid 1990s due to advances in nonoperative staging of prostate cancer. After initial, isolated but encouraging reports, Janetschek et al. performed laparoscopic retroperitoneal lymph node dissection in an attempt to reduce the morbidity of open retroperitoneal lymph node dissection (66). Kavoussi and coworkers reported the feasibility of laparoscopic retroperitoneal lymph node dissection for patients with stage I non-seminomatous germ cell tumors. Efficacy was similar to traditional retroperitoneal lymph node dissection (67).

Renal procedures are the main target for urologic laparoscopic organ resection. Laparoscopic nephrectomy in a porcine model was first attempted via a retroperitoneal approach by Weinberg and Smith in 1988 (68). In 1991, after extensive laboratory trials including the development of the basic concepts of organ entrapment and tissue morcellation, Clayman and coworkers performed the first clinical laparoscopic nephrectomy. Subsequent continued results of transperitoneal laparoscopic nephrectomy have been reported by the same group (69–71). With increasing skills and experience, the total operative time of almost eight hours required to complete the initial case was reduced to four hours. Such procedures heralded a new era in laparoscopic urology that began to challenge and compete with conventional open surgery. However, many technical refinements were necessary to make laparoscopy an appealing alternative to open surgery. Using retroperitoneal balloon dissection to create an adequate retroperitoneal space, Gaur obviated the initial difficulties with closed insufflation of the retroperitoneum (72). In addition to these advances, significant improvements in vascular control and soft tissue hemostasis are constantly evolving. As a result, more challenging laparoscopic renal procedures were progressively attempted and executed. Winfield and colleagues performed the first laparoscopic partial nephrectomy in 1993. Subsequent series of laparoscopic partial nephrectomy reported by many authors showed cancer control similar to open nephron-sparing procedures. Capitalizing on the relatively benign recovery from laparoscopic surgery, in 1994, Gill et al. demonstrated the feasibility of laparoscopic donor nephrectomy in the porcine model (73). The first clinical donor nephrectomy performed by Kavoussi and coworkers in 1995 (74). Over the next five years, the technique became more refined, and it has since spread

worldwide. At many centers, laparoscopic donor nephrectomy is the now standard of care. The development of a handport providing direct hand assistance has increased accessibility to renal surgery. The ability to manipulate tissue has greatly increased the comfort zone for many urologists, broadening the indications for minimally invasive procedures. One of the critiques raised by laparoscopic purists regards the size of the incision required to place the handport. Undoubtedly, hand-assisted laparoscopy provides greater control and easier organ retrieval for the naïve laparoscopic surgeon.

The next urologic milestone in laparoscopic organ resection was the management of prostate and bladder diseases. Laparoscopic radical prostatectomy was innovated and perfected in Paris by Guillonneau and Vallancien (2000) (75) as well as by Abbou et al.

(2000) (76). Although a steep learning curve was necessary to perform Laparoscopic radical prostatectomy in a time-sensitive manner, today several centers worldwide perform laparoscopic radical prostatectomies routinely with results similar to those of the open counterpart. Improved magnification and better identification of the anatomical structures are potential benefits, and decreased morbidity is anticipated. However, at the time of this writing, open prostatectomy remains the standard of care. Nevertheless, laparoscopic technology and experience on Laparoscopic radical prostatectomy, and their acceptance, continue to evolve.

Laparoscopy has been applied also to the technically demanding area of cystectomy. In 2000, Gill et al. reported their initial experience with bilateral pelvic lymphadenectomy, cystectomy, and ileal conduit urinary diversion in patients with muscle-invasive bladder cancer (77). The ability to complete this procedure intracorporeally required a high level of reconstruction that has also been applied to other areas in urology. The same laparoscopic techniques for suturing and knot tying were efficaciously employed to perform, ureteral reimplantation, ureteroureterostomy, and pyeloplasty. In fact, in select centers laparoscopic pyeloplasty is becoming the standard of care for ureteropelvic junction obstruction.

The development of robot technology (*da Vinci*® Surgical System[a]) is the epitome of surgical magnification and technical refinement (Fig. 14). Such expensive sophistication allows for intricate manipulation within a limited operative space.

It is becoming increasingly evident that laparoscopy has the potential to duplicate the principles of open urologic surgery for the management of several medical conditions involving the lymph nodes, kidney, adrenal gland, bladder, or ureter. However, although technical pioneers have demonstrated the feasibility of many demanding laparoscopic procedures, long-term results are awaited before these procedures would become routinely part of the urologic armamentarium. In order for evolution to occur and to continue, nuances must prove to be superior to the status quo. The hallmark of this current period of urologic laparoscopic history is the combination of technical achievement demonstrating what can be done, with the application of academic rigor to determine what should be done. In an increasing number of multi-institutional studies, laparoscopic procedures are compared with their open surgical counterparts. The evidence of comparable efficacy combined with improvements in postoperative pain, cosmesis, recovery, and length of hospital stay shows that laparoscopy belongs in the mainstream of urologic surgery.

FIGURE 14 ■ The *da Vinci*® Surgical System. *Source*: Courtesy of Intuitive Surgical, Inc.

In this current era, feasibility and benefit of many urologic laparoscopic procedures have been proven on a large scale. As we enter the new millennium, the craft of open surgery may have an ever-decreasing role in the treatment of urologic diseases. This evolution will require the demonstration of benefit over existing standard practice, which then must be embraced by urology in order to be implemented. This evolution, initially charted by the relentless pioneers mentioned in this chapter along with countless others, will continue to be written as an odyssey of innovations in the hands of modern stalwarts.

INTRODUCTION

Because every urologist has studied gross anatomy and basic surgical abdominal anatomy during general surgery and urology training, this chapter details urologic laparoscopic abdominal anatomy.

A clear and confident understanding of surgical anatomy and anatomic interrelationships is a prerequisite for performing laparoscopic surgery. The surgeon must understand the anatomy of the operated organ and its relationships with surrounding structures and what potential pitfalls exist.

Because every urologist has studied gross anatomy and basic surgical abdominal anatomy during general surgery and urology training, this chapter details urologic laparoscopic abdominal anatomy.

These topics will be reviewed in the following order: organ (kidney, adrenal), type of approach (transperitoneal vs. retroperitoneal), and anatomical caveats.

RIGHT KIDNEY

Transperitoneal

The first step in any approach to the right kidney is mobilizing the ascending colon off Gerota's fascia.

The right kidney, when viewed in the transperitoneal approach, lies posterior to the ascending colon, inferior to the liver, and anterior to the psoas muscle.

The first step in any approach to the right kidney is mobilizing the ascending colon off Gerota's fascia.

Laparoscopically, the defined layer of Gerota's fascia is clearly separate and evident from the mesenteric fat of the left mesocolon. The lateral border of the second portion of the duodenum may be attached to Gerota's fascia. When the duodenum is released from Gerota's fascia sharply (avoiding cautery so as to avoid thermal injury to the duodenum), the inferior vena cava comes into view. The gonadal vein and ureter lie directly on the psoas muscle. The gonadal vein is encountered more medially and posteriorly than the ureter in most cases. One must also beware that a relatively common venous abnormality is for the right gonadal vein to drain into the right renal vein, rather than the more usual inferior vena cava.

The renal vein is seen anterior to the pulsations of the renal artery.

One must remember that the gonadal vein can insert into the right renal vein, though its typical insertion is to the inferior vena cava. This is important as one may confuse the renal vein for the inferior vena cava.

With the 30 degree laparoscope rotated to the 9 o'clock position, the posterior relationship of the renal artery to the renal vein is well appreciated.

One must remember that the gonadal vein can insert into the right renal vein, though its typical insertion is to the inferior vena cava. This is important as one may confuse the renal vein for the inferior vena cava.

CAVEAT

When dealing with a large, hydronephrotic pelvis, it is may be best to dissect the colon and duodenum away from the pelvis prior to draining the pelvis, because the hydronephrosis serves as a good backboard to complete the dissection. It is advisable to have a preoperative three-dimensional computed tomography scan in order to appreciate, among other things, anomalous vasculature. This recognition will help avoid iatrogenic injury. Accessory renal blood vessels may or may not lie in a slightly more anterior plane than the main renal vessels and are end arteries without collateral supply. Anomalous accessory renal arteries and the often accompanying accessory renal vein are present in approximately 20% of patients.

Retroperitoneal

After the surgeon obtains proper retroperitoneal access, the psoas muscle becomes the horizontal floor of the surgeon's view. This horizontal orientation must be maintained at all times.

In order to see the bulk of the kidney and to get adequate anterior traction on the kidney, one must recognize the bands that attach Gerota's fascia to the psoas fascia. These bands must initially be incised sharply, followed by blunt dissection in order to get separation of the kidney and its investing Gerota's fascia from the fascia of the psoas muscle. The main renal blood vessels are encountered at a view such that the laparoscope is at a 45 degree angle with the body's horizon. Here the pulsations of the renal artery can be detected. Because this is the retroperitoneal approach, the renal artery is seen prior to the renal vein. The renal vein cannot be fully visualized until the renal artery is completely dissected.

After the renal artery is clipped and divided, the renal vein is seen more medially and superiorly. In this perspective, the ureter is seen just anterior to (above) the inferior vena cava. The gonadal vein is seen further anterior to the ureter. The kidney and investing Gerota's fascia can be dissected sharply from the peritoneum by incising the thin, bloodless areolar tissue between the two.

CAVEAT

One must identify the gently undulating venous pulsations of the inferior vena cava early in the operation. If this is not appreciated, one can inadvertently dissect posterior to the inferior vena cava in a retrocaval fashion. Additionally, there have been reports of inadvertent transection of the inferior vena cava via the retroperitoneal approach (inferior vena cava transection in the transperitoneal approach has also occurred). The sentinel points for avoiding this complication are three-fold: (i) identify the cranial and caudal right angle junction of the right renal vein to the inferior vena cava; (ii) ensure the horizon of the camera is properly oriented by seeing the psoas running horizontally; (iii) visualize the renal vein coursing toward the kidney (toward the top of the television monitor).

LEFT KIDNEY

Transperitoneal

The left kidney lies behind the descending colon, anterior to the psoas and caudal to the spleen.

The spleen lies directly adjacent to the superior pole of the kidney and should be mobilized away from the kidney early on in the dissection to avoid splenic injury. The renal vein is seen lying anterior to the renal artery. Although not commonly seen in most laparoscopic cases, the superior mesenteric artery, which courses directly anterior of the medial-most portion of the left renal vein, must always be kept in mind. The anatomic relationship of the superior mesenteric artery and the left renal vein is occasionally appreciated during left-sided transperitoneal laparoscopic donor nephrectomy in which left renal vein length is maximized by ligation at the interaortocaval region.

The left gonadal vein drains into the left renal vein. The adrenal vein junction with the left renal vein is almost always medial to the gonadal vein insertion. A lumbar vein is frequently encountered on the posterior aspect of the left renal vein, which is far less

The lumbar vein is best seen with gentle anterior traction on a clipped and ligated left gonadal vein.

common on the right renal vein. The lumbar vein location relative to the gonadal vein is more variable.

The lumbar vein is best seen with gentle anterior traction on a clipped and ligated left gonadal vein.

> **CAVEAT**
>
> It is a good idea to have a nasogastric tube placed to keep the stomach decompressed. Although uncommon, the body of the stomach at times can lie just cranial to the upper pole of the left kidney. As stated above, the lumbar vein runs directly posterior from the posterior surface of the left renal vein. When specific identification of this vein is required, as during a laparoscopic donor nephrectomy, it is good to place a Weck clip on the gonadal vein, leaving approximately a 2 cm stump attached to the renal vein. This can serve as a handle to obtain anterior traction on the renal vein, revealing the posterior lumbar vein (and potentially its branches).

Retroperitoneal

The retroperitoneal approach to the left kidney differs from the right in several critical aspects. First the aorta, rather than the inferior vena cava, is the horizontally running major vessel. Its sharp, horizontal pulsations are easily appreciated when the kidney is lifted anteriorly away from the psoas muscle. Although the renal artery pulsations are again seen when the laparoscope is at a 45 degree angle to the body, in the retroperitoneal view, the surgeon sees the renal artery lying superior (to the right on the screen) and slightly posterior to the renal vein. On the left side, the renal vein and artery can be seen at the same time running parallel to one another. As described above, this is not the case on the right side. Additionally the level at which the renal vein is ligated and transected is more lateral (toward the kidney parenchyma) than when the renal vein is transected on the right side. As a result, the adrenal vein usually enters the renal vein medial to the ligated renal vein. This has consequences when performing an adrenalectomy with the nephrectomy (see Left Adrenal Gland: Retroperitoneal below for details).

> **CAVEAT**
>
> At times a lumbar vein will be seen in the retroperitoneal approach. This should be ligated after the renal artery is controlled. When the lumbar vein is adequately controlled, the renal vein releases, facilitating further renal vein dissection.

Although it is rare and difficult to visualize the superior mesenteric artery via the retroperitoneal approach, the surgeon must be ever mindful of its anatomical location to ensure its safety.

Although it is rare and difficult to visualize the superior mesenteric artery via the retroperitoneal approach, the surgeon must be ever mindful of its anatomical location to ensure its safety.

The superior mesenteric artery runs anterior to the aorta and medial to the renal artery. Therefore one should not dissect medial to the renal artery and vein, so as to avoid entering the superior mesenteric artery territory. Medial attachments of the kidney to the aorta or posterior peritoneum should be approached from an anterior and lateral approach (over the kidney rather than under the kidney). This enables the surgeon to appreciate the attachments that run exclusively to the kidney, thereby avoiding the superior mesenteric artery. The same principle holds true for left adrenal gland dissection as described below.

RIGHT ADRENAL GLAND

Transperitoneal

The right adrenal gland lies cranial and slightly medial to the superior pole of the kidney. The medial portion of the adrenal gland abuts the inferior vena cava, and at times a significant portion of its parenchyma can be located retrocaval (posterior to the inferior vena cava).

The medial portion of the adrenal gland abuts the inferior vena cava, and at times a significant portion of its parenchyma can be located retrocaval (posterior to the inferior vena cava).

Superiorly, the adrenal gland abuts the under surface of the liver. Laterally, the adrenal gland is bounded by the most inferior portions of the diaphragm and the lateral abdominal wall. Posteriorly, the adrenal gland lies atop the psoas muscle.

It receives collateral blood supply from small arterial perforating vessels originating from the inferior phrenic artery, the aorta, and the right renal artery. Specific and identifiable arteries to the adrenal gland are usually not appreciated.

There is a single, short adrenal vein that drains directly into the inferior vena cava. The adrenal vein originates from the superior, medial aspect of the adrenal gland. This vein cannot be seen without significant cranial mobilization of the liver.

Controlling the adrenal vein before any mobilization is preferable. If the vein tears, it will avulse at its junction to the inferior vena cava, which can lead to significant and difficult-to-control bleeding.

Retroperitoneal

This is the author's preferred approach to most operations of the right adrenal gland. Three major anatomically related advantages that enable rapid and safe right retroperitoneoscopic adrenal surgery are: (i) no requirement for bowel and liver mobilization; (ii) rapid identification and control of the adrenal vein; (iii) direct access to any retrocaval portion of the adrenal gland to ensure complete resection in case of cancer surgery.

As is the case for all surgery, one must have a clear understanding of the retroperitoneal anatomy and the relation of the right adrenal gland to surrounding structures. The right adrenal vein is best approached by first noting the location of the right kidney hilum. This is performed as described above. If one then dissects immediately superior to the right renal vein and dissects directly along the inferior vena cava in a cranial direction, the adrenal vein will come into view. The inferior vena cava acts as the "highway" to the adrenal vein, which is usually seen in the retroperitoneal approach to be coursing anterior-medially when anterior traction is put on the adrenal gland.

Of course, the direction in which the adrenal vein is seen is entirely dependent on the vector of traction the surgeon puts on the adrenal gland itself. As is the case for the renal vein, the cranial and caudal junctions of the adrenal vein to the inferior vena cava must be seen before ligating the adrenal vein. If one dissects to far cranially on the inferior vena cava, superior to the adrenal vein, the hepatic veins will be encountered.

The adrenal gland is then mobilized by freeing it from its cranial attachments to the peritoneum and diaphragm. Next the adrenal gland is typically mobilized by freeing it of its anterior attachments to the peritoneum which is typically a bloodless, areolar tissue. Finally, the last attachments of the adrenal gland to the kidney are freed by entering Gerota's fascia and baring the superior pole of the right kidney.

> **CAVEAT**
>
> One must be aware that when the adrenal gland is on traction before ligating and transecting the adrenal vein, the inferior vena cava may be kinked and not course in the expected direction cranial to the adrenal vein. One must also be aware of the fact that if overzealous dissection is carried out too cranially along the inferior vena cava, one may approach the hepatic veins.

When mobilizing the adrenal gland, it is beneficial to delay freeing the caudal attachments of the adrenal gland to the kidney to be the last step of mobilization, reason being that once Gerota's fascia is entered, a significant amount of unwieldy perirenal fat narrows the surgeon's field of view.

LEFT ADRENAL GLAND

Transperitoneal

The left adrenal gland, similar to the right adrenal gland, lies cranial to the upper pole of the right kidney. Unlike the right adrenal gland, the left adrenal gland lies in a more medial position with respect to the upper pole of the right kidney.

Medially, just as the right adrenal gland lies contiguous with the inferior vena cava, the left adrenal gland lies in close proximity to the left, lateral boarder of the aorta. There is typically more clearance between the aorta and the left adrenal gland than there is between the inferior vena cava and the right adrenal gland. There is not a retroaortic portion of the left adrenal gland as there often is a retrocaval portion of the gland on the right side.

Superiorly, the adrenal gland abuts the under surface of the spleen. Laterally, the adrenal gland is bounded by the most inferior portions of the diaphragm and the lateral abdominal wall. Posteriorly, the adrenal gland lies atop the psoas muscle.

Margin notes:

Controlling the adrenal vein before any mobilization is preferable. If the vein tears, it will avulse at its junction to the inferior vena cava, which can lead to significant and difficult-to-control bleeding.

The inferior vena cava acts as the "highway" to the adrenal vein, which is usually seen in the retroperitoneal approach to be coursing anterior-medially when anterior traction is put on the adrenal gland.

When mobilizing the adrenal gland, it is beneficial to delay freeing the caudal attachments of the adrenal gland to the kidney to be the last step of mobilization, reason being that once Gerota's fascia is entered, a significant amount of unwieldy perirenal fat narrows the surgeon's field of view.

Unlike the right adrenal gland, the left adrenal gland lies in a more medial position with respect to the upper pole of the right kidney.

There is not a retroaortic portion of the left adrenal gland as there often is a retrocaval portion of the gland on the right side.

Unlike the right adrenal vein, the left adrenal vein drains into the left renal vein.

The blood supply to the left adrenal gland is similar to the right side: branches of the inferior phrenic artery, the left renal artery, and perforating branches of the aorta. Again, these named arteries are rarely appreciated. Unlike the right adrenal vein, the left adrenal vein drains into the left renal vein.

The adrenal vein drains into the renal vein in a more medial position relative to the gonadal and lumbar vein. The adrenal vein is visualized by partially skeletonizing the renal vein. When this medial dissection of the renal vein is carried out, the insertion of the adrenal vein will be seen on the cranial margin of the renal vein.

CAVEAT

The anterio-medial adrenal gland lies very close to the tail of the pancreas. If this relation is not understood and if there is a prominent tail of the pancreas, it is easy to confuse the initial dissection of the adrenal gland with the tail of the pancreas.

Retroperitoneal

The anatomical relation of the adrenal gland to surrounding structures is the same as described via the transperitoneal approach. However, the approach to the adrenal vein is quite different. Unlike the transperitoneal approach, the left renal vein need not be dissected at all. Rather the adrenal vein is seen just cranial (to the right on the television monitor) to the pulsations of the left renal artery. Furthermore, it courses approximately 0.5 to 1 cm anterior and parallel to the horizon of the anterior psoas muscle.

The mobilization of the adrenal gland is similar to that described for the right retroperitoneal approach. Specifically the gland is freed of its cranial attachments to the peritoneum underlying the spleen, then the anterior-medial attachments to the peritoneum, and lastly, cranially from the superior surface of the bared kidney.

CAVEAT

When dissecting the posterio-medial attachments of the adrenal gland, it is advisable to exert lateral traction (toward the surgeon) on the adrenal gland so that just the attachments connected to the adrenal gland are divided. This step further minimizes the chances of injury to the superior mesenteric artery.

CHAPTER 3

LAPAROSCOPIC ANATOMY OF THE MALE PELVIS

Bertrand Guillonneau, Karim A. Touijer, and Jeffery W. Saranchuk

Department of Urology, Sidney Kimmel Center for Prostate and Urologic Cancers, Memorial Sloan-Kettering Cancer Center, New York, New York, U.S.A.

INTRODUCTION

Anatomy is the key element to surgery. This is true for open or laparoscopic approach. Clear knowledge of anatomy is the "primum movens" of good surgical technique. In laparoscopy, the anatomical perspective of the surgical field is somewhat different from the one usually seen during open surgery. The magnification and the ease of access to the depths of the male pelvis bring into view anatomical details not fully described in currently available anatomy textbooks. To adapt and revise the anatomy incorporating this different perspective is thus a prerequisite to the realization of safe and efficient laparoscopic surgery. Furthermore, tactile feeling is somewhat diminished in laparoscopy and vision remains the primary fully available sense. Mastery of laparoscopic topographic anatomy is thus indispensable for visually identifying various structures and recognizing their spatial relationships with each other.

In this chapter we attempt to summarize our understanding of male pelvic anatomy from a laparoscopic standpoint.

INTRA-ABDOMINAL ANATOMY OF THE PELVIS

Upon entering the abdomen and visualizing the intra-abdominal pelvis, several structures are identifiable: the bladder and the median umbilical ligament in the mid-line, the medial and lateral umbilical ligament, and the spermatic vessels entering the deep inguinal ring more laterally (Fig. 1).

The Bladder

The bladder dome is median. It constitutes the mobile portion of the bladder, whose relationships change according to its state of distension. However, because a Foley catheter is routinely inserted into the bladder prior to creation of pneumoperitoneum, the bladder is empty and its anatomical boundaries are not visible at the inspection. To better delineate its limits, the bladder needs to be distended.

Once filled, the bladder visibly distends posteriorly, reduces the pouch of Douglas (also called rectovesical recess), and expands (i) laterally toward the medial umbilical ligament; (ii) anterosuperiorly underneath the anterior abdominal wall; and (iii) toward the umbilicus to which it is attached through the urachus.

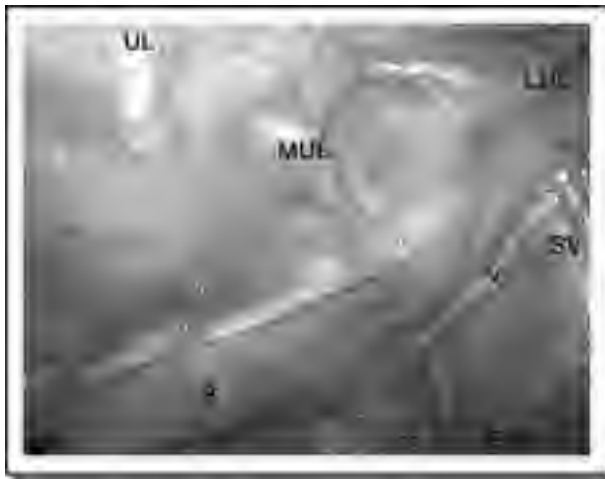
19


FIGURE 1 ■ The umbilical ligaments. Transperitoneal view of the right half of the pelvis. Ureter (*asterisk*). *Abbreviations*: UL, umbilical ligament; MUL, medial umbilical ligament; LUL, lateral umbilical ligament; B, bladder; V, vas deferens; SV, spermatic vessels; EIV, external ilial vein.
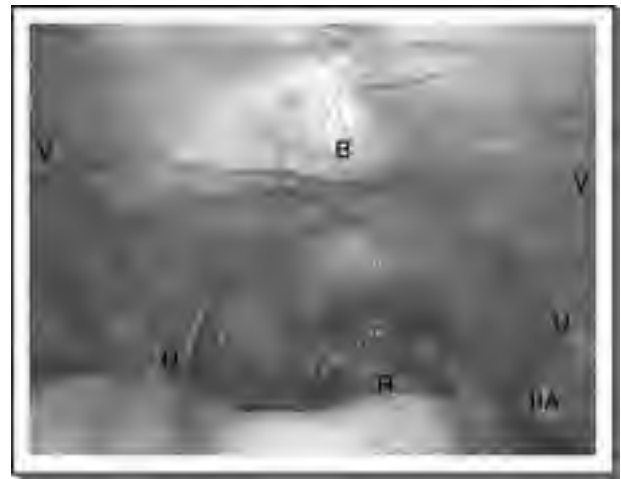

FIGURE 2 ■ The pouch of Douglas. *Abbreviations*: B, bladder; V, vas deferens; U, ureter; IIA, internal iliac artery.

The vesicular complex usually lies about 2 cm above the pouch of Douglas.

The urachus (median umbilical ligament) is visible along the anterior parietal peritoneum. It consists of a cord often accompanied by vessels that must be controlled when dividing the urachus. On either side, laterally, the median umbilical ligament is separated from the medial umbilical ligament by a peritoneal recess. The latter allows access to the vesical space (space of Retzious).

The pouch of Douglas (Fig. 2) appears as a cul-de-sac between the bladder anteriorly and the rectum posteriorly. Its depth varies among patients. Although in thin males the outline of the seminal vesicles and the distal portions of the vasa deferentia may be clearly visible through the visceral peritoneum covering the bladder posteriorly, most often the exact location of the vesicular complex is not visible. The vesicular complex usually lies about 2 cm above the pouch of Douglas.

The Medial Umbilical Ligament

The medical umbilical ligament can be used as a guide to approach the pelvic ureter because at this level, the superior vesical artery crosses the ureter medially.

The medial umbilical ligaments, the continuation of the obliterated hypogastric artery, are particularly easy to visualize in laparoscopy and represent an important anatomical landmark. The prominence of the medial umbilical ligament varies according to the amount of surrounding adipose tissue. The ligaments consist of an anteriorly tented cord between the umbilicus (superiorly) and the distal portion of the superior vesical artery branch of the internal iliac artery. At this anatomic location the hypogastric artery within the medial umbilical ligament is almost always completely obliterated, and does not bleed.

The medial umbilical ligament can be used as a guide to approach the pelvic ureter because at this level, the superior vesical artery crosses the ureter medially.

The umbilical fossa is divided in a superior and inferior portion by the vas deferens, providing access to the obturator fossa.

Laterally, the medial umbilical ligament is separated from the lateral umbilical ligament (fold of peritoneum covering the inferior epigastric artery) by the medial umbilical fossa.

The umbilical fossa is divided in a superior and inferior portion by the vas deferens, providing access to the obturator fossa.

The Lateral Umbilical Ligament

The lateral umbilical ligament can be used as a guide to approach the external iliac vessels.

The lateral umbilical ligament can be used as a guide to approach the external iliac vessels.

This ligament is the least pronounced of the three umbilical ligaments but its visualization is important for the insertion of the lower abdominal quadrant trocars. This ligament represents the peritoneal fold covering the inferior epigastric vessels. The inferior epigastric artery, a medial branch of the distal external iliac artery, ascends along the medial margin of the deep inguinal ring, continues between the rectus abdominis muscle and the posterior lamina of its sheath, and then raises the anterior parietal peritoneum creating the lateral umbilical ligament, which is crossed at its origin by the vas deferens superiorly.

The vas deferens and the medial umbilical ligament are major landmarks for pelvic lymph node dissection.

The Spermatic Cord

The convergence of the spermatic vessels—spermatic artery and veins—and the vas deferens with its proper vessels forms the spermatic cord. The spermatic vessels course over the psoas-iliac muscle and are joined by the vas deferens before entering the deep inguinal ring.

The vas deferens, rarely visible behind the prostate even at its posterolateral aspect, becomes more superficial and visible laterally, covered with the parietal peritoneum where it crosses the external iliac vessels.

The vas deferens and the medial umbilical ligament are major landmarks for pelvic lymph node dissection.

In fact, a vertical incision of the parietal peritoneal fold across the vas deferens, in the medial umbilical fossa, leads to the external iliac vessels, with the artery located anterolaterally and superficially and the vein located posteromedially and more deeply.

The genitofemoral nerve lies lateral to the external iliac artery. It can be used for nerve grafting after neurovascular bundle resection during radical prostatectomy.

The Iliac Vessels

Pulsations of the external iliac artery are usually seen through the overlying parietal peritoneum fold, at the level where the vas deferens joins the spermatic vessels.

The genitofemoral nerve lies lateral to the external iliac artery. It can be used for nerve grafting after neurovascular bundle resection during radical prostatectomy.

The external iliac vein, located medial to the external iliac artery, can be masked by a tortuous iliac artery. Furthermore, visualization of the vein may be impaired by the high-pressure pneumoperitoneum. In this situation, a reduction of the intra-abdominal pressure (5 mmHg) typically decompresses the iliac vein, bringing its gentle undulating pulsations into clear view.

To expose the external iliac vein, the parietal peritoneum directly overlying its medial aspect must be incised along the length of the vein. During such dissection, the surgeon should be aware of the presence of two medial venous branches. The first one, located proximally, or upstream, is the inconstant accessory circumflex vein, which reaches the external iliac vein just below the inferior aspect of the superior pubic ramus. The second branch, more distal, or downstream, is the internal iliac or hypogastric vein that runs in a posteroanterior orientation.

Dissection at the confluence of the internal and external vessels gives access to the superior vesical artery.

Dissection at the confluence of the internal and external vessels gives access to the superior vesical artery.

It should be noted that the left external iliac vessels are generally located somewhat more posteriorly, deeper in the pelvic cavity, as compared to the right external iliac vessels. As such, a laparoscopic left pelvic lymph node dissection may be technically somewhat more difficult.

The obturator nerve is located posteromedially to the external iliac vein. It appears as a white, shining, striated cord, usually flattened, entering the obturator fossa at the level of the convergence of the internal and external iliac veins, somewhat closer to the internal iliac vein. The obturator nerve enters the obturator canal at its superolateral edge. The nerve is accompanied by the obturator artery (branch of the internal iliac artery), and usually an obturator vein, which typically lies posterior to the nerve.

The obturator fossa, a triangular area formed by the pubic rami with the obturator muscle, and the internal and external iliac vein as its sides, comprises an important lymphatic drainage zone for the prostate and the bladder, and represents the area to be dissected during pelvic lymphadenectomy.

The obturator fossa, a triangular area formed by the pubic rami with the obturator muscle as its base, and the internal and external iliac vein as its sides, comprises an important lymphatic drainage zone for the prostate and the bladder, and represents the area to be dissected during pelvic lymphadenectomy.

The Ureter

The ureter crosses anteriorly over the common iliac vessels and can be readily identified at this level. The left ureter, covered by the parietal peritoneum and the pelvic mesocolon, remains medial to the internal iliac artery and crosses medially across the proximal part of the superior vesical artery before entering the bladder. Near its entrance in the detrusor, the ureter is also in the vicinity of the lateral aspect of the seminal vesicle, near the inferior hypogastric plexus (see The Seminal Complex).

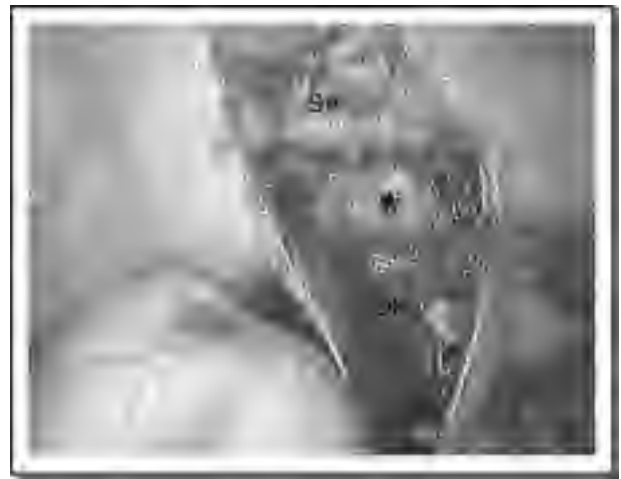
Transverse incision of the peritoneal fold about 2 cm above the base of the pouch of Douglas allows access to the seminal complex, and further distally to the Denonvilliers' fascia.

The Seminal Complex

The distal portion of the two vasa deferentia, the ampullas, and the two seminal vesicles compose the seminal complex. This complex is rarely visible through the visceral peritoneal fold of the anterior aspect of the pouch of Douglas.

Transverse incision of the peritoneal fold about 2 cm above the base of the pouch of Douglas allows access to the seminal complex, and further distally to the Denonvilliers' fascia (see The Denonvilliers' Fascia) (Fig. 3).

FIGURE 3 ■ Transperitoneal view of the Denonvilliers' fascia after its opening through an incision of the anterior peritoneal fold of the pouch of Douglas. Anterior of the rectum recovered by fatty layer (*asterisk*). *Abbreviations*: SV, seminal vesicle; DF, Denonvilliers' fascia.

The superior portion of the Denonvilliers' fascia appears as a vertically striated tissue, covering the seminal complex posteriorly. Its dissection leads to the prerectal space with the adipose tissue on its proximal aspect.


Transverse incision of the Denonvilliers' fascia exposes the seminal complex, where the vasa deferentia are identified laterally and ventrally. Anterior to each vas runs a deferential artery.

The seminal vesicles, whose size varies physiologically, lie posteriorly, inferiorly, and laterally to the vas. The posterior aspect of the seminal vesicle is easy to dissect from the prostatorectal fascia. The anterior aspect of the tip of the seminal vesicle is traversed by the seminal vesicular artery, often a sizable blood vessel, which is a branch of the superior vesical artery. The lateral aspect and tip of the seminal vesicle is in close relationship with the inferior hypogastric plexus also known as the pelvic plexus, which carries innervating fibers to the pelvis (1). The inferior hypogastric plexus measures about 40 mm in height, 10 mm in width and 3 mm in thickness, and is molded to the contours of the seminal vesicle as far as the vesiculoprostatic junction. The inferior hypogastric plexus receives afferent fibers from the superior hypogastric plexus-or preaortic plexus (sympathic fibers arising from the thoracic region) and from the pelvic splanchnic nerves-or erector nerves, nervi erigentes (parasympathetic preganglionic fibers arising from the sacral plexus S2 to S4). The cavernous nerves emerge at the level of the anteroinferior border of the inferior hypogastric plexus.

The Rectum and Sigmoid Colon

Only the superior half or superior third of the rectum is visible during pelvic laparoscopic surgery.

Trendelenburg positioning of the patient allows upward mobilization of the sigmoid colon by gravity, and access to the pouch of Douglas.

The sigmoid colon is attached by the sigmoid mesocolon to the left lateral aspect of the pelvis, overlying the left external iliac vessels.

THE RETROPUBIC SPACE

The retropubic or prevesical space can be approached laparoscopically either transperitoneally or extraperitoneally. The retropubic space has a triangular shape, limited (i) anteriorly by the pubis and the fascia transversalis covering the posterior surface of the anterior abdominal wall; (ii) posteriorly by the bladder through the umbilicoprevesical fascia and the endopelvic fascia; and (iii) laterally by the internal obturator muscles.

The Pubis

The superior ramus of pubis is covered witha fascia that thickens laterally, forming Cooper's ligament.

The Obturator Muscles

On each side of the pelvis, the obturator muscle is tented between the ischial spine and the inferior border of the pubic ramus, and is supported inferiorly by the tendinous arch

of the levator ani muscle. The muscle covers the obturator foramen, yielding, laterally and anteriorly, the passage of the obturator pedicle through the obturator canal.

The Bladder

The bladder is covered with a layer of fat that can be dissected easily off the detrusor. Therefore, there are two spaces of dissection that can be developed. The first one is close to the bladder wall, between the detrusor and the layer of perivesical fat. The second, corresponding to the Retzius space, is more anterior, between the layer of perivesical fat and the posterior aponeurosis of the rectus sheath, up to the arcuate line or aponeurosis of Douglas.

Laterally, the bladder is attached to the pelvic cavity through the vesical ligament, which, from top to bottom, carries the superior vesical artery and veins (a branch of which is obliterated and becomes the median umbilical ligament), the distal portion of the ureter, and (inferiorly) the inferior vesical veins and artery.

A branch of the inferior vesical artery joins the prostatic pedicle, gives origin to the prostatic arteries, the vesicular arteries, the deferential arteries, and the arteries running along the cavernous nerves forming the so-called "neurovascular bundle."

The Endopelvic Fascia

The endopelvic fascia is the inferior limit of the Retzius space. It is stretched between the tendinous arches of the levator ani muscle, and covers the anterior aspect of the prostate.

Laterally, the endopelvic fascia presents two recesses—or sulci—situated between the prostate medially and the pelvic muscles laterally.

The lateral recess of the endopelvic fascia constitutes a weak part of the endopelvic fascia that is incised to approach the lateral aspect of the prostate.

The endopelvic fascia recess is particularly weak and thin toward the prostate base, and anteriorly toward the apex where it is fenestrated between lateral expansions of the puboprostatic ligaments.

In some patients, an accessory pudental artery branch of the obturator artery, can be seen on the superior surface of the endopelvic fascia and should be preserved because it may represent the single major source of vascularization to the corpus cavernosum. (2)

The incision of the endopelvic fascia should start proximally, because there is a paucity of blood vessels at that level. This incision uncovers the medial aspect of the levator ani muscle, below the tendinous arch. In some patients, the dissection may be conducted medially up to the parietal fascia of this muscle, but most often the dissection has to be more lateral, leaving the levator ani fascia on the prostate. Inferiorly, this fascia fuses with the lateral aspect of the Denonvilliers' fascia in the area of the neurovascular bundle.

More laterally and anteriorly, posterior and inferior to the lateral oblique extension of the puboprostatic ligament, veins running from the levator ani muscle to the superolateral aspect of the prostatic apex may be identified. More specifically, it is not unusual to find an artery coming through the fibers of the levator ani muscle and running to the superolateral aspect of the prostatic apex where it turns toward the venous complex after giving a branch(es) to the apex.

Anteriorly, the puboprostatic ligaments are a condensation of the endopelvic fascia attached to the inferior border of the inferior pubic ramus. On each side, the puboprostatic ligament is either single and vertical or multiple with often a lateral oblique extension (Fig. 4). In the sagittal plane, the most medial ligament does not appear as a cord tended between the pubis and the prostatic apex, but more as a fold that is in continuity with the transverse perineal ligament (arcuate pubic ligament). Histologically, it has been shown that the puboprostatic ligaments are detrusor muscle extensions (detrusor apron) that partially cover the anterior surface of the prostate, hence the name pubovesical ligaments (3).

Between the two puboprostatic ligaments emerges the superficial dorsal vein separated from the deep venous complex by a plane easy to develop. Frequently, the superficial dorsal vein runs within the fat covering the anterior layer of the endopelvic fascia and gives multiple branches at the level of the vesicoprostatic junction where it enters the detrusor muscle. In some patients, the deep dorsal vein bifurcates or trifurcates immediately after its entrance into the pelvis. The puboprostatic ligaments are not vascularized and can be cut safely at their most anterior portion.

Laterally, the puboprostatic ligament fuses with the extension of the parietal fascia of the levator ani and the visceral prostatic fascia, creating a relatively thick "sphincteric" fascia that covers the lateral aspect of the deep venous complex. More posteriorly, this sphincteric fascia covers the ischioprostatic ligaments—or Müller's ligaments or

The puboprostatic ligaments are not vascularized and can be cut safely at their most anterior portion.

Walsh's pillars—which anchor the rhabdomyosphincter and the sphincteric membranous urethra to the bony structures.

Posteriorly, the endopelvic fascia becomes attenuated and merges with the detrusor muscle.

The Santorini's Plexus

The Santorini's plexus is composed of the superficial dorsal vein (described above) and the so-called or deep venous complex (Fig. 5). In fact, this complex is composed of large veins draining the penis, and one or two arteries. It may seem therefore more appropriate to name this complex the "deep vascular complex."

Posteriorly, the deep venous complex is separated from the anterior surface of the urethra by an avascular plane that can be developed easily as it extends cephalad, the deep venous complex branches into a network of veins on the anterior aspect of the prostate. Some branches penetrate the prostatic apron and drain into the prostatic pedicular veins. Others drain directly into the pudendal veins along the neurovascular bundles (4).

PROSTATIC FASCIA AND PROSTATIC PEDICLES

The Visceral Fascia

The visceral fascia covers the external surface of the prostate, bladder, and seminal vesicles.

Along the posterolateral surface of the prostate, the visceral fascia is in continuation with the Denonvilliers' fascia, and its dissection off the prostatic capsule delineates the medial surface of the neurovascular bundle.

An "interfascial" dissection conducted between the prostate capsule and the prostate visceral fascia leaves the neurovascular bundle totally intact and surrounded by its fascia.

With this approach the cavernous nerves, the vessels of the bundle, and the fatty tissue embedding them all are not directly seen. As mentioned, it seems appropriate to name this dissection as the "interfascial" neurovascular bundle dissection, as opposed to the "extrafascial" dissection where the dissection is performed with variable width into the neurovascular bundle itself (5). The term "intrafascial" dissection would imply that the plane of dissection is developed between the prostatic parenchyma and the capsule, an oncologically inappropriate plane of dissection.

Distally, the fusion of the visceral fascia with the inferior extension of the puboprostatic fascia and the parietal fascia of the levator ani muscle forms the "sphincteric" fascia that recovers laterally the deep venous complex and the ischioprostatic ligaments.

The Denonvilliers' Fascia

This fascia has several terminologies. It is variously known as "posterior prostatorectal fascia," "septum rectovesicale," or "prostatoseminal vesicular fascia." To comply with common custom, the eponym terminology, "Denonvilliers' fascia," will be used here. The Denonvilliers' fascia is posterior to the prostate and anterior to the rectum. Superiorly, it surrounds the seminal vesicles where it fuses with the usual visceral fascia. On the anterior aspect of the seminal vesicle, the Denonvilliers'

fascia merges with a prostatic extension of the detrusor and becomes multilayered and rich with muscular fibers. Inferiorly, it merges with the expansion of the rectourethralis muscle, posteriorly to the sphincteric–membranous urethra. Laterally, it merges with the lateral fold of the visceral fascia, determining the superomedial and inferomedial borders of the neurovascular bundle (Fig. 6).

The Denonvilliers' fascia is more adherent to the prostate than to the rectum, particularly on its superior aspect where it is separated from the rectum by a layer of fatty tissue. Distally, this layer of adipose tissue fades and the Denonvilliers' fascia becomes much more adherent to the rectal wall.

> The Denonvilliers' fascia can be closely adherent to the prostatic gland and at risk of malignant involvement in patients with invasive prostate cancer. Thus, the Denonvilliers' fascia should be posteriorly removed en bloc with the radical prostatectomy specimen.

The Denonvilliers' fascia can be closely adherent to the prostatic gland and at risk of malignant involvement in patientswith invasive prostate cancer. Thus, the Denonvilliers' fascia should be posteriorly removed en bloc with the radical prostatectomy specimen (6).

Rectourethralis Muscle

The rectourethralis is a Y-shaped muscle arising within the substance of the rectal wall deep to the outer longitudinal smooth muscle and inserts into the central tendon of the perineum. As such, this structure is rarely encountered in laparoscopy (7). It is currently accepted that the Denonvilliers' fascia inserts distally on the rectourethralis muscle, merging with it.

The Prostatic Neurovascular Plexuses

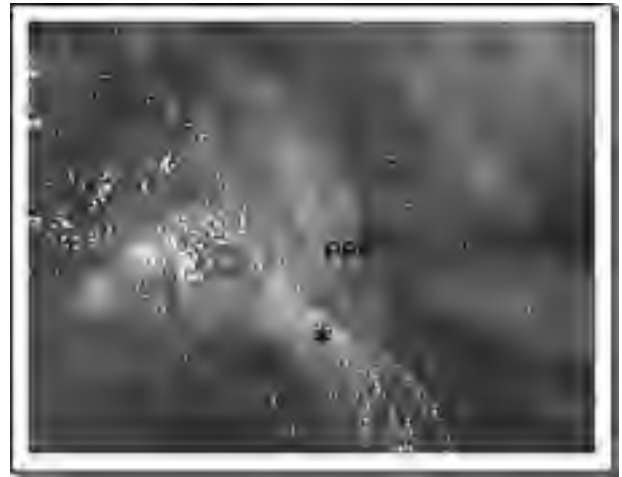
The prostatic neurovascular plexus contains veins, arteries and autonomic nerves. Its limits are the parietal fascia of the levator ani laterally, and the fusion of the Denonvilliers' fascia and the prostatic visceral fascia medially.

The Cavernous Nerves

The cavernous nerves arise from the inferior hypogastric plexus and contain autonomic, sympathetic and parasympathetic fibers. These nerves appear like a network distributed to the prostate and to the corpus cavernosum. The nerves join the prostatic artery at the level of the pedicle. The cavernous branches of the network then follow the posterolateral aspect of the prostate toward the apex, accompanied by veins and arterial branches of the prostatic pedicular artery (8). Apically, the nerves run more posteromedially to the prostate. Along their course, small branches of the cavernous nerves penetrate the prostate capsule (intracapsular nerves). However, visualization of these branching nerves is difficult, even during the laparoscopic "interfascial" dissection. Nonetheless, their existence is confirmed by pathological studies (9).

The Arteries

The arteries are very visible during laparoscopic dissection and are important landmarks for initiating the dissection plane of the "interfascial" neurovascular

FIGURE 7 ■ Right prostatic pedicle. Main prostatic pedicular artery (*asterisk*). *Abbreviation*: PPF, periprostatic fascia.


dissection (Fig. 7). At the level of the arborescence of the prostatic arteries into prostatic, vesicular, and deferential arteries, at least one branch runs anteroinferiorly on the lateral aspect of the base of prostate and joins the cavernous nerves to form the neurovascular bundle posterolaterally. Once within the neurovascular bundle, the artery generates an arterial network. Rarely, one of these arteries crosses the medial visceral fascia to enter the prostatic capsule at the mid portion of the gland. More often the arteries run all along the prostate and only give a retrograde branch to the apex.

The Veins

A vein originating from the deep venous complex and running along the anterior tip of the crescent shape neurovascular bundle can be used as a landmark for the neurovascular preservation.

Although the veins usually follow the course of the artery, it is not infrequent in the case of a large vein originating from the deep venous complex and running along the anterior tip of the crescent shape neurovascular bundle.

SPHINCTERIC COMPLEX

The Rhabdomyosphincter

Urinary continence relies on a combined function of detrusor, trigone, and urethral sphincter muscles. The external urethral sphincter covers the ventral surface of the prostate as a crescent shape above the veru montanum, assumes a horseshoe shape below the veru montanum, and then becomes more crescent shaped along the proximal bulbar urethra. The levator ani muscles form an open circle around the external sphincter with a hiatus at the ventral aspect. The smooth and striated muscle components of the urethral sphincteric complex are inseparable (10).

The length of the sphincteric urethra measured by magnetic resonance imaging is variable among individuals (between 6 and 24 mm; average, 14 mm) and seems to be directly related to the recover of continence (11).

Innervation of the Rhabdomyosphincter

The innervation of the so-called "rhabdomyosphincter" is supported mainly by fibers coming from the S2 to S4 roots and traveling via the pudendal nerve. These nerves are not visualized during a laparoscopic pelvic surgery because they run posterolateral to the rectum, and then inferior to the levator ani muscle. More distally the main trunk gives terminal branches to the inferolateral aspect of the urethral sphincter.

Extrapudendal nerves can sometimes be found inside the pelvis and may be damaged during pelvic surgery (12,13).

Rhabdomyosphincteric innervation by branches arising from the pelvic plexus (S4 root) have also been described as a branch of the pelvic splanchnic nerve. They also are posterolateral to the rectum and are not visible during a pelvic dissection for urologic disease (14).

A vein originating from the deep venous complex and running along the anterior tip of the crescent shape neurovascular bundle can be used as a landmark for the neurovascular preservation.

The length of the sphincteric urethra measured by magnetic resonance imaging is variable among individuals (between 6 and 24 mm; average, 14 mm) and seems to be directly related to the recovery of continence.

Extrapudendal nerves can sometimes be found inside the pelvis and may be damaged during pelvic surgery.

CONCLUSION

The understanding of anatomy is ever evolving. Laparoscopy with its inherent limitations and advantages necessitates a somewhat different comprehension of the surgical anatomy, adapted to a certain angle of vision and magnification. There is no doubt that the knowledge of the laparoscopic anatomy of the pelvis will grow over time, and will allow surgery to reach its ultimate goal: being curative without being deleterious.

PHYSIOLOGIC ASPECTS OF LAPAROSCOPY

J. Stuart Wolf, Jr.

Division of Minimally Invasive Urology, Department of Urology, University of Michigan, Ann Arbor, Michigan, U.S.A.

INTRODUCTION

Laparoscopy for the most part is physiologically beneficial for the patient, especially with regard to pulmonary function, but the benefits occur in the post-operative period (1–4). During the procedure itself, laparoscopy is physiologically more stressful on the patient than open surgery.

Pronounced positional issues, increased intra-abdominal pressure, and the sequelae of absorbed CO_2 combine to create unfamiliar physiologic effects. Fortunately, most patients tolerate the physiologic insult of laparoscopy well. On occasion, either in a patient with significant cardiovascular compromise or owing to unusual response, significant and potentially life-threatening complications that have little to do with the inherent steps of the particular surgical procedure but instead result from physiologic reactions to the laparoscopic environment can occur.

In a survey of outcomes of laparoscopic cholecystectomy, one-half of the mortality was due to physiologic rather than surgical events (5). A prepared surgeon can avoid these complications, or at least manage them appropriately if they do occur.

> In a survey of outcomes of laparoscopic cholecystectomy, one-half of the mortality was due to physiologic rather than surgical events. A prepared surgeon can avoid these complications, or at least manage them appropriately if they do occur.

PHYSIOLOGIC FACTORS

The primary factors influencing the physiologic response to laparoscopy are

■ The increased intra-abdominal pressure from intraperitoneal insufflation of gas and
■ The absorption of CO_2, which is used as the insufflant gas in most procedures.

Patient positioning, such as extreme Trendelenburg (head down) or extreme lateral flexion, can play a significant role. These factors can have both stimulatory and inhibitory effects, and their influence can be varied independently to some extent.

Positioning

The lateral position used for laparoscopic renal surgery does not have much effect on hemodynamics unless impingement on the vena cava by extreme lateral flexion reduces venous return (6). For upper abdominal laparoscopic procedures, the patient is sometimes placed in a head-up tilt (reverse Trendelenburg) position to drop bowel away from the operative field. This position decreases cardiac output (7,8), and there is inconsistent evidence that this position may improve pulmonary mechanics during laparoscopy (9–11).

The intraperitoneal approach to radical prostatectomy and other laparoscopic pelvic surgeries is facilitated by a head-down tilt (Trendelenburg) position, which tends to modestly increase cardiac output (12–15). Most, but not all, studies suggest that this position restricts diaphragmatic movement and increases ventilation–perfusion mismatch during laparoscopy (10,16,17).

> The intraperitoneal approach to radical prostatectomy and other laparoscopic pelvic surgeries is facilitated by a head-down tilt (Trendelenburg) position, which tends to modestly increase cardiac output. Most, but not all, studies suggest that this position restricts diaphragmatic movement and increases ventilation–perfusion mismatch during laparoscopy.

Insufflation of gas elevates the intra-abdominal pressure. Increase in intra-abdominal pressure is the most prominent of the physiologic insults of laparoscopy and can have dramatic effects with only small changes.

Increased Intra-Abdominal Pressure

Insufflation of gas elevates the intra-abdominal pressure. Increase in intra-abdominal pressure is the most prominent of the physiologic insults of laparoscopy and can have dramatic effects with only small changes.

Increased intra-abdominal pressure compresses the splanchnic circulation (Fig. 1) (18), in both capillaries and capacitance vessels, and in both the venous and arterial systems (14,15,19–22). An intra-abdominal pressure of 20 mmHg or more diminishes blood flow to all abdominal and retroperitoneal organs except the adrenal gland (18,23–25).

Vascular compression by elevated intra-abdominal pressure increases the systemic vascular resistance, which tends to reduce cardiac output. The magnitude of the effect of intra-abdominal pressure on systemic vascular resistance varies with the extent and duration of insufflation pressure and the volume status of the subject.

Vascular compression by elevated intra-abdominal pressure increases the systemic vascular resistance, which tends to reduce cardiac output. The magnitude of the effect of intra-abdominal pressure on systemic vascular resistance varies with the extent and duration of insufflation pressure and the volume status of the subject.

In the canine model, Kashtan et al. (22) found that at an intra-abdominal pressure of 20 mmHg, the cardiac output fell slightly in the presence of normovolemia, decreased significantly with experimental simulation of hypovolemia, and increased with experimental simulation of hypervolemia. The adverse effects of hypovolemia (26,27) and the beneficial effect of volume loading (28) in the presence of increased intra-abdominal pressure are now well recognized. Thus, it is recommended that patients should be well hydrated prior to undergoing laparoscopy.

Intra-abdominal pressure directly impacts venous return, which also affects cardiac output.

Intra-abdominal pressure directly impacts venous return, which also affects cardiac output.

At an intra-abdominal pressure less than 10 mmHg in normovolemic subjects, venous return, and therefore cardiac output, is augmented by emptying of abdominal capacitance vessels (29–31). High intra-abdominal pressure (>20 mmHg) decreases venous return and cardiac output (Fig. 2) (19–21,32). Even variation of intra-abdominal pressure between approximately 7 and 15 mmHg has a discernable effect, with more adverse hemodynamic impact at the greater pressure (31,33,34).

Mean arterial pressure is the product of cardiac output and arterial resistance. At intra-abdominal pressures less than 20 mmHg, increases in arterial resistance are more than decreases in cardiac output, and therefore mean arterial pressure is elevated (14,15,20,29,30,32,35,36). At excessive intra-abdominal pressures (>40 mmHg), the more dramatic reduction in cardiac output reduces arterial pressure (21,37). Similarly, venous pressure is determined by venous resistance and the volume of blood returning from capillary beds. However, the increase of venous resistance and pressure with insufflation (19,29) is difficult to accurately measure during insufflation. Intracardiac (transmural) venous pressure is the effective cardiac filling pressure, but central venous pressures as measured by a catheter within the right atrium also include

FIGURE 1 ■ Splanchnic circulation is restricted by pneumoperitoneum. *Source*: From Ref. 122.

FIGURE 2 ■ Reduction of venous return and cardiac output during laparoscopy. *Source*: From Ref. 122.

intrathoracic (pleural) pressures. The intrathoracic pressure rises along with increases in intra-abdominal pressure (20,22). This impedes venous return and cardiac filling, such that the central venous pressure measured by a right atrial catheter is a poor indicator of cardiac filling unless intrathoracic pressure is taken into account.

The complex effects of increased intra-abdominal pressure on hemodynamics are best understood in the context of the volume status of the patient. An increase in intra-abdominal pressure by less than 10 mmHg increases venous pressure more than resistance, thereby augmenting venous return and cardiac output. As intra-abdominal pressure rises, the increase in resistance exceeds the increase in pressure at some point, and venous return falls. The transition point occurs at a low intra-abdominal pressure in the hypovolemic state where vessels collapse easily. As volume status increases, increases in vascular pressure remain proportional to that of intra-abdominal pressure transition point at greater intra-abdominal pressures, because the full vessels do not collapse (and dramatically increase resistance) as readily.

> The balance between the resistance and pressure changes that determine venous return and cardiac output is dependent upon circulating blood volume. Given normovolemia, an intra-abdominal pressure less than 20 mmHg is not associated with major hemodynamic alterations in most patients.

The balance between the resistance and pressure changes that determine venous return and cardiac output is dependent upon circulating blood volume. Given normovolemia, an intra-abdominal pressure less than 20 mmHg is not associated with major hemodynamic alterations in most patients.

Increased intra-abdominal pressure also effects pulmonary function in a negative manner similar to that of the head-down tilt position. Elevation and restriction of the diaphragm (38) reduces lung capacity and compliance (30,39), with worsening of ventilation–perfusion mismatch (Fig. 3) (38).

Carbon Dioxide

Carbon dioxide (CO_2), introduced for insufflation by Zollikofer in 1924, is the most popular insufflant for laparoscopy under anesthesia (40).

> The primary advantages of using CO_2 during laparoscopy include its rapid absorption and its noncombustible nature.

The primary advantages of using CO_2 during laparoscopy include its rapid absorption and its noncombustible nature.

The absorption of CO_2 has contradictory effects at different sites. CO_2 is directly cardioinhibitory, reducing heart rate, cardiac contractility, and vascular resistance (41). However, CO_2 also stimulates the sympathetic nervous system, and the increase in heart rate, cardiac contractility, and vascular resistance mediated by sympathetic nerves and circulating catecholamines counteract the direct effects of CO_2 (42,43).

> Mild-to-moderate hypercapnia (excess of CO_2 in the blood) during laparoscopy with CO_2 pneumoperitoneum causes a mild respiratory acidosis.

Mild-to-moderate hypercapnia (excess of CO_2 in the blood) during laparoscopy with CO_2 pneumoperitoneum causes a mild respiratory acidosis (21,44).

Severe hypercapnia induces more dramatic acidosis (see below), and the parasympathetic nervous system is also stimulated (41).

> Overall, moderate levels of CO_2 absorption elevate cardiac output and blood pressure and decrease systemic vascular resistance. The tendency to reduce systemic vascular resistance counteracts the increase caused by the increased intra-abdominal pressure.

Overall, moderate levels of CO_2 absorption elevate cardiac output and blood pressure and decrease systemic vascular resistance. The tendency to reduce systemic vascular resistance counteracts the increase caused by the increased intra-abdominal pressure.

Insufflation of gases other than CO_2 results in a lower cardiac output for a given intra-abdominal pressure (35,36,45–47).

During intra-abdominal insufflation, the sum of gas movement is directed outwards from the peritoneal cavity into the surrounding tissue because the intra-abdominal pressure is greater than the atmospheric pressure (48). Partial-pressure gradients determine the direction of movement of each gas. The rate of movement is determined by the absorptive capacity of the surrounding tissue, temperature, the area of tissue exposed, and the tissue permeance of the gas. The well-vascularized peritoneal membrane has a high absorptive capacity, so gases with high tissue permeance are

FIGURE 3 ■ Elevation of diaphragm and restriction of lung expansion during pneumoperitoneum. *Source*: From Ref. 122.

absorbed readily. Of the gases used for insufflation during laparoscopy, CO_2 has the highest tissue permeance (Table 2) (49). Insufflated CO_2 rapidly diffuses into the blood stream. The baseline production of CO_2 in adults is 150–200 mL/min (50). During intra-abdominal insufflation at typical pressures, CO_2 is absorbed into the body at a rate of 14–48 mL/min (51). The amount of absorbed CO_2 can be greater with increased intra-abdominal pressure.

CO$_2$ absorbed or produced by tissue metabolism is eliminated by ventilation. CO_2 is first hydrated to carbonic acid (catalyzed by carbonic anhydrase), which rapidly ionizes to bicarbonate and hydrogen ions (50). Bicarbonate is soluble in blood. Hydrogen ions reduce hemoglobin in red blood cells. Hemoglobin is reoxidized in the alveolar capillaries, and the hydrogen ions are released to bind bicarbonate, produce carbonic acid, and subsequently form CO_2 and water for expiration.

If CO_2 elimination does not equal the sum of metabolic production and absorption of CO_2, hypercapnia and respiratory acidosis develop.

The vascular content of CO_2 (estimated by $PaCO_2$ or partial arterial pressure of carbon dioxide) is the "rapid" compartment of CO_2 storage. The rise in $PaCO_2$ is tempered by storage of CO_2 in the "medium" (primarily skeletal muscle) and "slow" (fat) compartments. These storage sites can hold up to 120 L of CO_2 (50). Therefore, not all of the absorbed CO_2 is immediately available for elimination. In a patient with compromised ventilation, large amounts of $PaCO_2$ can build up in the body and several hours may be necessary to eliminate the accumulation (39,52).

Hypercapnia can develop or persist after the conclusion of a prolonged laparoscopic procedure (53).

PHYSIOLOGIC RESPONSES

Cardiovascular

Cardiovascular effects of intra-abdominal insufflation with CO_2 are clinically insignificant in healthy and normovolemic patients.

Table 1 summarizes the cardiovascular effects of an intra-abdominal pressure of 15 mmHg with typical CO_2 absorption (moderate hypercapnia). Certainly, the response of any individual patient will vary.

With 15 mmHg pressure of CO_2 insufflation, central venous pressure, systemic vascular resistance, heart rate, and mean arterial pressure increase. However, the effect on cardiac output may range from a decrease of 17% to 28% (15,31,32), to no net change (14,19), to an increase of 5% to 7% (35,54).

Intra-abdominal CO_2 insufflation pressure between 5 and 10 mmHg may increase cardiac output in patients by 4% to 28% (29–31). Intra-abdominal pressure above 40 mmHg risks marked reduction of cardiac output (19). Hypovolemia will negatively alter these hemodynamic effects. The head-down tilt position for pelvic laparoscopy has a moderately favorable impact on hemodynamics.

Urine output decreases during laparoscopy (64,65).

Patients with cardiac disease (ischemic or myopathic) are at greater risk for intra-operative hemodynamic problems (55,56).

Numerous studies have confirmed the more marked cardiovascular effects of laparoscopy in individuals with cardiac disease. However, thorough patient preparation, attentive monitoring, and careful intraoperative management make pneumoperitoneum tolerable even for these patients (57–59).

TABLE 1 ■ Hemodynamic Response to Laparoscopy

	Intra-abdominal pressure of 15 mmHg	Moderate hypercapnia	Combined
Central venous pressure	Increase	Increase	Increase
Systemic vascular resistance	Increase	Decrease	Increase
Heart rate	Increase	Increase	Increase
Mean arterial pressure	Increase	Increase	Increase
Cardiac output	Decrease	Increase	Variable

Operative laparoscopy can be performed safely in patients with cardiac ejection fractions less than 15% (60), or morbid obesity (54).

Pulmonary

Reduction in lung capacity and compliance, and worsening of ventilation–perfusion mismatch are the most pronounced pulmonary effects of intra-abdominal insufflation with CO_2. These effects are exacerbated by the head-down tilt position for pelvic laparoscopy.

The response to these factors is a tendency toward atelectasis, hypoxemia, and hypercapnia. CO_2 absorption has no direct effect on pulmonary function. The anesthesiologist's manipulation of ventilatory parameters during laparoscopy allows the body to keep pace with the excess CO_2 absorbed by the peritoneal membrane.

Normal pulmonary function is adequate to eliminate the small amount of absorbed CO_2. In most patients, any tendency toward an increase in $PaCO_2$ owing to CO_2 absorption and worsened lung mechanics is easily addressed by increasing minute ventilation.

Because invasive arterial-blood gas sampling is required to measure $PaCO_2$, end-tidal CO_2 [$P(et)CO_2$] is monitored intraoperatively with capnography to estimate the $PaCO_2$ during general anesthesia; the $P(et)CO_2$ is 3 to 5 mmHg lower than the $PaCO_2$. The $P(a\text{-}et)CO_2$ gradient, equal to the difference between $PaCO_2$ and $P(et)CO_2$, is not significantly worsened during short laparoscopic procedures in healthy patients (39,53,61). Therefore, a sustained $P(et)CO_2$ between 30 and 40 mmHg indicates acceptable $PaCO_2$ in most patients. In patients with pulmonary disease, however, a $PaCO_2$ rise causes an unpredictable $P(a\text{-}et)CO_2$ increase (62,63). Sampling of arterial blood gases may be necessary to monitor accurately the CO_2 elimination in patients with pulmonary disease.

Renal and Hormonal

Urine output decreases during laparoscopy (64,65). In one study, urine output during laparoscopy was only 0.03 mL/kg/hr, compared to 1.70 mL/kg/hr immediately postoperatively, despite an average intravenous intraoperative fluid administration of 13.0 mL/kg/hr (66). In rodents, an intra-abdominal pressure less than 10 mmHg produces only mild oliguria, whereas pressures greater than 10 mmHg reduce urine output by 50% to 100% (67). Using a porcine model, McDougall et al. observed a 29% reduction of the urine output during intra-abdominal insufflation at pressures lesser than 10 mmHg, and a 65% reduction with pneumoperitoneum greater than 10 mmHg pressure (68).

The mechanisms involved in oliguria during CO_2 insufflation include (i) increased renal vein resistance (with subsequent decreased renal blood flow); (ii) renal parenchymal compression; (iii) activation of hormonal factors such as the renin–angiotensin system; and (iv) increased levels of antidiuretic hormone (67,69–76).

A reduction in creatinine clearance occurs corresponding to the decreased urine output during laparoscopy. In one study on laparoscopic cholecystectomy, creatinine clearance decreased in 29 of 48 patients, with the decrease being more than 50% in eight patients (77). Creatinine clearance decreased 18% with intra-abdominal pressures less than 10 mmHg, and 53% with pressures above 10 mmHg also in the porcine model studied by McDougall et al. (68).

The kidney appears to be particularly compromised more than other organs by the combination of hypovolemia and increased intra-abdominal pressure (27).

In addition to the respiratory acidosis that usually accompanies CO_2 insufflation, various investigators have reported coexisting trends toward both metabolic alkalosis (61) and metabolic acidosis (53,78). Experimentally, metabolic acidosis is noted only at gas insufflation pressures greater than 20 mmHg (68). The cause does not appear to be lactate acidosis from splanchnic hypoperfusion because there is no increase in the anion gap. Reduction in renal function due to acid retention occurring at high intra-abdominal pressures is a more likely etiology (68).

Several studies have evaluated systemic stress, immunologic derangement, and inflammation associated with laparoscopy using a number of humoral and cell-mediated measures.

When compared to open surgery, laparoscopy tends to be associated with less stress, immunologic compromise, and inflammation. However, results of published studies have been markedly variable in this regard (73,79–89).

Many of the effects appear to be related to CO_2 directly (84,90). Although laparoscopy appears to be beneficial in terms of less impact on nitrogen balance and energy metabolism when compared to open surgery, the clinical significance of these findings is uncertain (88,91,92).

Responses to Alternative Techniques

Retroperitoneal Insufflation

Pathophysiology of laparoscopy has been investigated vis-a-vis intraperitoneal insufflation of gas. Although many of the phenomena pertaining to gas insufflation into the peritoneal cavity likely apply to retroperitoneal insufflation as well, some important differences need to be highlighted. Some clinical studies have suggested that extraperitoneal insufflation (51,93,94) increases CO_2 absorption; however, experimental studies failed to prove this finding (95–97). Using cuffed-balloon ports that minimized gas leakage into the subcutaneous tissue as opposed to the conventional ports used in prior clinical studies, Ng et al. (98) found no difference in CO_2 absorption during extraperitoneal versus transperitoneal laparoscopy, suggesting that subcutaneous emphysema may have confounded the earlier clinical studies.

When compared to intraperitoneal insufflation, extraperitoneal insufflation appears to have less untoward physiologic sequelae.

In two different experimental studies in the porcine model, extraperitoneal insufflation altered venous pressures and cardiac output similar to intraperitoneal insufflation, but of a lesser magnitude (96,97). Giebler et al. found no change in cardiac output up to retroperitoneal insufflation pressures of 20 mmHg (99). In a comparative clinical study, the same investigators subsequently determined that retroperitoneal insufflation actually augmented venous return slightly, whereas intraperitoneal insufflation reduced venous return (100). The smaller volume of gas required to fill the retroperitoneal space compared to the intraperitoneal space may possibly account for some of these differences.

Alternative Insufflants/Gasless Laparoscopy

The rapid absorption of CO_2 is well tolerated physiologically as long as the hypercapnia can be maintained at moderate levels ($PaCO_2$ = 45 mmHg). In fact, cardiovascular stimulation by moderate hypercapnia alleviates some of the hemodynamic burden of pneumoperitoneum (35,36,45–47). However, because excessive hypercapnia is cardiodepressive and can produce dysrhythmias (see below), there has been interest in investigating alternative gases for laparoscopic insufflation. Following the first published reports of the physiologic hazards of CO_2 pneumoperitoneum (101), nitrous oxide (N_2O) was employed as an alternative gas insufflant (102). N_2O is similar to CO_2 in its rapid absorption (Table 2) and has fewer physiologic effects at the blood concentration achieved with intraperitoneal insufflation. N_2O, however, can support combustion in the abdominal cavity.

N_2O is a suitable alternative for intra-abdominal insufflation only if a heat source (electrocautery or laser) is not used. N_2O insufflation is excellent for diagnostic laparoscopy under local anesthesia because it is less irritating than CO_2 to the peritoneal membrane (103–105).

Helium and argon, monoatomic noble gases not supporting combustion, are other alternative gases (47,106). These gases are not associated with insufflant-related cardiopulmonary problems (106,107), and are absorbed slowly (Table 2). Because argon may have some adverse hemodynamic effects, helium appears more attractive (105). Helium insufflation has been successfully employed in several clinical laparoscopic series (46,108–110). For example, laparoscopic nephrectomy being performed in a patient with severe pulmonary disease who developed extreme hypercapnia was completed after switching the insufflant gas to helium (111). The slow absorption of helium is a liability, however, because the clinical effects of a venous gas embolism may be exacerbated (see below). Because the risk of venous gas embolism is higher during the initial insufflation, starting the procedure with CO_2 insufflation and then switching to helium

---

Sidebar 1: When compared to intraperitoneal insufflation, extraperitoneal insufflation appears to have less untoward physiologic sequelae.

Sidebar 2: N_2O is a suitable alternative for intra-abdominal insufflation only if a heat source (electrocautery or laser) is not used. N_2O insufflation is excellent for diagnostic laparoscopy under local anesthesia because it is less irritating to the peritoneal membrane than CO_2.

TABLE 2 ■ Insufflant Characteristics

	Solubility[a]	Diffusibility[a]	Tissue permeance[a]
Nitrogen	1.0	1.0	1.0
Helium	0.7	2.7	1.3
Oxygen	1.9	0.9	1.8
Argon	2.2	0.9	2.0
Nitrous oxide	33.0	0.9	28.0

Gasless laparoscopy is another alternative to CO_2 pneumoperitoneum in patients with significant cardiac or pulmonary disease, which would place them at risk of physiologic complications during CO_2 pneumoperitoneum.

to address the occurrence of dangerous hypercapnia is probably the best approach (111,112). The gas regulator used for helium is different than that for CO_2; thus, even if helium tanks are available to the surgeon, these gases cannot be used until the appropriate gas-specific regulator has been fitted to the laparoscopic insufflator. Due to flow characteristics different from CO_2, helium alters the behavior of the insufflator and leaks more easily around laparoscopic ports.

Finally, laparoscopy can be performed with an abdominal wall–lifting device creating a working space without insufflation of gas. There are many technical concerns with this approach, including more difficult surgical exposure for some procedures and no pneumoperitoneum-induced tamponade of bleeding by increased intra-abdominal pressure from gas insufflation. From the physiological standpoint, however, the use of an abdominal wall–lifting device rather than pneumoperitoneum obviates all of the aforementioned physiological considerations (65,113,114).

Gasless laparoscopy is another alternative to CO_2 pneumoperitoneum in patients with significant cardiac or pulmonary disease, which would place them at risk of physiologic complications during CO_2 pneumoperitoneum.

PHYSIOLOGIC COMPLICATIONS

The knowledge of laparoscopic physiology facilitates the avoidance, recognition, and management of physiologic complications.

Most physiologic complications may be prevented by knowledgeable control of intra-abdominal pressure and fluid status, and careful intraoperative patient monitoring. However, complications can occur even in prepared hands.

Most physiologic complications may be prevented by knowledgeable control of intra-abdominal pressure and fluid status, and careful intraoperative patient monitoring. However, complications can occur even in prepared hands.

Cardiovascular Collapse
Tension Pneumoperitoneum

Tension pneumoperitoneum is the precipitous reduction of venous return, cardiac output, and blood pressure due to increased intra-abdominal pressure from gas insufflation.

Tension pneumoperitoneum is the precipitous reduction of venous return, cardiac output, and blood pressure due to increased intra-abdominal pressure from gas insufflation (115).

Fatalities have been reported (116). As intra-abdominal pressure becomes excessive, e.g., greater than 40 mmHg, vascular resistance increases and overwhelms the increase in venous pressure driving venous return. The effect of elevated intra-abdominal pressure is potentiated by hypovolemia (21,22); therefore, volume status must be optimized before laparoscopy. Parra et al. (117) reported the development of tension pneumoperitoneum caused by a malfunctioning insufflator allowing the intra-abdominal pressure to exceed 32 mmHg. Although the procedure was completed after returning to an appropriate level of pneumoperitoneum and administrating atropine, the patient exhibited hypotension and bradycardia, and suffered a cerebrovascular accident thought to be due to the intraoperative event.

Whenever hemodynamic compromise due to excessive intra-abdominal pressure is suspected, immediate desufflation will quickly improve the situation, and the surgeon may be able to complete the procedure using a lower intra-abdominal pressure.

Whenever hemodynamic compromise due to excessive intra-abdominal pressure is suspected, immediate desufflation will quickly improve the situation, and the surgeon may be able to complete the procedure using a lower intra-abdominal pressure (115).

Although brief periods of intra-abdominal pressures of 20 mmHg and above during laparoscopy are well tolerated in healthy patients and are used by many surgeons at the outset of a procedure to make primary port insertion safer and easier, the pressure should be kept at 15 mmHg or less for the majority of the duration of the procedure. Occasionally, even typically acceptable pressures (15 mmHg) can be associated with hemodynamic deterioration (118). A reasonable precaution against hemodynamic compromise is to operate at the minimal intra-abdominal pressure that provides adequate exposure (87).

A reasonable precaution against hemodynamic compromise is to operate at the minimal intra-abdominal pressure that provides adequate exposure.

Venous Gas Embolism

A venous gas embolism is a gas bubble in the venous system. Clinically significant venous gas embolism passes into the heart and pulmonary circulation, blocking the pulmonary circulation with subsequent hypoxemia, hypercapnia, and depressed cardiac output. Several fatalities have been reported (119–121). If pressure in the right heart exceeds that in the left heart, a foramen ovale defect may allow gas to embolize into the arterial system (20,119,120). Symptomatic venous gas embolism is rare during laparoscopy, with an estimated incidence of 0.002% to 0.08% (122). Using careful surveillance with echocardiography, however, detectable venous gas embolism were noted in 0.59% of laparoscopic cases in one study (123).

Most venous gas embolisms occur during and within a few minutes of initial gas insufflation, but delayed cases have been reported.

Most venous gas embolisms occur during and within a few minutes of initial gas insufflation, but delayed cases have been reported (119).

The most useful indication of venous gas embolism is (i) a sudden fall in P(et)CO$_2$ on capnometry if the CO$_2$ embolus is large or (ii) its abrupt but transient increase if the CO$_2$ embolus is small.

Venous gas embolism has also been produced experimentally in a bleeding vena cava model. In this setting, the risk is greatest when blood flow cephalad from the venotomy is reduced, owing to either mechanical occlusion of the vena cava or significant blood loss (124). At any point in the laparoscopic procedure, when a venotomy is created and flow past the injury is reduced, venous gas embolism must be considered. However, if the cavotomy is appropriately managed with attention to minimizing blood loss and potential for gas entering the proximal end, then venous gas embolism is unlikely (125).

The most useful indication of venous gas embolism is (i) a sudden fall in P(et)CO$_2$ on capnometry if the CO$_2$ embolus is large or (ii) its abrupt but transient increase if the CO$_2$ embolus is small (121,126).

Other clinical signs of venous gas embolism include hypoxemia, pulmonary edema, increased airway pressure, hypotension, jugular venous distention, facial plethora, dysrhythmias, auscultation of a mill-wheel cardiac murmur, or the appearance of a widened QRS complex with right heart strain patterns on electrocardiography.

Venous gas embolism should be suspected in the presence of clinical indicators, especially if they occur suddenly or during initial insufflation. Swift response may be lifesaving.

Venous gas embolism should be suspected in the presence of clinical indicators, especially if they occur suddenly or during initial insufflation. Swift response may be lifesaving.

The goal is to minimize further passage of gas into the pulmonary circulation, and to correct the ventilation problems.

Immediate desufflation prevents more gas from entering the venous system. Placing the patient in a steep head-down tilt position with the right side up tends to trap gas in the right ventricle and prevent passage into the pulmonary circulation. Rapid ventilation with 100% oxygen and general resuscitative maneuvers are recommended to address hypoxemia, hypercapnia, and hypotension.

Immediate desufflation prevents more gas from entering the venous system. Placing the patient in a steep head-down tilt position with the right side up tends to trap gas in the right ventricle and prevent passage into the pulmonary circulation. Rapid ventilation with 100% oxygen and general resuscitative maneuvers are recommended to address hypoxemia, hypercapnia, and hypotension.

If a central venous catheter is already in place, attempts to aspirate the gas are reasonable (127).

The nature of the gas that embolizes is an important determinant of the outcome of venous gas embolism (128). As outlined in Table 2, CO$_2$ is 47 times more soluble than nitrogen. A venous gas embolism composed of CO$_2$ would therefore be reabsorbed much more quickly than one composed of nitrogen. Comparing intravenous injection of air versus CO$_2$ in a canine model, LD50 (lethal dose in 50% of subjects) of air (~80% nitrogen) was five times lesser than LD50 of CO$_2$ (129). Helium, used as an alternative to CO$_2$ for insufflation in some series (46,108–110), is even less soluble than nitrogen. In canine experiments, intravenous injection of helium was lethal on four of six occasions whereas injection of the same amount of CO$_2$ was followed by hemodynamic recovery in all cases (Fig. 4) (130). Argon venous gas embolism during use of a laparoscopic argon beam coagulator has been reported (131).

Hypercapnia

The moderate hypercapnia that occurs during most laparoscopic procedures using CO$_2$ pneumoperitoneum is beneficial via a mild sympathetically mediated cardiostimulatory effect. However, the direct cardiodepressive effects of CO$_2$ and the severe respiratory acidosis associated with hypercapnia of this magnitude can lead to cardiovascular collapse and/or fatal dysrhythmias if the level of PaCO$_2$ exceeds 60 mmHg (132–134).

The moderate hypercapnia that occurs during most laparoscopic procedures using CO$_2$ pneumoperitoneum is beneficial via a mild sympathetically mediated cardiostimulatory effect. However, the direct cardiodepressive effects of CO$_2$ and the severe respiratory acidosis associated with hypercapnia of this magnitude can lead to cardiovascular collapse and/or fatal dysrhythmias if the level of PaCO$_2$ exceeds 60 mmHg.

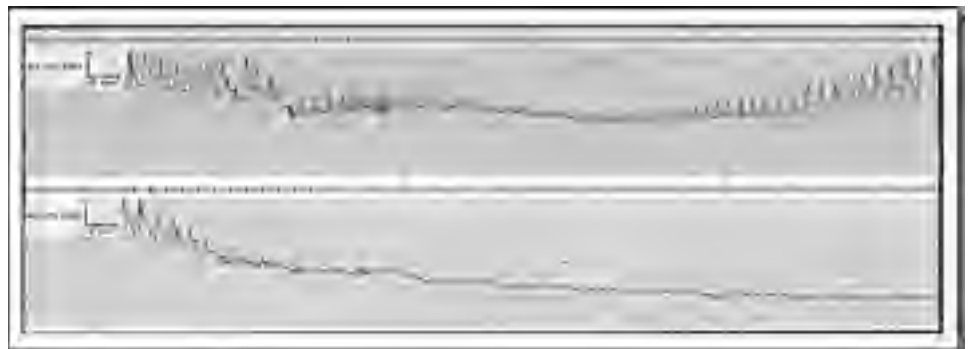
In healthy patients, hypercapnia is due to absorption of the insufflated CO$_2$, rather than any change in tissue metabolism or pulmonary function (106). In three clinical studies comparing N$_2$O insufflation to CO$_2$ insufflation during laparoscopy under general anesthesia with fixed ventilation, the increase in PaCO$_2$ averaged 10.7 mmHg in the CO$_2$ group and 0.5 mmHg in the N$_2$O group (45,78,102). The clinical practice during laparoscopy of increasing ventilation rates and tidal volumes to increase CO$_2$ elimination is usually but not always effective. In one laparoscopic cholecystectomy series,


FIGURE 4 ◼ Arterial tracing after rapid intravenous injection of 7.5 cc/kg CO$_2$ (*top*) and helium (*bottom*) in a dog. There is recovery within one minute after the CO$_2$ injection but complete cardiovascular collapse after the helium injection. *Source*: From Ref. 130.

A diffusion limit of carbon monoxide measurement less than 50% of the predicted value is predictive of the inability to adequately eliminate CO_2 during laparoscopy with CO_2 pneumoperitoneum. In such patients, open surgery, alternative gases, or gasless laparoscopy should be considered.

Reduction of intra-abdominal pressure to the lowest pressure that allows acceptable exposure is prudent, facilitates CO_2 elimination by reducing the interference of pneumoperitoneum with pulmonary mechanics, and reduces CO_2 absorption.

Typically, tachycardia and ventricular extrasystoles associated with CO_2 stimulation are benign and can be prevented by avoiding excessive hypercapnia.

Intraperitoneal gas may leak into several extraperitoneal tissue planes or spaces. Subcutaneous emphysema is the most common site.

Spontaneous pneumomediastinum and pneumothorax may occur during laparoscopy without any evidence of diaphragmatic injury. Although usually with no clinical significance, they can inhibit cardiac filling and limit lung excursion. Fatality has been reported.

6.7% of procedures had to be converted to open surgery because of hypercapnia (62), and similar conversion rates have been reported during urologic laparoscopy (49,135). Preoperative pulmonary assessment is recommended for patients with clinically significant pulmonary disease.

A diffusion limit of carbon monoxide measurement less than 50% of the predicted value is predictive of the inability to adequately eliminate CO_2 during laparoscopy with CO_2 pneumoperitoneum (136). In such patients, open surgery, alternative gases, or gasless laparoscopy should be considered.

Patients with chronic obstructive pulmonary disease without such severe diffusion impairment can usually undergo laparoscopy without complication (137).

Clinical studies have suggested that CO_2 absorption is increased in the presence of subcutaneous emphysema (51,94,138), elevated intra-abdominal pressure (19), and increased duration of insufflation (38,46,78,112). Some authors have found extraperitoneal insufflation to increase CO_2 absorption (51,93,94), whereas others have not (95–97). As the anesthesiologist monitors the $P(et)CO_2$, any worrisome elevation must be immediately reported to the operating surgeon. Often, just a brief period of desufflation to eliminate the excess CO_2 is all that is needed. When laparoscopy is resumed, rapid ventilation should be continued.

Reduction of intra-abdominal pressure to the lowest pressure that allows acceptable exposure is prudent, facilitates CO_2 elimination by reducing the interference of pneumoperitoneum with pulmonary mechanics, and reduces CO_2 absorption (19).

If hypercapnia recurs, options include aborting the procedure entirely, converting to open surgery, or using alternative insufflants or gasless laparoscopy.

Cardiac Dysrhythmias

When carefully monitored during laparoscopy, cardiac dysrhythmias are noted to occur in 17% to 50% of cases (139,140). Fatal dysrhythmias can occur with marked elevation of $PaCO_2$ (41).

Typically, tachycardia and ventricular extrasystoles associated with CO_2 stimulation are benign and can be prevented by avoiding excessive hypercapnia.

Hypercapnia potentiates parasympathetic actions in some situations (41). Vagal stimulation by peritoneal manipulation or distention during CO_2 laparoscopy can occasionally produce bradydysrhythmias. Asystolic arrest during CO_2 laparoscopy has been reported (132,134). Because vagal reactions may be accentuated during awake laparoscopy (local anesthesia), some recommend premedication with atropine in this setting (141).

Extraperitoneal Gas Collections

Intraperitoneal gas may leak into several extraperitoneal tissue planes or spaces. Subcutaneous emphysema is the most common site.

Etiology of extraperitoneal gas collections may be a technical error such as incorrect insufflation due to superficial needle placement, excessive intra-abdominal pressure, or a malfunctioning insufflator. However, subcutaneous emphysema most commonly occurs due to leakage around a laparoscopic port. Subcutaneous gas is a risk factor for hypercapnia, so its presence should prompt an assessment for hypercapnia and its effects. Gas insufflation into the preperitoneal space or omentum is usually not a concern (although it may also increase the risk of hypercapnia) unless it occurs during the initial Veress needle placement in which case it might interfere with subsequent laparoscopic visualization. Preperitoneal insufflation is occasionally the cause for aborting a laparoscopic procedure (117).

Spontaneous pneumomediastinum and pneumothorax may occur during laparoscopy without any evidence of diaphragmatic injury (Fig. 5) (142–145). Although usually with no clinical significance, they can inhibit cardiac filling and limit lung excursion. Fatality has been reported (146).

Insufflated gas may enter the thorax through many pathways, such as (i) persistent fetal connections (pleuroperitoneal, pleuropericardial, and pericardioperitoneal); (ii) extrafascial plane around great vessels; (iii) in between diaphragmatic fibers (extraperitoneal or extrapleural); or (iv) dissection of subcutaneous gas from the anterior neck directly into the superior mediastinum (Fig. 6) (122). Pneumothorax also may occur secondary to barotrauma when the peak airway pressure rises with pneumoperitoneum (39). When pneumothorax occurs, it is usually accompanied by pneumomediastinum and subcutaneous emphysema (51,94,122). Extraperitoneal gas can more easily gain access into the thoracic cavity, either via the extrafascial planes described above or via an increase in subcutaneous emphysema. In a pair of reports from the same institution, pneumomediastinum and/or pneumothorax were noted in 36% of

FIGURE 5 ■ Portable antero-posterior chest radiograph demonstrating extensive subcutaneous emphysema, pneumomediastinum (*black arrowheads*), and bilateral pneumothoraces (white arrowheads) found after laparoscopic pyeloplasty with no evidence of diaphragm injury. Intraperitoneal gas is still present. *Source*: From Ref. 145.

> If CO_2 or N_2O has been insufflated, the pneumothorax usually will resolve. Thoracostomy should be performed to manage a large or symptomatic pneumothorax.

patients undergoing extraperitoneal laparoscopy and in 6% of patients after transperitoneal laparoscopy (51,94).

If CO_2 or N_2O has been insufflated, the pneumothorax usually will resolve (147). Thoracostomy should be performed to manage a large or symptomatic pneumothorax.

Pneumopericardium has also been reported after laparoscopy (142). Subcutaneous gas has been present in all reported cases of pneumopericardium, and in most cases, there has been radiographic evidence of pneumomediastinum as well. The entry of mediastinal gas into the pericardial space alongside blood vessels is the most likely mechanism, although persistent embryological pleuropericardial and pericardioperitoneal connections would also allow gas into the pericardium.

Intra-Abdominal Explosion

The use of pure oxygen for pneumoperitoneum was abandoned after Fervers' (148) 1933 report of an intra-abdominal explosion during laparoscopy with oxygen insufflation. N_2O supports combustion (149) and is explosive in the presence of methane or

FIGURE 6 ■ Possible routes of gas into mediastinum, pericardial sac, or pleural cavity during laparoscopy include persistent fetal connections at the site of pleuroperitoneal membrane (A1, forme fruste of diaphragmatic hernia), pleuropericardial membrane (A2), and pericardioperitoneal canal (A3); leakage of gas through intact membrane at a weak point such as diaphragmatic hiatus (B1), at pulmonary hilum (B2), and pericardial sac alongside blood vessels (B3); gas outside membrane-bound cavities such as pro- or retroperitoneal gas in between fibers of the diaphragm or alongside great vessels (C1) or subcutaneous gas from the anterior neck (C2); gas from the rupture of an airspace (barotrauma) enters the mediastinum or pleural cavity by dissecting along the pulmonary vasculature (D). *Source*: From Ref. 122.

To reduce the risk of explosion, both inhaled and insufflated N_2O should be avoided when electrocautery or laser might be used.

hydrogen (150). Although the necessary conditions for explosion in association with N_2O pneumoperitoneum are rare (151), cardiac rupture and death from an explosion during N_2O pneumoperitoneum has been reported (152). Hydrogen at a concentration of 69% (the maximum reported content of hydrogen in bowel gas) is combustible in the presence of 29% N_2O (153). It has been determined that when the anesthetic gas contained 60% N_2O, the N_2O content in the peritoneal cavity increased to 36% after 30 minutes of CO_2 pneumoperitoneum (153).

To reduce the risk of explosion, both inhaled and insufflated N_2O should be avoided when electrocautery or laser might be used.

Even without N_2O insufflation, electrocautery injury to the colon can produce explosion (154).

Other Physiologic Complications

Venous Thrombosis

As demonstrated by Doppler flow studies, the increased intra-abdominal pressure of pneumoperitoneum diverts blood from the splanchnic circulation into the lower extremities, with subsequent lower-extremity venous engorgement and stasis during transperitoneal laparoscopy.

As demonstrated by Doppler flow studies, the increased intra-abdominal pressure of pneumoperitoneum diverts blood from the splanchnic circulation into the lower extremities (155), with subsequent lower-extremity venous engorgement and stasis during transperitoneal laparoscopy (Fig. 7) (156–158).

Femoral vein pressure generally parallels intra-abdominal pressure. Comparing intraperitoneal and preperitoneal gas insufflation in the same patients, one study demonstrated that femoral vein flow decreased with the former but not the latter (159). In two studies comprising 133 patients, no cases of deep venous thrombosis were detected with lower limb venous duplex scans following low-risk laparoscopic surgery (157,160). Larger series using clinical rather than routine imaging assessment have described a 0% to 1% incidence of deep venous thrombosis after laparoscopy (161–164). Pulmonary emboli following laparoscopy have also been reported (161,164–167).

The relative risk of thrombotic complications following laparoscopic surgery compared to open surgery is unknown. Until certain laparoscopic procedures have been determined to be at very low risk, prophylaxis against venous thrombosis is recommended.

FIGURE 7 ■ Pneumoperitoneum promotes lower-extremity venous engorgement and stasis. *Source*: From Ref. 122.

The relative risk of thrombotic complications following laparoscopic surgery compared to open surgery is unknown. Until certain laparoscopic procedures have been determined to be at very low risk, prophylaxis against venous thrombosis is recommended.

Use of sequential compression devices during laparoscopy reverses the pneumoperitoneum-induced reduction of femoral vein flow (168). In a study at the author's institution, of 354 consecutive urologic patients, 189 received subcutaneous fractionated heparin for venous thrombosis prophylaxis, and 165 were managed with sequential compression devices (164). Thrombotic complications in the heparin group included two deep venous thromboses without pulmonary emboli (1.0%). In the sequential compression devices group, there were two pulmonary emboli and one thrombosis of a dialysis fistula (1.8%) ($p = 0.03$). The rates of hemorrhagic complication were 18/189 (9.5%) and 6/165 (3.6%), respectively ($p > 0.05$). For urologic laparoscopic patients, these data suggest that fractionated subcutaneous heparin is associated with increased hemorrhagic complications without an apparent reduction in thrombotic complications as compared to sequential compression devices.

Elevated Intracranial Pressure and Cerebral Ischemia

In a small study of pigs insufflated with CO_2 at a pressure of 15 mmHg, the intracranial pressure increased by 5 mmHg (169). In two myelomeningocele patients with ventriculoperitoneal shunts, the intracranial pressure increased more than 15 mmHg above baseline during a CO_2 pneumoperitoneum of 10 mmHg pressure only (170). In another study of 18 patients with ventriculoperitoneal shunts undergoing 19 laparoscopic procedures, however, bradycardia and hypertension, which would be expected if the intracranial pressure increase is clinically significant, were not observed (171). Cerebral vascular engorgement is the probable mechanism of increased intracranial pressure during laparoscopy, although in patients with ventriculoperitoneal shunts, obstruction of the catheter may play a role as well. Patients with significant cerebral vascular disease could suffer ischemia because the cerebral circulation responds to the increased intracranial volume and pressure with a decrease in blood flow (172).

Fluid Overload

Intravenous fluid requirements during laparoscopy are less than during open surgery. The combination of decreased insensible losses (no body cavity open to air) and decreased urine output predisposes patients to volume overloading during laparoscopy.

Intravenous fluid requirements during laparoscopy are less than during open surgery. The combination of decreased insensible losses (no body cavity open to air) and decreased urine output predisposes patients to volume overloading during laparoscopy.

In Clayman's initial nephrectomy series, 2 of the first 10 patients developed transient congestive heart failure, possibly due to excessive intravenous fluid and blood products administration at a time when the decreased urine output during

laparoscopy was not yet appreciated (173). Similar cases have been reported after other laparoscopic procedures (174). Intraoperative fluid administration should be limited to appropriate replacement for blood loss plus a maintenance rate of 5 mL/kg/hr. Because hypovolemia predisposes patients to adverse hemodynamic effects of pneumoperitoneum, the volume status of the patient should be optimized prior to insufflation.

Acute Renal Failure

Despite the well-documented oliguria associated with laparoscopy, acute renal failure following laparoscopy, in the absence of another obvious etiology, is rare.

However, in one 67-year-old man with chronic renal insufficiency, renal tubular acidosis, and hypertension, renal failure lasted for two weeks following laparoscopy (175). The effect of laparoscopy on kidney function is transient, with renal indices returning almost to baseline within two hours of the release of pneumoperitoneum (68). This has been shown to be the case even in a high-risk renal insufficiency model (176). The adverse effects of nephrotoxic agents such as aminoglycosides are not worsened by laparoscopy (177).

If acute renal failure does occur after laparoscopy, other etiologies should be evaluated before ascribing this adverse event to the pneumoperitoneum.

Hypertension

The mild increase in arterial pressure, which occurs in the setting of PaO_2 pneumoperitoneum of 15 mmHg in a healthy patient, is not problematic. Clinically significant hypertension during laparoscopy may be due to pneumoperitoneum-related causes such as hypervolemia (fluid overload in the setting of oliguria), hypoxemia, hypercapnia, or moderately increased intra-abdominal pressure. Hypertension in this setting is a clue to look for these other problems, and the underlying cause, rather than the hypertension itself, should be addressed first.

Hypoxemia

PaO_2 may decrease during laparoscopy for several pneumoperitoneum-related causes, such as decreased cardiac output, worsened ventilation–perfusion mismatch, decreased alveolar ventilation, acidosis, venous gas embolism, and pneumothorax (178). Clinical studies revealed a slight but clinically insignificant reduction of PaO_2 during laparoscopy (21,39,44,62,102). Although one group reported a less than 100 mmHg drop in PaO_2 during N_2O laparoscopy in two patients with heavy smoking history (179), others have found PaO_2 during laparoscopy to be unaffected significantly by preoperative pulmonary status (62).

Hypothermia

Because cold CO_2 is cycled through the pneumoperitoneum, heat may be absorbed from the patient, resulting in hypothermia (180,181). Studies have shown that heating

---

Despite the well-documented oliguria associated with laparoscopy, acute renal failure following laparoscopy, in the absence of another obvious etiology, is rare.

If acute renal failure does occur after laparoscopy, other etiologies should be evaluated before ascribing this adverse event to the pneumoperitoneum.

TABLE 3 ■ Physiologic Recommendations for Laparoscopy

Cardiac and pulmonary status should be assessed preoperatively
Adequate circulating blood volume should be attained preoperatively, but once this is achieved, maintenance level of fluids should be administered intraoperatively
Verify insufflator settings before and during initiation of pneumoperitoneum
Intraoperative monitoring must include end-tidal carbon dioxide
Use the lowest intra-abdominal pressure that will allow adequate exposure of the field
Low-pressure pneumoperitoneum, abdominal wall–lifting devices, or helium for insufflation may be beneficial in some very high-risk patients
Apply sequential compression devices for venous thrombosis prophylaxis

and humidifying the insufflant prevents a decrease in core temperature (182,183), while others have found that there is no effect from this intervention (184–186). With the use of other modalities such as simple heating blankets, core temperatures may actually increase rather than decrease during laparoscopy, even without heating the insufflant (186,187).

SUMMARY

- ■ The primary determinants of the physiologic effects of laparoscopy are the intra-abdominal pressure, the type of gas insufflated, and the position of the patient.
- ■ Table 3 lists physiologic recommendations grounded in scientific evidence and good practice, which should be considered by every surgeon performing laparoscopy.
- ■ Important physiologic issues for the surgeon are the cardiopulmonary health of the patient, preoperative volume status, and careful intraoperative monitoring.
- ■ Surgeons need to be aware of the prevention, recognition, and treatment of physiologic complications during laparoscopy (Table 4). Intraoperative cardiovascular collapse can occur from the physiologic complications of tension pneumoperitoneum, venous gas embolism, hypercapnia, cardiac dysrhythmias, extraperitoneal gas collections, and intra-abdominal explosion.
- ■ Other physiologic complications include venous thrombosis, elevated intracranial pressure/cerebral ischemia, fluid overload, acute renal failure, hypertension, hypoxemia, and hypothermia.

INTRODUCTION

Advances in both imaging capabilities and postprocessing methods have broadened the way in which radiologists can assist urologists in managing laparoscopic surgery patients. For instance, the days of merely characterizing and staging a renal tumor and then later assessing for recurrent or metastatic disease are now gone. The development of multislice computed tomography scanners that can rapidly obtain thin slice image data, advancements in magnetic resonance imaging software design and coil technology, the emergence of sophisticated three-dimensional rendering methods, and the development of laparoscopic ultrasound probes have now allowed the radiologist to participate in the planning of laparoscopic surgery, guiding its performance, and then following patients for possible complications or tumor recurrence.

The laparoscopic urologist must have an accurate understanding of the renal parenchymal and vascular anatomy and tumor location to preserve normal renal tissue and, thus, preserve renal function (1,2).

Imaging methods must now provide anatomic information not previously considered when interpreting computed tomography scans, such as a description or demonstration of the arterial anatomy, venous anatomy, and tumor location and extension into the parenchyma or central renal sinus. The proximity of the tumor to the vascular structures and the pelvocalyceal system, and the number and course of both ureters must also be identified (3–6).

Accurate surgical planning information helps to minimize postoperative complications, such as urinary leak or renal infarct, and to maximize preserved renal parenchyma.

The radiologist's role has also expanded into the operating room. Imaging is frequently used during nephron-sparing surgery. Intraoperative ultrasound is used to localize a tumor, to identify and characterize any additional lesions, and to demarcate surgical margins. Ultrasonography can be performed laparoscopically using specially designed ultrasound transducers. When ablative techniques such as laparoscopic radiofrequency or cryoablation are performed, ultrasound is used to monitor the ablation. After surgery, magnetic resonance or computed tomography is used to assess the success of an ablation and to follow the patient for complications, local recurrence, and metastatic disease.

This chapter discusses the use of computed tomography and magnetic resonance as surgical planning tools specifically for nephron-sparing laparoscopic surgery, although many of these principles have been applied in several other areas of urologic surgery. Dedicated computed tomography and magnetic resonance imaging protocols, their importance for surgical planning, and the use of three-dimensional renderings will be discussed. A discussion of intraoperative laparoscopic ultrasound for nephron-sparing surgery and tumor ablation will follow. Lastly, postoperative imaging follow-up will be discussed.

> The laparoscopic urologist must have an accurate understanding of the renal parenchymal and vascular anatomy and tumor location to preserve normal renal tissue and thus preserve renal function.

> Accurate surgical planning information helps to minimize postoperative complications, such as urinary leak or renal infarct, and to maximize preserved renal parenchyma.

COMPUTED TOMOGRAPHY

Computed tomography is considered the gold standard for detection, diagnosis, and staging of renal cell carcinoma (7,8).

However, both computed tomography (9–14) and magnetic resonance (15,16) are highly sensitive and specific for the detection of solid renal masses and can characterize cystic renal lesions. Magnetic resonance has higher soft-tissue contrast resolution and is more sensitive to intravenous contrast enhancement than computed tomography, but spatial resolution and availability are less than that of computed tomography.

Magnetic resonance is often reserved for problem solving, or for those patients with renal insufficiency or a history of severe allergy to iodinated contrast.

Either computed tomography or magnetic resonance imaging can be used for surgical planning (7,8,15–19). Success with 3-D real-time rendering using computed tomography datasets has led to a preferential use of computed tomography by most centers.

Computed tomography examinations are performed before and after intravenous contrast, but without oral barium contrast because positive enteric contrast material interferes with three-dimensional renderings.

- Patients with a normal or mildly elevated creatinine level (below 2.0 mg/dL) are given a full dose of low-osmolar nonionic contrast agent.
- Patients with any degree of renal insufficiency are instructed to drink fluids after the scan.
- Patients with elevated creatinine levels between 2.0 and 2.5 mg/dL are hydrated intravenously with 0.9 normal saline solution before the examination and also instructed to drink fluids after the scan. Iso-osmolar contrast agents are recommended in these patients because of the reduced nephrotoxicity that has been reported in studies evaluating renal function after coronary angiography (20).
- Patients with creatinine levels of 2.5 g/dL or higher are referred for magnetic resonance imaging, which avoids the increased risk for nephrotoxicity in already compromised kidneys. Also, when renal function is poor, the enhancement of normal parenchyma that is needed in order to detect small tumors does not occur.

Developments in computed tomography technology have been dramatic in the last 15 years. Spiral or helical computed tomography was developed in the early 1990s. This revolutionary advancement allows for the constant acquisition of computed tomography data while the patient moves through the scanner gantry, with the X-ray tube rotating continuously around him. Rather than the individual slices that were obtained with prior nonspiral technology, a volume of data is acquired. To better depict anatomy or pathology, this volume can then be reformatted electronically into planes other than the axial plane in which it was obtained. Additional advantages of spiral technology include faster image acquisition, so that the dynamics of contrast enhancement can be exploited and motion artifacts reduced. By late 1998, computed tomography manufacturers developed a further advancement consisting of multirow detector arrays (multirow or multislice helical computed tomography) (21). Rather than one X-ray detector row encircling the patient as he moves through the scanner, multiple rows of detectors are used in this advanced model. In addition to further increasing the speed of scanning compared to single row scanners, multiple row scanners achieve true isotropic voxel (volume element) resolution. The elements that are summed up to make an image are cubic and, therefore, can be reformatted in any plane and be equally sharp. This development has allowed for true three-dimensional imaging.

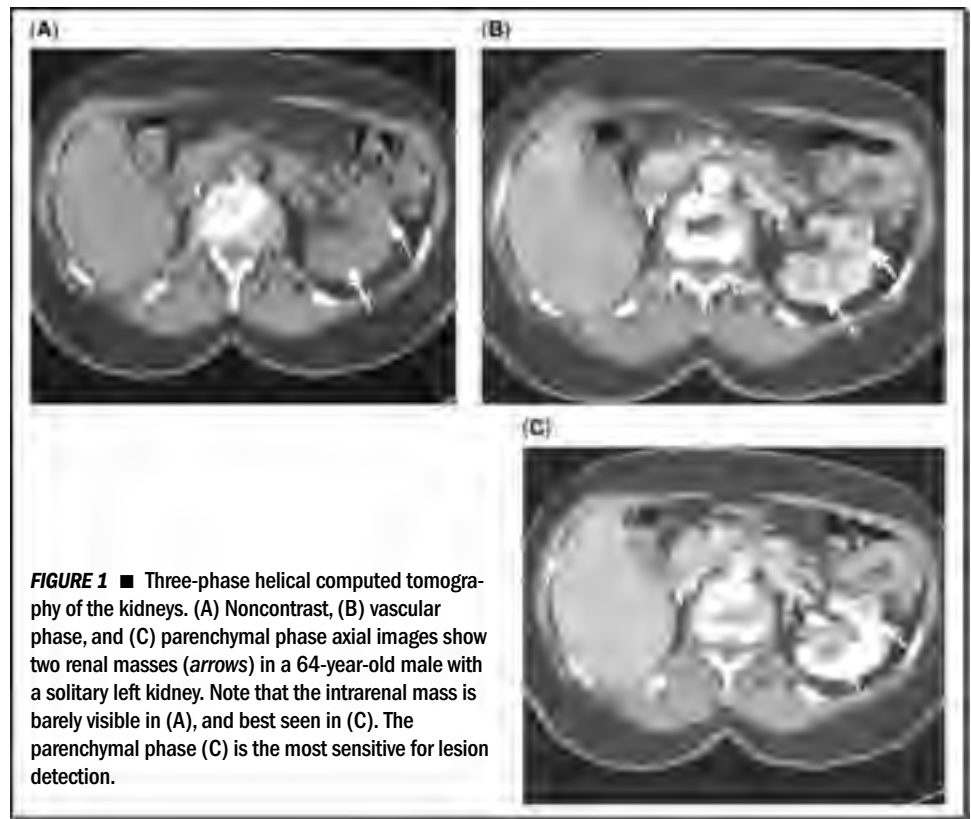
COMPUTED TOMOGRAPHY PROTOCOL FOR LAPAROSCOPIC SURGICAL PLANNING

Three-phase computed tomography protocols are the state-of-the-art for imaging the kidneys and provide all the necessary information for surgical planning for laparoscopic surgery (Fig. 1) (3–5).

These scans should be performed on a multidetector helical scanner, which allows efficient use of intravenous contrast and facilitates creating thin-slice datasets for smooth two-dimensional and three-dimensional reformations.

The first scan phase is a noncontrast computed tomography scanning of the abdomen, including the adrenal glands and both kidneys. This is essential not only to plan the contrast study, but because it provides baseline attenuation value for all renal masses and detects calcifications in the urinary tract and renal lesions.

The second scan phase is a vascular phase computed tomography scan (22). The timing for this phase is determined either by scanning after a test bolus of 20 mL of contrast injected at 3 or 4 mL/sec or by using an automated bolus-tracking technique set to trigger from a threshold value set from enhancement in the upper abdominal aorta. Because extra time is needed to ensure enhancement of the renal

FIGURE 1 ■ Three-phase helical computed tomography of the kidneys. (A) Noncontrast, (B) vascular phase, and (C) parenchymal phase axial images show two renal masses (*arrows*) in a 64-year-old male with a solitary left kidney. Note that the intrarenal mass is barely visible in (A), and best seen in (C). The parenchymal phase (C) is the most sensitive for lesion detection.


veins, an additional five seconds is added. Most scan delays are between 25 and 35 seconds in otherwise healthy patients.

The third scan phase is obtained during the parenchymal or nephrographic phase of enhancement, after a delay of 120 to 150 seconds from the initiation of the bolus contrast injection (the longer delay times are used for older patients or patients with cardiac dysfunction). The parenchymal phase scan is the most sensitive and specific for lesion detection and characterization, but the vascular phase scan is also useful when characterizing masses (7,9–11,15,16,22).

For each scan phase, thin sections (typically 3 mm) are reconstructed without image overlap for diagnostic interpretation and filming. Softcopy (electronic) reading is recommended using a picture archiving and communication system workstation.

In addition to the 3 mm slices for diagnostic interpretation, a separate set of 1 mm thick slices with 20% overlap (reconstruction interval of 0.8 mm) are created and used for multiplanar reformations and three-dimensional real-time volume rendering reconstructions.

The thin slices with image overlap improve the smoothness of reformations and three-dimensional rendering. The computed tomography data is depicted in an imaging plane other than the axial by a process called "multiplanar reformation." multiplanar reformations that are true sagittal and coronal oblique images oriented parallel to the long axis of the kidney are helpful for localization of the tumor within the kidney and are sent to the referring urologist with the diagnostic images. Summing up the highest attenuation pixels within a volume creates a maximum intensity projection.

Thin-section (3–5 mm thickness) coronal oblique thin-slab maximum intensity projections through the aorta and kidneys are helpful for delineating the renal vasculature.

These thin-slab maximum intensity projection images improve visualization of the renal vasculature and facilitate measurements of the distance to first renal arterial branches and distances between renal arterial ostia in those patients with multiple renal arteries. These multiplanar reformations and maximum intensity projection reformations are performed at the scanner console by the technologists using the thin-section (1 mm) dataset and sent for image review along with the diagnostic axial images (Figs. 2 and 3).

MAGNETIC RESONANCE IMAGING

As with computed tomography evaluations, the preoperative evaluation for laparoscopic surgery with magnetic resonance also includes both pre- and postcontrast

---

Sidebar notes (left margin):

In addition to the 3 mm slices for diagnostic interpretation, a separate set of 1 mm thick slices with 20% overlap (reconstruction interval of 0.8 mm) are created and used for multiplanar reformations and three-dimensional real-time volume rendering reconstructions.

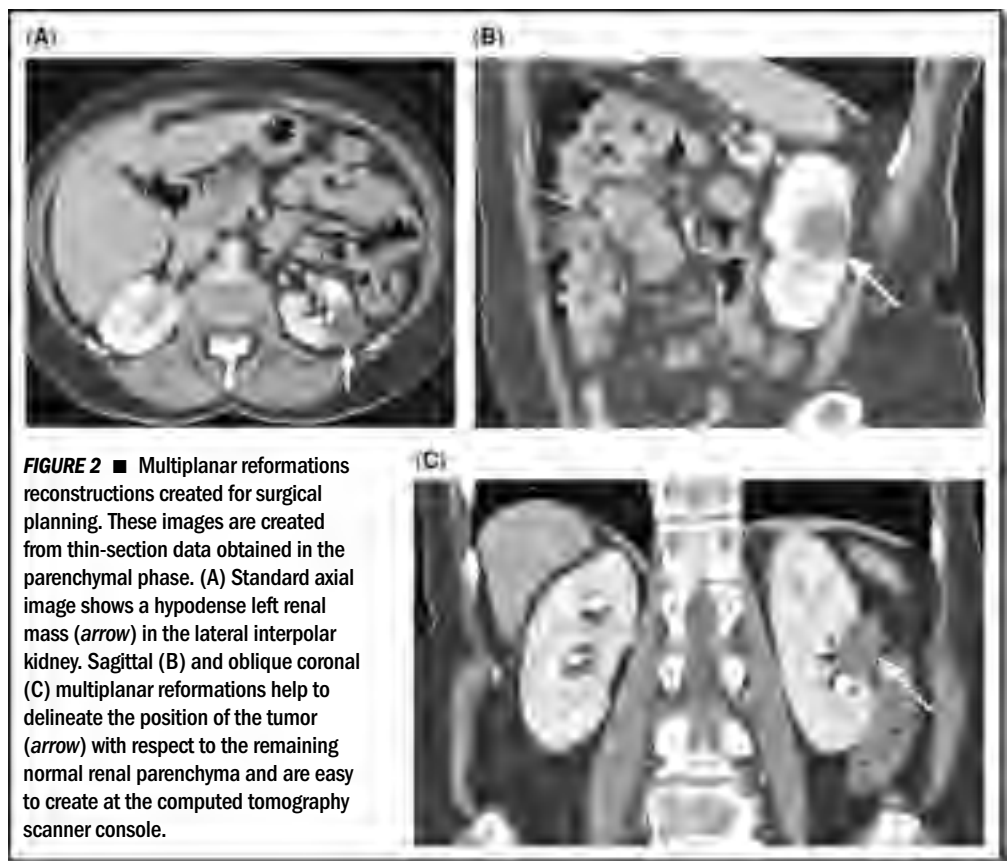
Thin-section (3–5 mm thickness) coronal oblique thin-slab maximum intensity projections through the aorta and kidneys are helpful for delineating the renal vasculature.


FIGURE 2 ■ Multiplanar reformations reconstructions created for surgical planning. These images are created from thin-section data obtained in the parenchymal phase. (A) Standard axial image shows a hypodense left renal mass (*arrow*) in the lateral interpolar kidney. Sagittal (B) and oblique coronal (C) multiplanar reformations help to delineate the position of the tumor (*arrow*) with respect to the remaining normal renal parenchyma and are easy to create at the computed tomography scanner console.

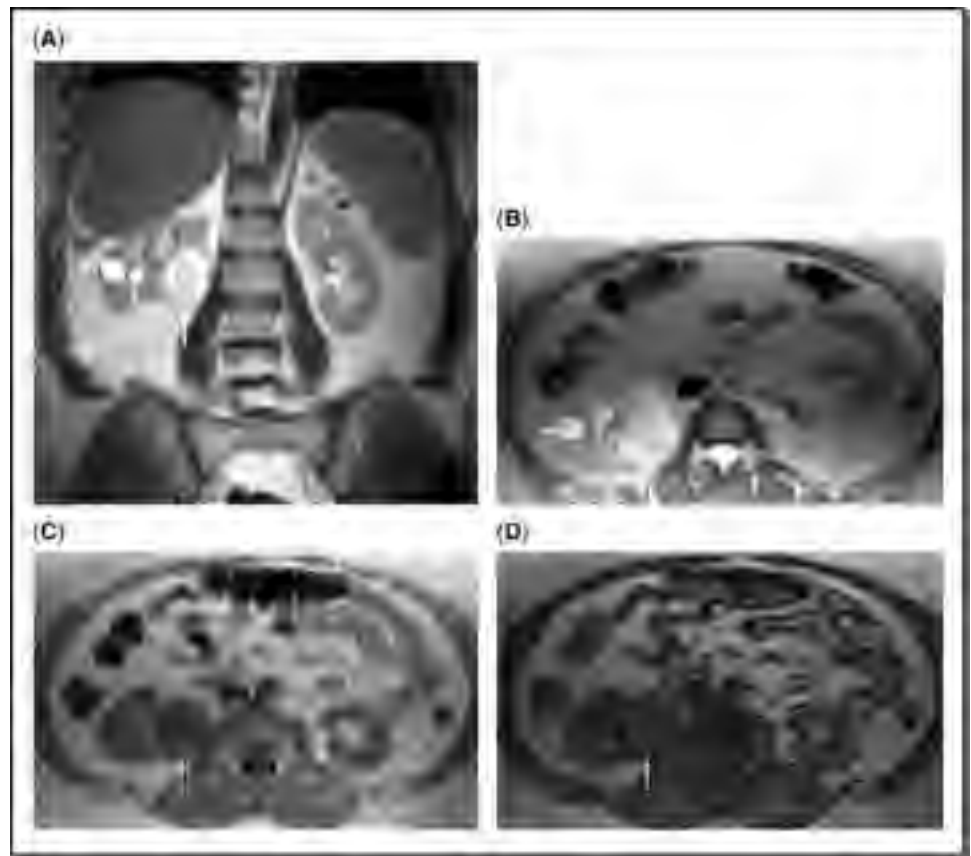
FIGURE 3 ■ Thin-slab maximum intensity projection reconstruction. This image created for surgical planning is created from thin-section data obtained in the vascular phase. Coronal oblique maximum intensity projection through the aorta shows two right renal arteries (*arrows*).

exams (23). As in most body magnetic resonance imaging, the precontrast T1- and T2-weighted imaging is performed to evaluate anatomy, identify abnormalities, and begin characterizing any identified renal or adrenal lesions (Fig. 4). Following intravenous gadolinium administration, postcontrast T1-weighted sequences are performed in multiple phases to define the enhancement characteristics of lesions and to define the anatomy for surgical planning, specifically the arterial, venous, and collecting system anatomy.

The importance of patient preparation and general technique in body magnetic resonance imaging cannot be understated. Anterior and posterior phased array surface coils, rather than a body coil, should be used to increase the signal and must be positioned over the kidneys. Patient motion during image acquisition, including respiratory motion, leads to image blurring and artifacts. Eliminating this motion is an important factor in improving imaging quality in body magnetic resonance imaging. In addition to eliminating image artifacts from respiratory motion, the reproducible suspension of respiration is needed to take advantage of a variety of postprocessing techniques.

The most sensitive technique used to determine the presence of lesion enhancement is image subtraction.

> The most sensitive technique used to determine the presence of lesion enhancement is image subtraction.

FIGURE 4 ■ Precontrast T1- and T2-weighted magnetic resonance images. Coronal (A) and axial (B) precontrast, T2 weighted (half-Fourier single-shot turbo spin echo) show the heterogeneous mixed intensity of this exophytic renal cell carcinoma (*arrow*), a homogeneously hyperintense simple cortical cyst (*arrowhead*), and a distended collecting system in the right kidney (*thin arrow*). (C) Axial, in-phase and (D) out-of-phase, precontrast T1-weighted images showing the generally low-precontrast, T1-weighted signal of a renal cell carcinoma (*arrow*).


With this technique, images obtained before intravenous contrast are mathematically subtracted from images obtained with contrast, so that any remaining signal intensity represents enhancement.

> To perform accurate image subtraction, the datasets to be manipulated must be nearly perfectly aligned in three-dimensional space. Thus, this technique requires reproducible breath holding. This is especially true for evaluating small lesions.

To perform accurate image subtraction, the datasets to be manipulated must be nearly perfectly aligned in three-dimensional space. Thus, this technique requires reproducible breath holding. This is especially true for evaluating small lesions.

To obtain motion-free imaging with specific temporal resolution, the magnetic resonance sequences are kept as short as possible and patients are asked to hold their breath during image acquisition at end expiration. Breath holding is done during end expiration because it is more reproducible. This can be a challenge for some patients; in those who have difficulty suspending respiration at end expiration, hyperventilation and supplemental oxygen can allow longer breath holds, enabling examinations of a much higher quality.

> In anxious, nervous, or claustrophobic patients, using mild anxiolytic medication can allow diagnostic studies to be carried out in patients who would otherwise be unable to follow instructions.

In anxious, nervous, or claustrophobic patients, using mild anxiolytic medication can allow diagnostic studies to be carried out in patients who would otherwise be unable to follow instructions.

MAGNETIC RESONANCE PROTOCOL FOR LAPAROSCOPIC SURGICAL PLANNING

T1-weighted in- and out-of-phase images are obtained using a two-dimensional fast gradient echo sequence without fat saturation. On this sequence, voxels (volume elements) containing both fat and water will have a degree of signal cancellation leading to signal-intensity loss or signal dropout on the out-of-phase images when compared to the in-phase images. Thus, tissue such as lipid-rich adrenal adenomas and liver with fatty infiltration with intracellular or microscopic fat are identified by signal dropout on the out-of-phase images (Fig. 5). A T1-weighted sequence with frequency-specific fat saturation is also employed to identify regions of bulk or macroscopic fat, such as that seen in an angiomyolipoma. This is one of the same sequences used after contrast administration.

> Two goals are achieved by acquiring precontrast and postcontrast data using the same sequence: the precontrast images identify bulk and macroscopic fat, and postprocessing can be performed using the precontrast sequence as a mask for image subtraction.

Two goals are achieved by acquiring precontrast and postcontrast data using the same sequence: the precontrast images identify bulk and macroscopic fat, and postprocessing can be performed using the precontrast sequence as a mask for image subtraction.

Because intravenous contrast volume is small in magnetic resonance imaging, there is typically only a 10-second window of ideal arterial opacification. Therefore, obtaining the proper timing for scans obtained during the arterial phase of imaging is critical.

In patients whose lesions approach the renal sinus, it is desirable to distend the calyces in order to better assess calyceal involvement. Administration of a small dose (10 mg) of intravenous furosemide during the timing examination will promote diuresis, distending the collecting system to achieve a better quality magnetic resonance urogram.

Tumor size, renal vein, and inferior vena cava tumor thrombus, and lymphadenopathy are all criteria used for staging. If the patient is a nephron-sparing surgery candidate, images are transferred to a dedicated three-dimensional imaging workstation for postprocessing, typically using real-time volume-rendering techniques.

Next, T2-weighted images are obtained to detect and evaluate areas of fluid including cystic lesions and the collecting system. These are generally obtained using fast techniques, either fast or turbo spin echo, or single shot fast spine echo or half-Fourier acquisition single-shot turbo spin-echo.

Because intravenous contrast volume is small in magnetic resonance imaging, there is typically only a 10-second window of ideal arterial opacification. Therefore, obtaining the proper timing for scans obtained during the arterial phase of imaging is critical.

A timing examination has been proven useful to consistently obtain images during the arterial phase of contrast enhancement.

Postcontrast imaging is obtained in multiple phases using a gradient echo T1-weighted, three-dimensional interpolated, fat-saturated sequence. This allows a slice resolution of 1.5 mm for images in the coronal plane and 2 mm for images in the axial plane. In-plane resolution for the sequences is at or below the slice thickness. This yields near isotropic voxels and allows data manipulation in multiple planes. Both arterial and venous phase imaging in the coronal plane is obtained using an angiographic sequence. This sequence tends to suppress background tissue signal, thereby highlighting vascular structures (24). Following this, anatomic imaging in the axial plane is obtained during the cortical phase of renal enhancement using a more tissue-sensitive sequence (25). Accurate assessment of the vasculature and characterization of renal lesions is possible by combining these different techniques.

To obtain an magnetic resonance urogram, coronal images are obtained at about 5 to 10 minutes after contrast administration.

In patients whose lesions approach the renal sinus, it is desirable to distend the calyces in order to better assess calyceal involvement. Administration of a small dose (10 mg) of intravenous furosemide during the timing examination will promote diuresis, distending the collecting system to achieve a better quality magnetic resonance urogram.

In patients who are not on chronic furosemide therapy, a dose of 10 mg given intravenously is almost always adequate. For patients who are on chronic therapy, dosage adjustments must be made.

IMAGE INTERPRETATION AND THREE-DIMENSIONAL VOLUME RENDERING

Computed tomography and magnetic resonance images are reviewed to characterize all lesions for lesion size and location and to determine the number of arteries and veins; whether it is local, regional, or distant lymphadenopathy; the presence of renal vein tumor extension; and if it is a local or regional metastatic disease.

Tumor size, renal vein, and inferior vena cava tumor thrombus, and lymphadenopathy are all criteria used for staging. If the patient is a nephron-sparing surgery candidate, images are transferred to a dedicated three-dimensional imaging workstation for postprocessing, typically using real-time volume-rendering techniques (26).

In the past, surface-shaded display renderings have been used for nephron-sparing surgical planning, but they are limited by the need for intensive image editing, which is too time consuming for most radiologists. As shown in Figures 6 and 7, volume rendering typically requires little image editing and preserves the entire dataset (3,4,26,27).

To film images from the diagnostic study, a computed tomography technologist can perform multiplanar reformations and maximum intensity projections easily. However,

FIGURE 6 ■ Volume rendering of renal tumor before nephron-sparing surgery. (A) Conventional axial image and (B) volume-rendered image. Volume rendering uses the entire dataset and projects a three-dimensional view of the renal tumor (*arrow*). The psoas muscle (p) and spleen (s) are seen and provide relational cues to interpreting the image.

because of the quality of information needed for surgical planning, the radiologist typically uses a dedicated three-dimensional workstation to perform real-time three-dimensional volume rendering.

■ Although a set of static images, either digital or filmed, may also suffice, our current practice is to create one or two short MPEG-encoded (.avi) digital movie files for each case, which illustrates the critical anatomy for surgical planning.

FIGURE 7 ■ Volume rendering for nephron-sparing surgery: (A) Vascular phase and (B,C) parenchymal phase computed tomography data volume renderings show a right lower pole renal tumor (*arrows*). With the anterior plane of the image outside the kidney, the surface of the kidney is seen, and the component of the tumor exophytic from the kidney is identified. By using a "clip plane" to image inside the kidney, a large arterial branch is seen within the tumor in (A) (*short arrow*), and the depth of extension of the tumor into the renal hilum is seen in (B) (*arrowhead*).

> ■ At our institution, the anatomical structures and relationships shown by three-dimensional imaging were defined in conjunction with a urologist highly experienced in performing nephron-sparing surgery.
> ■ A thorough discussion between the radiologist and the referring urologist regarding their surgical approach and surgical planning needs is recommended.

Control of the renal vasculature is necessary during nephron-sparing surgery and, therfore, the renal vessels are rendered first. This portion of the rendering shows the size, origin, and course of all renal arteries, renal veins, major segmental arterial branches, left adrenal vein, gonadal vein, and any prominent lumbar veins (Figs. 8–11). Next, using the renal parenchymal phase, renderings show the position of the kidney, tumor location, and depth of tumor extension and its relationship to the pelvocalyceal system (Fig. 12). The rendering process takes between 10 and 30 minutes, depending on the user's experience and case complexity.

Postcontrast three-dimensional magnetic resonance datasets are manipulated and displayed in the same manner as computed tomography data, using a combination of the postcontrast image series. Image subtraction facilitates data analysis and display. Subtraction of the precontrast data from the cortical phase data results in a dataset that can then be used to assess true enhancement within renal lesions, and facilitates the characterization of the lesion (Fig. 13). A gadolinium-enhanced three-dimensional gradient echo magnetic resonance sequence provides inherent suppression of background signal and gives excellent volume-rendered views of the renal vasculature (Fig. 14). Subtraction of the precontrast data from the arterial phase data results in a dataset that has high signal

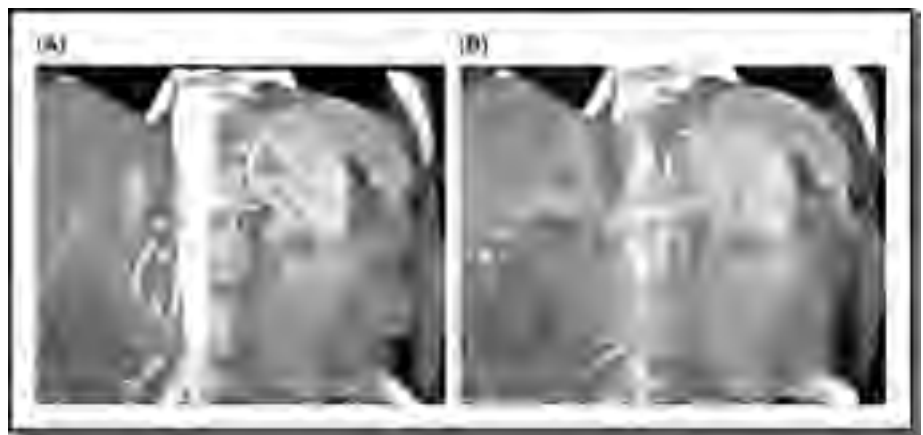
FIGURE 8 ■ Conventional left renal vascular anatomy: Volume-rendered image of the left kidney during the vascular phase shows (A) single left artery (*arrow*) and (B) single left renal vein (*arrow*).


FIGURE 9 ■ Anatomic left renal arterial and vein variants. An early apical polar branch is seen (*black arrow*) supplying the upper pole of the left kidney entering from the cortex. A retroaortic left renal vein (*arrow*) is also identified; retroaortic left renal veins usually cross behind the aorta several centimeters below the level of the renal artery.
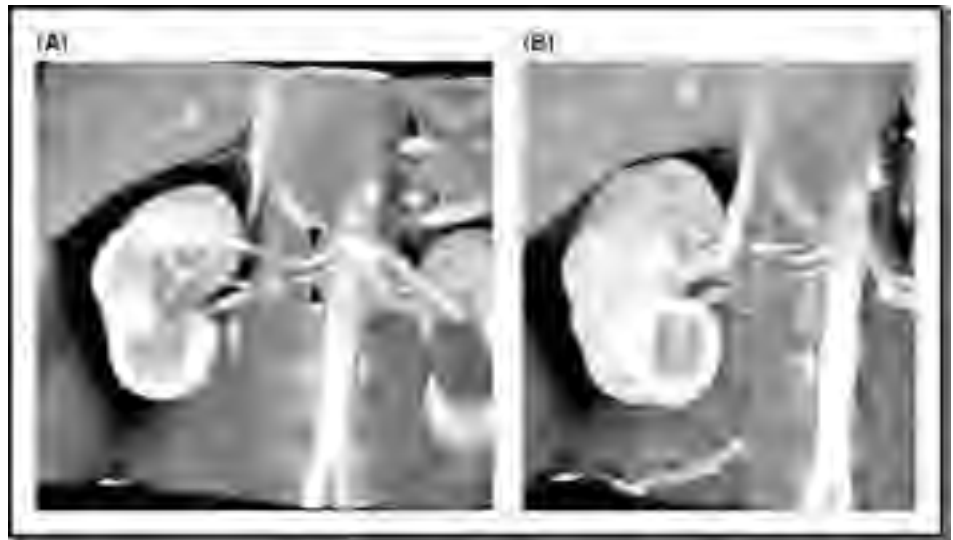

FIGURE 10 ■ Anatomic right renal arterial and vein variants. (A) Two right renal artery origins are seen (*arrowhead*) along with an accessory right renal vein (*arrow*). (B) The main right renal vein is seen (*arrow*) along with an unusual branch of the vein (*long thin arrow*) that results in a third renal vein entrance into the inferior vena cava. The plane in image (B) is slightly more anterior than in image (A).

The enhanced images obtained during the venous phase are useful in assessing vascular invasion (Fig. 15).

contrast within the arteries and suppressed signal in the rest of the image. These can then be used to produce angiographic images, such as maximum intensity projections, with minimal additional editing (28).

The enhanced images obtained during the venous phase are useful in assessing vascular invasion (Fig. 15).

Sequences acquired or reconstructed in the coronal or sagittal plane yield diagnostic information and help localize a lesion within the kidney.

RADIOLOGIC GUIDANCE DURING LAPAROSCOPIC SURGERY

Intraoperative guidance for partial nephrectomy using laparoscopic ultrasound and guidance for laparoscopic tumor ablation is another important role for imaging during nephron-sparing surgery. Dedicated intraoperative probes, which yield high-resolution

FIGURE 11 ■ Accessory right renal artery. Vascular phase volume rendering shows an accessory right renal artery (*arrow*). Right renal arteries that arise from inferior side of the inferior vena cava, off the aorta, often course anterior to the inferior vena cava, as in this patient.

FIGURE 12 ■ Depth of tumor extension. Tumors that extend into the renal hilum (*arrow*) will often abut larger vessels and the pelvocalyceal system (*thin arrow*). This is important for the urologist, who may opt for conservative surgery or be ready to anticipate repair of the collecting system and cauterize the vasculature.

The laparoscopic ultrasound transducer is constructed with the transducer elements on a flexible arm that fits through a 10 mm laparoscopic port. The transducer elements can typically be steered into different positions, although limited by the access ports and flexibility of the transducer. Doppler capability is helpful to identify vascular structures in proximity to the surgical site.

images, are used for intraoperative ultrasound during partial nephrectomy, whether open or laparoscopic (Fig. 16) (29). Such probes are smaller in size than conventional probes, and are shaped for the laparoscopic operative environment. The ultrasound transducer can be placed directly on the surface of the kidney during an open partial nephrectomy.

The laparoscopic ultrasound transducer is constructed with the transducer elements on a flexible arm that fits through a 10 mm laparoscopic port. The transducer elements can typically be steered into different positions, although limited by the access ports and flexibility of the transducer. Doppler capability is helpful to identify vascular structures in proximity to the surgical site.

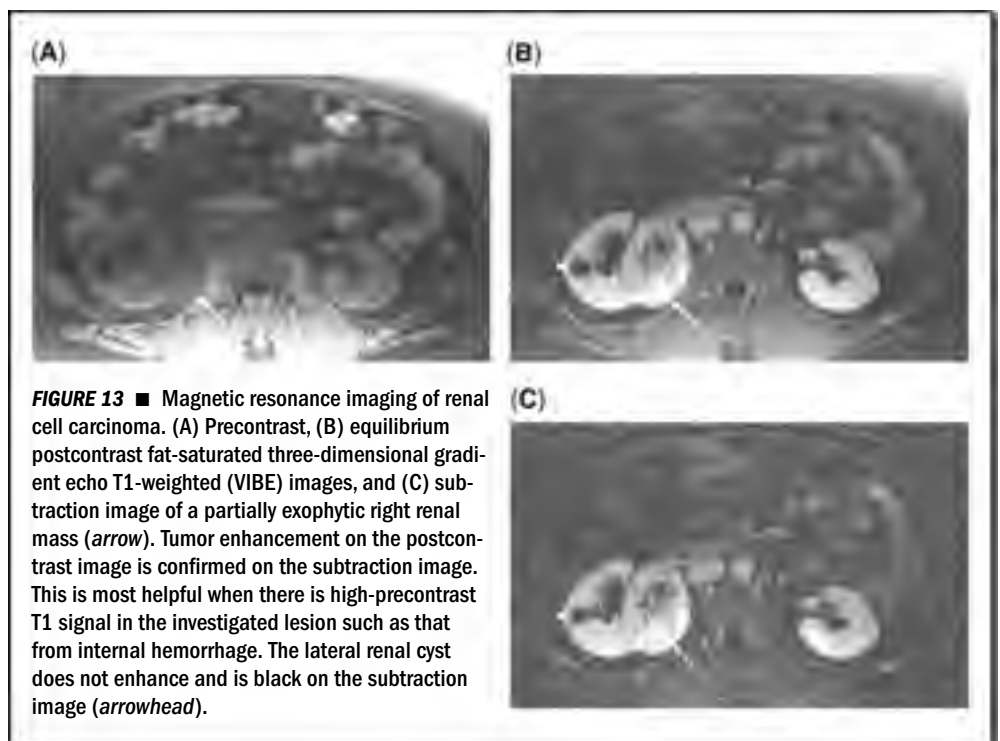
During open partial nephrectomy, the urologist can palpate masses that extend to the renal surface. In this setting, ultrasound is used to localize small intrarenal


FIGURE 13 ■ Magnetic resonance imaging of renal cell carcinoma. (A) Precontrast, (B) equilibrium postcontrast fat-saturated three-dimensional gradient echo T1-weighted (VIBE) images, and (C) subtraction image of a partially exophytic right renal mass (*arrow*). Tumor enhancement on the postcontrast image is confirmed on the subtraction image. This is most helpful when there is high-precontrast T1 signal in the investigated lesion such as that from internal hemorrhage. The lateral renal cyst does not enhance and is black on the subtraction image (*arrowhead*).

FIGURE 14 ■ Volume-rendered arterial phase magnetic resonance for renal vasculature. Both the main right renal artery (*arrowhead*) and a small inferior accessory renal artery (*thin arrow*) are demonstrated on this volume-rendered angiogram. The partially exophytic tumor (*arrow*) is also seen. The arterial phase fat-saturated three-dimensional gradient echo T1-weighted (FLASH) data were used to create the image.

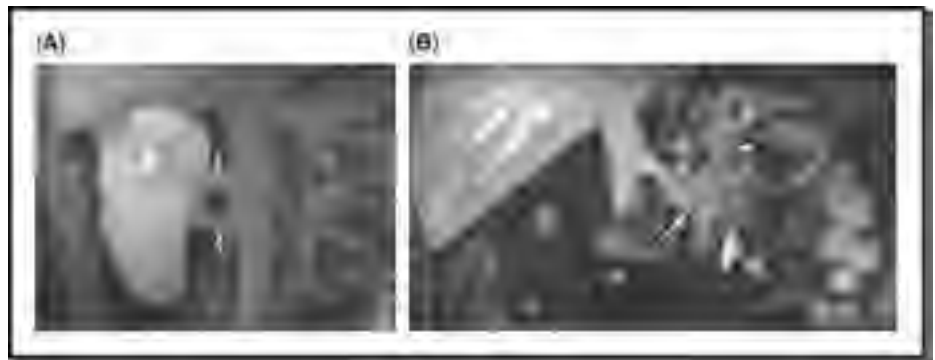
FIGURE 15 ■ Renal vein evaluation by magnetic resonance. Oblique, coronal, thin, maximum-intensity, projection images show two right renal veins (A, *arrows*) and left renal vein expanded by tumor thrombus (B, *arrow*) that does not extend to the inferior vena cava but is seen to extend into the left adrenal vein (*arrowhead*). The images are derived from the equilibrium phase postcontrast fat-saturated 3-D gradient echo T1-weighted (VIBE) data.


FIGURE 16 ■ Intraoperative laparoscopic ultrasound shows an ovoid hyperechoic mass (*arrows*) that extends from the lower pole into the hyperechoic fat of the central renal sinus (S).

During laparoscopic partial nephrectomy, unless a hand-assisted procedure is performed, the ability of ultrasound to localize a renal mass is invaluable, because the tactile cues available during open surgery are not available.

Laparoscopic ultrasound is also used to guide and monitor both cryoablation and radiofrequency ablation of renal masses.

Ultrasound findings correlate well with the actual size and location of the iceball at surgery. Scanning from the surface opposite the cryotherapy probe ensures that shadowing does not obscure deep margin and protects the probe from the cryoablation. Using multiple probe positions (i.e., rotating and translating the probe along the renal surface) may be necessary to ensure complete ablation. Extension of the iceball more than 3 mm beyond the tumor margin ensures adequate freezing of the lesion for cell death.

masses and assess the proximity to the central sinus structures, the pyelocalyceal system, and vessels. The margins of the mass are determined using ultrasound and subsequently demarcated on the renal surface using the electrocautery to score the kidney surface. A search for additional lesions that may not have been identified on preoperative imaging is also performed.

During laparoscopic partial nephrectomy, unless a hand-assisted procedure is performed, the ability of ultrasound to localize a renal mass is invaluable, because the tactile cues available during open surgery are not available.

Most masses treated laparoscopically are small, and some may not be visible on the renal surface. After identifying the mass by ultrasound, the surface of the kidney is scored using electrocautery as during the open procedure.

Laparoscopic ultrasound is also used to guide and monitor both cryoablation and radiofrequency ablation of renal masses.

The position of the mass, as determined by preoperative imaging and any history of prior retroperitoneal or abdominal surgery, is the information used to determine the laparoscopic approach. Once the kidney is mobilized and fat excised for pathological analysis, the tumor and remainder of the kidney are imaged with ultrasound. The mass is biopsied and then punctured with the ablative probe under ultrasound guidance. The probe is visualized as an echogenic line that casts an acoustic shadow.

The critical steps of cryoablation are rapid freezing, slow thawing, and repetition of the freeze–thaw cycle (30,31). The cryoprobe tip is advanced to the deep margin of the mass. The probe tip defines the deep margin of the ablation zone. Cryoablation, unlike radiofrequency ablation, creates a distinct margin of the ablated tissue on ultrasound. The deep margin of the tumor is most at risk for incomplete ablation (32). As cryoablation progresses, an iceball is seen as hyperechoic arc with posterior shadowing (Fig. 17).

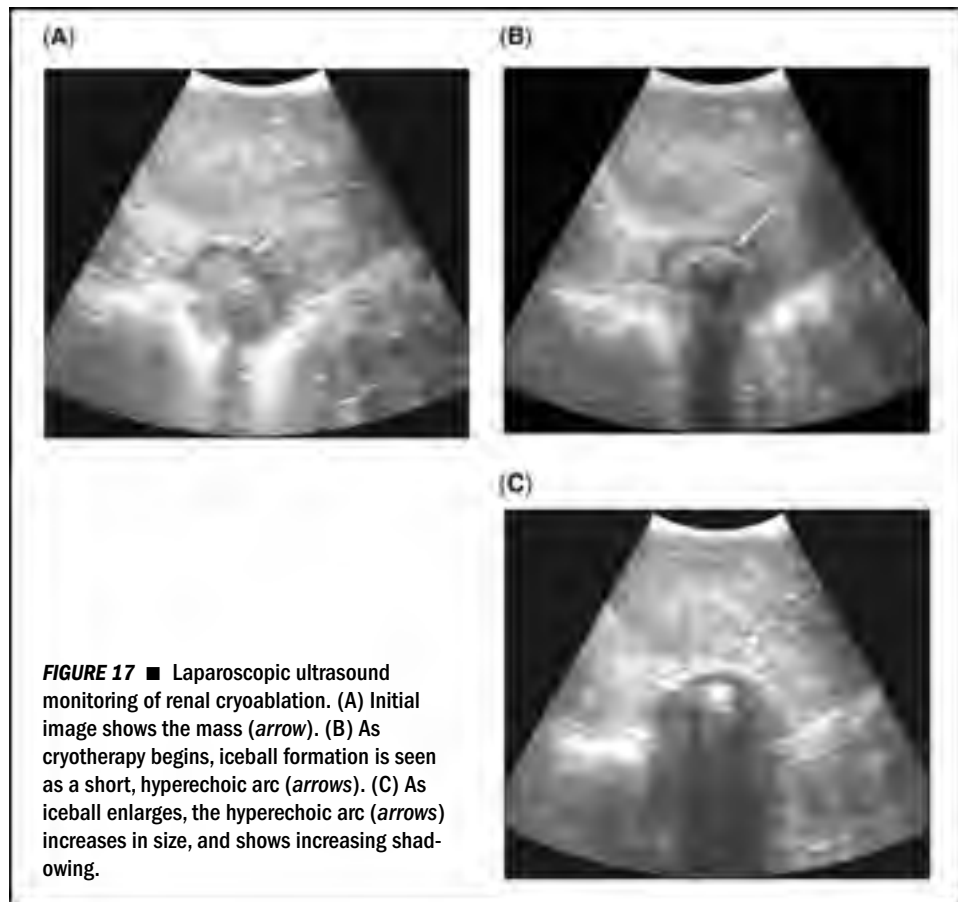
Ultrasound findings correlate well with the actual size and location of the iceball at surgery. Scanning from the surface opposite the cryotherapy probe ensures that


FIGURE 17 ■ Laparoscopic ultrasound monitoring of renal cryoablation. (A) Initial image shows the mass (*arrow*). (B) As cryotherapy begins, iceball formation is seen as a short, hyperechoic arc (*arrows*). (C) As iceball enlarges, the hyperechoic arc (*arrows*) increases in size, and shows increasing shadowing.

FIGURE 18 ■ Percutaneous ultrasound guidance for renal radiofrequency ablation. The radiofrequency ablation electrode is seen as a linear echogenic structure (*arrow*). As the procedure continues, additional bright echoes (*arrowhead*) obscure the renal mass.

shadowing does not obscure deep margin and protects the probe from the cryoablation (33). Using multiple probe positions (i.e., rotating and translating the probe along the renal surface) may be necessary to ensure complete ablation. Extension of the iceball more than 3 mm beyond the tumor margin ensures adequate freezing of the lesion for cell death (34).

During radiofrequency ablation, an electrical current flows from the tip of a needle electrode into the surrounding tissue toward grounding pads placed on the patient's thighs, and produces heat and coagulative necrosis (35). Adequate tissue treatment temperature is 70°C. When monitoring the ablation, increasing bright echoes are visualized from the electrode tip on ultrasound due to microbubble formation (Fig. 18). This provides a rough estimate of the size of the treatment area (36). Larger lesions require the use of multiple overlapping treatment zones to achieve adequate coverage for complete ablation.

> During radiofrequency ablation, the extent of coagulation cannot accurately be predicted, and postprocedural imaging is necessary in order to assess the success of the ablation.

During radiofrequency ablation, the extent of coagulation cannot accurately be predicted, and postprocedural imaging is necessary in order to assess the success of the ablation.

POSTOPERATIVE IMAGING

As laparoscopic techniques are newer than open ones, guidelines for postoperative imaging are less well established.

Patients are seen at four to six weeks after open partial nephrectomy for routine follow-up and have a physical examination, a serum creatinine level check, and an excretory urogram (37). Imaging with computed tomography or ultrasound is performed earlier in any patient who has clinical signs or symptoms of abscess, hematoma, urinary leak, or fistula.

> Patients are seen at four to six weeks after open partial nephrectomy for routine follow-up and have a physical examination, a serum creatinine level check, and an excretory urogram. Imaging with computed tomography or ultrasound is performed earlier in any patient who has clinical signs or symptoms of abscess, hematoma, urinary leak, or fistula.

Generally, a computed tomography scan with intravenous contrast is performed, and if a urine leak is of concern, delayed images should be obtained.

Postoperative surveillance for recurrent disease should be tailored to the initial pathological tumor stage (37).

■ All patients are evaluated annually with a review of history, physical examination, and blood tests including serum calcium, alkaline phosphatase, liver function tests, BUN, serum creatinine levels, and electrolytes.

■ Patients with T1 tumors do not require early postoperative imaging because there is a low risk of recurrent malignancy (38,39).

■ A yearly chest radiograph is recommended for patients with T2 or T3 tumors because the lung is the most common site of metastasis; low-dose chest computed tomography may also be used.

■ Patients with T2 tumors should have computed tomography every two years.

■ Patients with T3 tumors have a higher risk of developing local recurrence, especially during the first two postoperative years, and they should have a computed tomography every six months for two years, then at two-year intervals, if there is no documented tumor recurrence.

The effectiveness of renal tumor ablation and laparoscopic partial nephrectomy has not yet been proven in long-term follow-up studies, and therefore, imaging protocols following the procedure are not standardized, varying among institutions. In our opinion, conservative surveillance is appropriate.

- Patients who have had laparoscopic partial nephrectomy undergo follow-up abdominal and pelvic computed tomography and chest X-ray at six months, one year, and then at yearly intervals.
- Patients who have had cryoablation undergo postoperative magnetic resonance imaging at one day, one month, six months, one year, and annually thereafter.
- Contrast-enhanced computed tomography is the test of choice to search for tumor recurrence in those patients with a normal serum creatinine (40).

Contrast enhancement is important in detecting visceral organ metastases and local recurrence, but there is a risk of nephrotoxicity from iodinated computed tomography contrast in those patients who have had nephron-sparing surgery and have compromised renal function. magnetic resonance imaging is not generally used as a screening examination.

In patients who underwent nephron-sparing surgery and have compromised renal function, magnetic resonance imaging is a reasonable alternative to computed tomography, because the gadolinium contrast used does not pose a risk to renal function in patients with renal insufficiency.

Local recurrence after nephron-sparing surgery manifests as an enhancing mass at the resection site in the residual kidney (Fig. 19). Early on, postsurgical changes are significant after both laparoscopic partial nephrectomy and ablation and should not be confused for residual disease. These postsurgical changes can include perinephric fluid, fat necrosis, urine leak, scarring, or a defect at the operative site (Figs. 20 and 21). Hemostatic agents such as oxidized cellulose (Surgicel®ᵃ) may be present (41) and can mimic abscess formation (Fig. 22). After ablation, the mass progressively decreases in size over time (42,43) and eventually is seen as only a cortical defect (Fig. 23). Incomplete ablation is seen as a residual enhancement at the site of the mass. In our experience, enhancement or mass-like contour change suggests recurrent disease (44).

Metastatic disease can occur in regional lymph nodes or in distant sites. Lung, mediastinal, bone, liver, contralateral kidney, adrenal gland, and brain metastases are common, but metastatic disease can also be seen in the small bowel and peritoneal cavity (45). In this event, imaging reverts to the role of monitoring the treatment of metastatic disease.

> In patients who underwent nephron-sparing surgery and have compromised renal function, magnetic resonance imaging is a reasonable alternative to computed tomography, because the gadolinium contrast used does not pose a risk to renal function in patients with renal insufficiency.

FIGURE 19 ■ Recurrence at site of open partial nephrectomy. A 62-year-old woman had left open partial nephrectomy and right radical nephrectomy 2.5 years previously. Contrast-enhanced computed tomography shows round soft-tissue mass (*arrow*) abutting surgical clips and left renal vein (*arrowhead*).

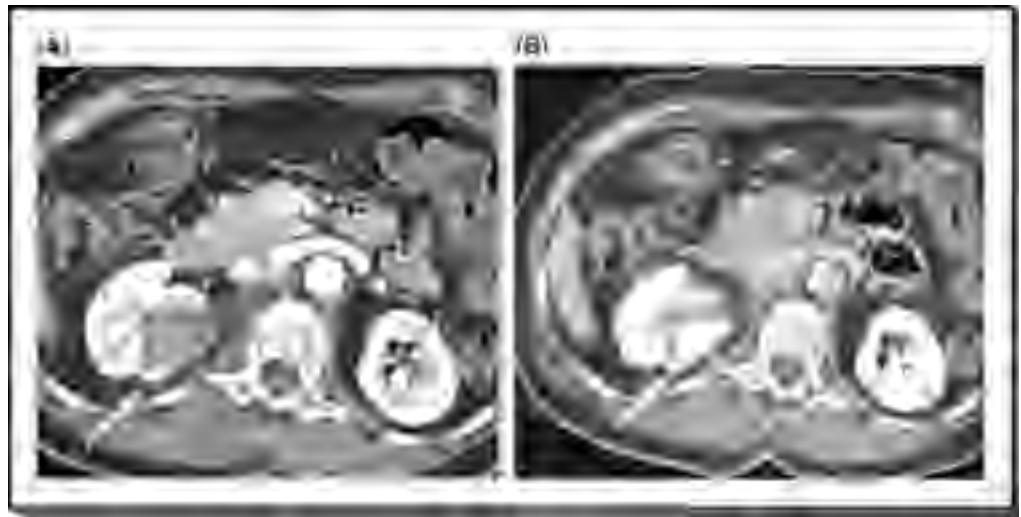
FIGURE 20 ■ Postoperative urine leak following partial nephrectomy. If entry into the collecting system is not identified and repaired at surgery, urine leaks can result. This patient has a perinephric fluid collection (A, *arrow*) after partial nephrectomy that fills in with contrast on a delayed scan (B).


FIGURE 21 ■ Postoperative hemorrhage following partial nephrectomy. The mass (*arrow*) in (A) was resected laparoscopically; the patient complained of left flank pain following the surgery and had a low hemoglobin concentration. Postoperative, unenhanced computed tomography scan (B) shows a perinephric hematoma (*thin arrows*).
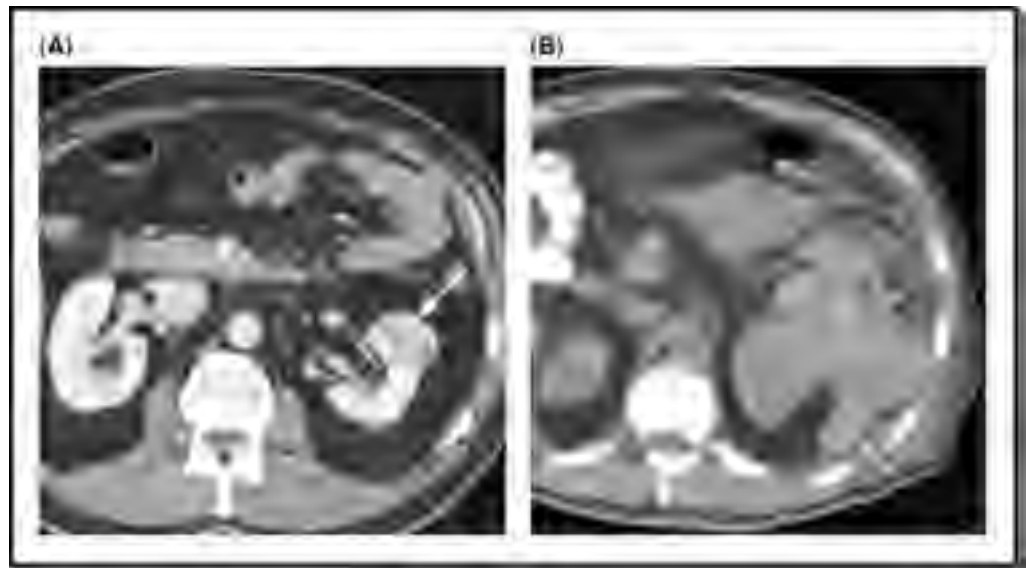

FIGURE 22 ■ Oxidized cellulose (Surgicel®) mimics abscess at laparoscopic partial nephrectomy site. This patient presented to emergency department with flank pain after laparoscopic partial nephrectomy and had a normal white blood cell count. (A) Contrast-enhanced computed tomography demonstrates ovoid collection with scattered gas foci at partial nephrectomy site (*arrow*). No intervention was performed. (B) Computed tomography six months later shows resolution of collection with minimal residual low attenuation (*arrow*).
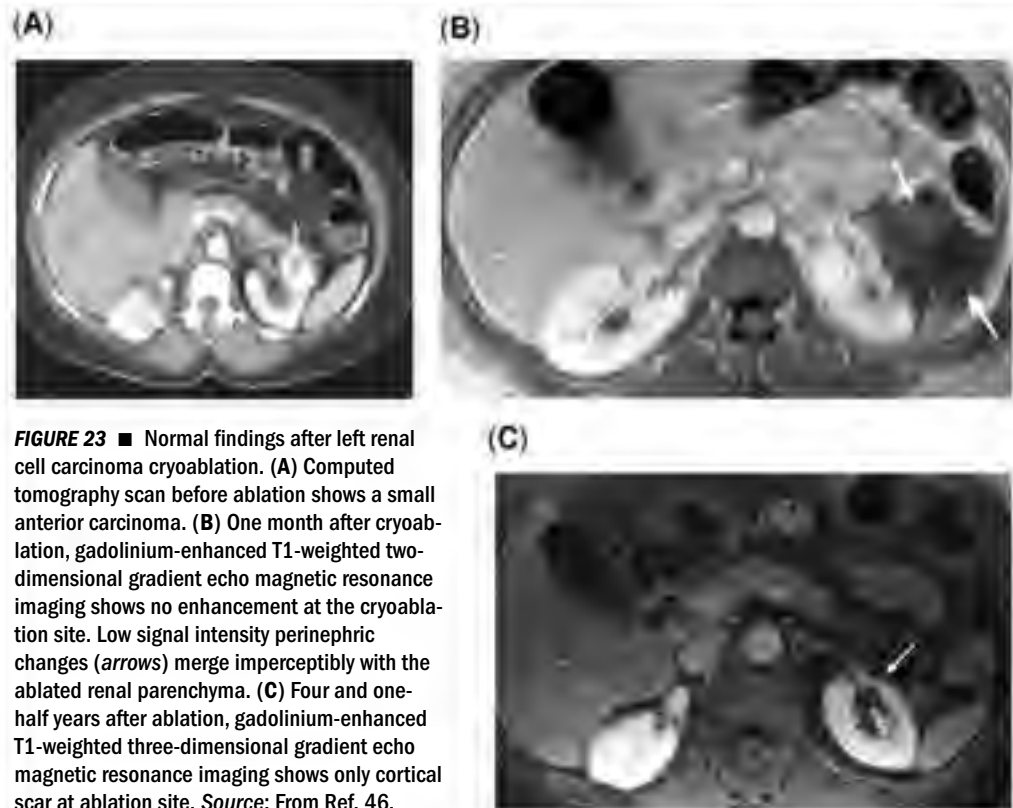

FIGURE 23 ■ Normal findings after left renal cell carcinoma cryoablation. (**A**) Computed tomography scan before ablation shows a small anterior carcinoma. (**B**) One month after cryoablation, gadolinium-enhanced T1-weighted two-dimensional gradient echo magnetic resonance imaging shows no enhancement at the cryoablation site. Low signal intensity perinephric changes (*arrows*) merge imperceptibly with the ablated renal parenchyma. (**C**) Four and one-half years after ablation, gadolinium-enhanced T1-weighted three-dimensional gradient echo magnetic resonance imaging shows only cortical scar at ablation site. *Source*: From Ref. 46.

SUMMARY

- The development of multislice computed tomography scanners that can rapidly obtain thin slice image data, advancements in magnetic resonance imaging software design and coil technology, the emergence of sophisticated three-dimensional rendering methods, and the development of laparoscopic ultrasound probes have now allowed the radiologist to participate in the planning of laparoscopic surgery, guiding its performance, and then following patients for possible complications or tumor recurrence.
- The laparoscopic urologist must have an accurate understanding of the renal parenchymal and vascular anatomy and tumor location to preserve normal renal tissue and, thus, preserve renal function.
- Accurate surgical planning information helps to minimize postoperative complications, such as urinary leak or renal infarct, and to maximize preserved renal parenchyma.
- Computed tomography is considered the gold standard for detection, diagnosis, and staging of renal cell carcinoma.
- Magnetic resonance is reserved for problem solving or for those patients with renal insufficiency or a history of severe allergy to iodinated contrast.
- Three-phase computed tomography protocols are the state-of-the-art for imaging the kidneys and provide all the necessary information for surgical planning for laparoscopic surgery. Thin slices are employed.
- A thorough discussion between the radiologist and the referring urologist regarding their surgical approach and surgical planning needs is recommended.
- The ability of intraoperative ultrasound to localize a renal mass during laparoscopic partial nephrectomy is invaluable.
- Guidelines for postoperative imaging after laparoscopic procedures are still evolving.
- Magnetic resonance imaging is a reasonable alternative to computed tomography for the postoperative follow-up of patients with compromised renal function.

CONCLUSION

Radiologic imaging plays an increasingly important role for the diagnosis and treatment of renal cell carcinoma. Imaging is no longer solely restricted for the detection and

characterization of renal tumors. It is now critical for surgical planning and monitoring of surgical and ablative therapies, both during and after these technically demanding, minimally invasive procedures.

EQUIPMENT

LAPAROSCOPIC INSTRUMENTATION

Mihir M. Desai

Section of Laparoscopic and Minimally Invasive Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

There has been an exponential increase in laparoscopic urologic surgery, reconstructive and ablative, in the treatment of a variety of benign and malignant conditions affecting the urinary tract. Advances in instrumentation and technology have played a pivotal role in expanding the application of laparoscopic surgery. Proper understanding of instrumentation and certain basic principles of laparoscopic surgery is fundamental to the safe and effective practice of minimally invasive surgery. This chapter will highlight the fundamental and practical aspects of laparoscopic instrumentation and techniques common to most laparoscopic urological procedures.

LAPAROSCOPIC INSTRUMENTATION

Instruments for Laparoscopic Access

Transperitoneal Access

Closed Access Using the Veress Needle

During closed transperitoneal access, a Veress needle is initially placed percutaneously into the peritoneal cavity, usually through one of the subsequent trocar sites (1). The standard reusable Veress needle is a metallic needle with a retractable protective blunt tip. The blunt tip retracts exposing the sharp end when the tip of the Veress needle is pushed against a tough structure such as fascia. Once the needle has penetrated the layers of the abdominal wall and enters the peritoneal cavity, the blunt tip springs back into place, thereby protecting the abdominal viscera from injury likely to be caused by the sharp edge. The Veress needle has a valve-operated port for initial peritoneal insufflation.

The Veress needle is available as a disposable or a reusable instrument. The 2-mm Minisite trocar™ᵃ, a modified Veress-type device, is the author's instrument of preference for obtaining closed peritoneal access. The Minisite trocar has a retractable blunt tip similar to a standard Veress needle, and can also be used as a 2-mm cannula by removing the inner trocar needle. In cases where the correct position of the needle is questionable, a 1.9/2.0 mm telescope can be passed through the Minisite cannula to confirm intraperitoneal position.

For pelvic laparoscopic procedures, the patient is typically supine with a slight Trendelenburg tilt, and the Veress needle is introduced through a subumbilical incision. The needle is directed toward the pelvis in order to avoid injury to the great vessels. For upper tract laparoscopic procedures, the patient is generally in the flank position, and the Veress needle is placed through the iliac fossa in order to minimize inadvertent

---

ᵃU.S. Surgical Corp., Norwalk, CT.

injury to the bowel, which typically gravitates medially toward the umbilicus. It is preferable to avoid a Veress needle puncture in the vicinity of a previous abdominal scar. The tactile feedback of the Veress needle passing through the various layers of the abdominal wall is critical in ensuring optimal positioning. Typically one feels two distinct "pops" each at the level of the external oblique/rectus fascia, and at the level of the transversalis fascia/peritoneum. The disposable Veress needles have a ball that visually confirms the "pops." After insertion, the Veress needle is aspirated to rule out the presence of blood or bowel content. The correct placement of the needle is further confirmed by injecting a few drops of saline, and demonstrating the rapid drop of the meniscus. Final confirmation is obtained by documenting a low opening intra-abdominal pressure after initiating insufflation at a low flow (1 L/min). Once the correct intra-abdominal position of the needle has been confirmed, insufflation flow rate can be increased to the maximum. Once the abdomen has been insufflated adequately (intra-abdominal pressure 15–20 mmHg), the primary trocar is placed. This author prefers to initially insufflate the abdomen up to 20 mmHg prior to inserting the first trocar. This keeps the abdomen tense and reduces the chances of inadvertent visceral injury during the first "blind" trocar placement. It is important to make a generous skin incision for the initial port-site to reduce the gripping of the skin on the trocar. Additional trocars are subsequently inserted under direct laparoscopic visualization thereby minimizing the risk of inadvertent visceral or vascular injury.

Open Access Using the Hasson Technique

Many laparoscopic surgeons prefer the open Hasson approach to obtain initial transperitoneal laparoscopic access (2). Herein, primary access is obtained through a 1 inch incision made at one of the port-sites. The incision is carried down through the various abdominal wall layers to reach the peritoneum. The peritoneum is then grasped between hemostats and sharply incised. A finger is introduced through the incision to confirm presence within the peritoneal cavity.

With the open access system, it is of critical importance to obtain an airtight seal at the site of entry through the abdominal wall in order to minimize gas leak of the insufflate. A Hasson cannula may be used for this purpose (Fig. 1). The Hasson blunt-tip cannula is inserted into the peritoneal cavity and secured in place with fascial sutures. The author prefers to use a blunt-tip balloon cannula (vide infra) in lieu of the Hasson cannula since, in my opinion, the seal provided by the balloon port is better.

Retroperitoneal Access

Retroperitoneal access is obtained by an open technique (3). The primary incision is placed below the tip of the 12th rib. The skin, subcutaneous tissue, and external oblique fascia are incised sharply. The fibers of the internal oblique and transverses are separated bluntly with the index finger up to the level of the dorsolumbar fascia, which is divided sharply to gain entry into the retroperitoneal space. The retroperitoneal position is confirmed by palpating the psoas muscle posteriorly and the lower pole of the kidney superiorly. Initially, the retroperitoneal space is developed with the help of the finger. A variety of devices have been used for subsequent rapid development of the initial working space during retroperitoneoscopy. Simple contraceptions such as rubber catheters attached to a latex glove or condom though inexpensive, in our opinion, are not very efficient. We prefer to use the PDB™ balloon dilator[b] to balloon dilate the retroperitoneal space for several reasons (Fig. 2). First, the balloon dilator has a rigid shaft, thereby enabling optimal positioning of the balloon in the retroperitoneum. Second, the balloon dilator has a transparent cannula and balloon through which a 10 mm laparoscope can be introduced to confirm proper positioning. Visualization of the psoas muscle inferiorly and the perinephric fat superiorly confirms the correct balloon position between the kidney and the posterior abdominal wall. Occasionally, other retroperitoneal structures, such as the ureter, gonadal vein, and inferior vena cava may be identified through the transparent balloon. Third, since the balloon lies entirely in the retroperitoneum, inflating the balloon does not widen the initial incision made through the skin and abdominal wall. The balloon dilator is incrementally inflated up to 800 cc (each pump delivers approximately 20 cc air) (Fig. 3).

Subsequently, a 10 mm blunt tip balloon trocar is inserted through the incision (Fig. 4). The balloon port provides optimal sealing of the abdominal wall, thereby minimizing leak of CO_2 and subcutaneous emphysema. This is of critical importance, given the already limited working space in the retroperitoneum (3).

Many laparoscopic surgeons prefer the open Hass on approach to obtain initial transperitoneal laparoscopic access.

Laparoscopic Trocars

Types of Trocars

Trocars are either disposable or reusable and are available in various sizes (2, 5, 10, 12, and 15 mm). The obturator tip may be bladed or blunt; bladed trocars are available with or without (usually reusable trocars) a safety shield. The larger (10, 12, 15 mm) trocars have a valve and reducer system at the proximal end to allow instruments of various sizes to be passed without causing an air leak. The blunt-tip trocars may be associated with a lower incidence of injury to abdominal wall vessels and intraperitoneal structures, and are the preferred trocars at the author's institute. Longer trocars are also available for use in the morbidly obese population.

Sites for Trocar Placement

Procedure-specific trocar placement is described in detail with each individual operative procedure. However, certain general principles govern correct trocar placement. The camera port ideally should be in line with and at a 45° angle to the principal structure of interest (e.g., renal hilum during laparoscopic nephrectomy). The right- and left-hand working ports should be on either side of and at an adequate distance from the primary camera port creating a triangulation. Proper trocar arrangement is ideal for creating optimal orientation and angles of the rigid laparoscopic instruments.

Technique of Trocar Insertion

The primary trocar insertion has been described earlier. Secondary trocars must be inserted under direct laparoscopic visualization to avoid inadvertent visceral injury. The proposed site of trocar placement on the abdominal wall is pressed with a finger, and the indentation made is viewed internally via the laparoscope. We prefer to localize the site of trocar placement by puncturing the abdominal wall with a hypodermic needle attached to a syringe. The skin incision is made commensurate with the size of trocar to be inserted. The trocar is firmly grasped against the palm of the hand and inserted perpendicular to the abdominal wall. Tangential skewing of the trocar through the abdominal wall results in limited mobility of the port and instrument, additionally, as the procedure progresses the trocar hole tends to progressively enlarge, leading to gas leakage around the trocar. We prefer to fix all trocars to the skin using a 0-Vicryl suture.

Grasping Instruments

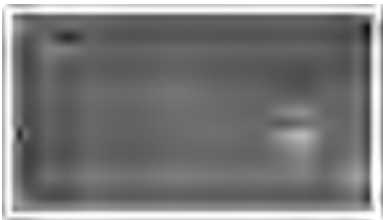
A variety of laparoscopic grasping instruments, disposable and reusable, are currently available. The grasping instruments may be traumatic or atraumatic, or locking or nonlocking, have a single or double action jaw, and be available in various sizes (2–12 mm). Atraumatic graspers generally have serrated tips that are gentle on visceral tissues. The traumatic graspers have toothed tips that offer a firm grasp on rigid fascial or similar nonvital structures. Typically, the reusable instruments are modular, wherein different tips can be attached to different handles using varying shaft lengths.


FIGURE 5 ■ Electrosurgical scissors.

Cutting Instruments

Monopolar electrosurgical instruments are generally used for cutting tissues during laparoscopic surgery. Straight or curved scissors (Fig. 5) and electrosurgical electrodes of various tip configurations (Fig. 6) are available for laparoscopic tissue cutting. Usually a setting of 55 W for coagulation and 35 W for cutting is employed. The shaft of these instruments is insulated to prevent thermal damage to adjacent structures. Keeping the tissues on stretch allows for precise and rapid cutting using monopolar electrosurgical instruments.

Energy Sources for Laparoscopic Surgery

Apart from monopolar and bipolar electrocautery, a variety of different energy sources have been introduced for tissue cutting and/or hemostasis that can be used laparoscopically. These include ultrasonic energy, LigaSure,[c] hydrodissector, and argon beam coagulator.

Ultrasonic energy has been successfully used for tissue dissection and hemostasis during laparoscopic procedures (4). The commercially available ultrasonic generators provide a variety of effecter tips (5 and 10 mm) for laparoscopic surgery. With ultrasonic

Source: From Ref. 6.

energy, tissue cutting and coagulation is achieved at lower temperatures (50–100°C) as compared to electrocautery. This reduces the lateral scatter, charring, and smoke production. Disadvantages of the ultrasound dissection include equipment cost and decreased speed of dissection compared to conventional electrocautery.

The LigaSure system is designed for providing hemostatic sealing of blood vessels up to 7 mm in diameter (5). Specific to urologic surgery, the LigaSure has been used for securing blood vessels, such as the lumbar, gonadal, and adrenal vein in select cases in lieu of surgical clips. The LigaSure technology combines compression pressure and thermal energy to cause denaturation of the vessel wall collagen and secure vessel occlusion. A feedback mechanism regulates the amount of energy to be delivered and gives an audible signal to the surgeon when effective vessel occlusion has been achieved. The LigaSure system is thought to produce less charring and tissue sticking compared to conventional bipolar coagulators. Landman et al. compared the relative efficacy of ultrasonic energy versus bipolar cautery versus LigaSure in the laboratory and found that LigaSure had the best hemostatic efficacy and ultrasonic shears had the least collateral scatter (Table 1) (6).

Argon beam coagulation provides excellent superficial hemostasis for superficial bleeding surfaces (7). It is particularly helpful for controlling mild oozing from parenchymal bleeding surfaces, such as liver, spleen, kidney, and muscle. Additionally, the argon beam coagulator does not produce any forward scatter. The use of the argon beam coagulator during laparoscopic surgery may cause a precipitous rise in intra-abdominal pressure; therefore, one of the trocars should be continuously vented during its use.

Clips and Staplers

Surgical clips and staplers are predominantly used for securing medium and large caliber vessels during laparoscopic surgery. Surgical clips may be either titanium (Fig. 7) or polymer-plastic and are available in various sizes. Titanium clips can be applied through manual loading (reusable applicator) or automatic self-loading (disposable) applicators. The titanium clips may fall off during subsequent dissection and manipulation and hence multiple clips should be applied, especially during ligation of larger caliber blood vessels. The clips should be evenly spaced and should not cross each other in order to be effective. It is also important to leave a sufficient vessel stump after the last clip to ensure safety of the clip ligature.

The locking plastic clips have significantly improved the security of surgical clips (Fig. 8). These clips are applied such that the entire clip encircles the vessel and once fired, locks into place. The clips are available in 5, 10, and 16 mm sizes. The 5 mm clip also has a disposable, automatically reloading applicator. These clips are generally more reliable than titanium clips and are currently our preferred method of securing medium to large vessels such as the renal artery and venous tributaries. Although various reports have supported the use of such clips on the main renal vein, we currently reserve tissue staplers for that purpose. The availability of the 16 mm Hem-O-Lok™ d clip may lead to the routine use of the Hem-O-Lok technology for renal vein control.

Endoscopic stapling devices are generally employed for securing hemostasis for large vascular structures such as the renal vein and rapid division of tissues. Typical endoscopic staplers are of a linear GIA type and lay six staggered rows of staples and cut between rows 3 and 4. The latest generation of endoscopic stapling devices can both articulate and reticulate allowing an increased range of angles for soft tissue and vascular stapling. The stapling cartridges are available in various lengths (30, 45, and 60 mm) and various staple heights (2, 2.5, and 3 mm). The 2 mm stapling loads are typically used for

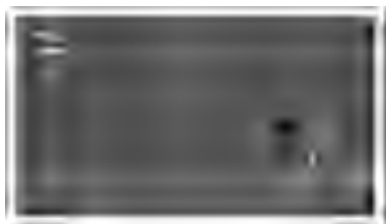
FIGURE 7 ■ Titanium surgical clip.


FIGURE 8 ■ Locking plastic surgical clip.

---

dWeck Closure System, Research Triangle Park, NC.

hemostatic vascular stapling. The 3.5 mm loads are typically used for soft tissue stapling wherein vascularity of the stapled edges needs to be preserved (e.g., bowel anastomosis). Certain precautions need to be taken to ensure safety of endoscopic staplers. First, the correct load of staples must be used as per the type and thickness of tissue to be stapled. Second, care must be taken not to fire staplers over clips. However, staples can be safely fired over previous staple lines.

Suturing and Knot Tying

Suturing and knot tying are critical skills for the advanced laparoscopic surgeon (8).

The Endoloop™ [e] consists of a preformed loop of suture with a slipknot at the end of a plastic knot pusher. This device may be used for ligating tubular organs such as the appendix.

Extracorporeal knotting involves formation of the knot by a longer suture outside the cavity and pushing it through the port with the help of one of the many available knot pushers. Intracorporeal suturing and knot tying is the author's preferred method of laparoscopic reconstruction. The needle can be easily inserted through a laparoscopic port by grasping the suture about 3 cm from the needle. The trocar sleeve valve should be kept in an open position while the suture is being inserted. The size of the needle determines the trocar size required. Although a 10–12 mm port is preferred, certain smaller needles may be passed through a 5 mm trocar. The suture is generally cut to a length of 7–10 cm for intracorporeal knot tying. A longer suture may be used for certain applications that require continuous suturing. In general, the longer the suture, the more difficult it is to handle in the laparoscopic environment. The long end of the suture is looped two to three times around the tip of the needle driver and to complete the first throw of the surgeon's knot. The second and the third throws complete a square knot. Suturing can be performed in interrupted or running fashion. A variety of needle drivers with varying tip and handle configurations and locking mechanisms are currently available. A novice laparoscopist may consider starting out with a self-righting needle-driver, although the non self-righting devices afford the greatest versatility for the more experienced surgeon. Our personal preference is the Ethicon needle driver E705R (Fig. 9).

A variety of specialized suturing devices is available to facilitate laparoscopic intracorporeal suturing and knot tying. These include Endostitch™ [f] and SewRight™ [g]. Although these devices may facilitate the beginner laparoscopist, in our opinion, they lack the finesse of freehand suturing. Additionally, with these specialized devices, the laparoscopic surgeon is limited in terms of the type of suture and needle configurations available. In contrast, with freehand laparoscopic suturing, the surgeon can use the full array of suture available for open surgery.

FIGURE 9 ■ Ethicon needle driver.

Glues, Bioadhesives and Hemostatic Agents

Details of various biological hemostatic and tissue agents are detailed elsewhere in the text. Closure of laparoscopic port-site incisions with skin adhesives such as octylcyanoacrylate has been found to be as effective as subcuticular suturing with the advantage of requiring less operative time (9). Although there are other adhesives such as *N*-butyl-2-cyanoacrylate, only octylcyanoacrylate has the approval of the Food and Drug Administration. octylcyanoacrylate has to be applied to dry, well-approximated incisions and the product must not be allowed to come in contact with subcutaneous tissues as a vigorous foreign body reaction resembling an infection often ensues.

Aspiration/Irrigation Instruments

A variety of suction-irrigation systems is currently available (Fig. 10). The aspirator, which is connected to a suction system, consists of a 5 or 10 mm metal or plastic tube, with suction controlled by either a one-way stopcock or a spring-controlled trumpet valve. The irrigation channel is also operated by the same mechanism. The irrigation may be pressurized to adequately clear blood clots for optimal visualization. Usually normal saline or lactated Ringer solution is used as irrigation fluid. Heparin (5000 U/L) may be added to prevent clots from forming in the surgical field. Furthermore, a broad-spectrum antibiotic may be added to the irrigant fluid in situations where infection may be a concern.

FIGURE 10 ■ A suction-irrigation system.

Instrumentation for Port-Site Closure

The simplest method is retracting the skin with retractors, grasping the fascia with Kocher's clamps, and suturing it with sutures. However, external suture of 1 cm port-site incisions may be extremely difficult especially in the obese population.

Several specialized devices for secure port-site closure have been introduced (10–13). The Carter-Thomason Needlepoint Suture Passer™ [h] consists of a 10-mm metal cone that has two cylindrical openings located diagonally opposite each other. The Carter-Thomason needle grasper is used to insert one end of the suture loop through one of the cylinders within the cone, thereby traversing the full thickness of the abdominal wall. The end of the suture within the peritoneal cavity is grasped with a 5-mm grasper via one of the other ports by the assistant. The Carter-Thomason needle grasper is reintroduced through the diagonally opposite cylinder of the metal cone. The intraperitoneal end of the suture is fed to the needlepoint grasper and pulled out of the abdomen. The metal cone is slid off both ends of the suture. Subsequently, the suture is tied after desufflating the abdomen to provide adequate fascial closure. Alternatively, the Carter-Thomason needle grasper may be used without the cone using finger guidance. In general, it is our recommendation to close all 10 mm or larger port sites.

Insufflant System

The insufflant system (i.e., insufflator, tubing, and insufflant gas) is essential for establishing a pneumoperitoneum, or pneumoretroperitoneum, as the case may be. Insufflation is commenced after either closed (i.e., Veress needle) or open (i.e., Hasson cannula) access to the desired cavity is optimally established.

Most commonly, CO_2 is used as the insufflant because it does not support combustion and is highly soluble in blood (14). However, in patients with chronic respiratory disease, CO_2 may accumulate in the blood stream to dangerous levels. In such cases, helium may be used for insufflation once the initial pneumoperitoneum has been established with CO_2. The drawback of helium is that it is much less soluble in blood than CO_2 but may be useful in avoiding hypercarbia. Other gases, such as room air, oxygen, and nitrous oxide are no longer routinely used owing to their potential side effects (e.g., air embolus, intra-abdominal explosion, potential to support combustion). "Noble gases" such as xenon, argon, and krypton are inert and nonflammable but are not routinely used for insufflation owing to their high cost and poor solubility in blood.

Initially, insufflator pressure is set at 20 mmHg with a rate of gas flow of 1 L/min. Once safe entry into the peritoneal cavity has been achieved, the flow can be increased to maximum.

The insufflated CO_2 is typically cold (21°C) and is unhumidified. This results in minimal systemic hypothermia and likely contributes to problems of fogging of the endoscope during the procedure. Accessory devices for insufflators that warm and humidify CO_2 to physiologic conditions are available. However, the benefit of this technology is largely of an anecdotal nature. Indeed, warming the insufflant by itself may be of no benefit or even detrimental.

System for Visualization

Four components are required to obtain an image during laparoscopic surgery: laparoscopic telescope, light source with cable, Endovision[i] camera, and monitor. Laparoscopes that are most commonly used have 0° or 30° lenses (range, 0–70°) and a size of 10 mm (range, 2.7–12 mm). Image transmission uses an objective lens, a rod-lens system with or without an eyepiece, and a fiberoptic cable. The advantage of the larger laparoscopes is that they are able to provide a wider field of view, better optical resolution, and a brighter image. From the eyepiece, the optical image is magnified and transferred to the camera and onto the monitor. Light is transmitted from the light source through the fiberoptic cable onto the light post of the laparoscope. A special variant is the offset "working laparoscope," which includes a working channel for passage of basic laparoscopic instrumentation. Use of this type of laparoscope enables the surgeon to work in direct line with the image and may allow a reduction in the number of trocars needed to accomplish a particular procedure. However, the working channel occupies space that would otherwise be used for the optical system; hence, the resulting image is usually of lesser quality compared with that of laparoscopes without this feature.

---

[h]Inlet Medical Inc., Eden Prairie, MN.
[i]Endovision Pty Ltd., Camberwell, Australia.

The camera system consists of a camera and a video monitor. Earlier, cameras could not be sterilized; hence, a sterile plastic camera wrap had to be passed over the camera and the eyepiece of the laparoscope. The camera wrap was then affixed to the shaft of the laparoscope with wire ties. Fortunately, all currently made cameras can be gas sterilized or soak sterilized, thereby facilitating their use and avoiding a possible source of intraoperative contamination. The camera is attached directly to the end of the laparoscope and transfers the view of the surgical field through a cable to the camera box unit. After reconstruction of the optical information, the image is displayed on one or two video monitors.

A wide variety of cameras is currently available: single-chip, single-chip/digitized, three-chip, three-chip/digitized, interchangeable fixed-focus lenses, zoom lenses, beam splitter, and direct coupler. Direct couplers are superior to beam splitters, in which light and image are shared between monitor and eyepiece and in which the surgeon may view the area of interest directly through the laparoscope. Three-chip cameras are superior to single-chip cameras in that they provide a higher-quality image with superior color resolution.

To obtain a "true" upright image of the surgical field on the monitor, the camera's orientation mark must be placed at the 12 o'clock position. With 0° laparoscopes, the camera is locked to the eyepiece in the true position. In contrast, with the 30° laparoscope, the camera is loosely attached to the eyepiece of the laparoscope so the laparoscope can be rotated. Accordingly, the assistant must hold the camera in the true upright position with one hand while rotating the laparoscope through a 360° arc to peer over and around vascular and other intra-abdominal structures; the 30° lens thus provides the surgeon with a more complete view of the surgical field than does a 0° lens.

The most vexing problem with the laparoscope is fogging of the lens. To prevent fogging of the laparoscope after insertion into the warm intraperitoneal cavity, it is advisable to initially warm the laparoscope in a container holding warm saline before it is passed into the abdomen. In addition, wiping the tip with a commercial defogging fluid or with povidone-iodine solution is also recommended. Should moisture buildup occur between eyepiece and camera, both components must be disconnected and carefully cleansed with a dry gauze pad.

Video monitors are available in 13- or 19-inch sizes. A larger monitor does not produce a better picture; indeed, given the same number of lines on both monitors, a higher-resolution image is obtained with the smaller screen. To obtain a better image, more lines of resolution are needed. High-resolution monitors with 1125 lines of resolution must be matched with a camera system of similar capability.

Light sources use high-intensity halogen, mercury, or xenon vapor bulbs with an output of 250–300 W. Xenon, 300 W lamps are currently preferred. In addition to manual control of brightness, some units have automatic adjustment capabilities to prevent too much illumination, which may result in a "washed-out" image. Any breakage of fibers in the fiberoptic cable, which may occur during sterilization and/or improper handling, results in decreased light transfer from the light source to the laparoscope, and hence to the operating field.

> To prevent fogging of the laparoscope warm the laparoscope in a container holding warm saline before it is passed into the abdomen.

OPERATING ROOM SETUP

The operating room should be large enough to accommodate all necessary personnel and the technologic equipment required by both the laparoscopist and the anesthesiologist. Positioning of equipment, surgeon, assistants, nurses, anesthesiologist, and other support staff should be clearly defined and established for each standard laparoscopic case. Generally, ceiling mounted beams are preferred for placing the necessary optical, insufflation, and electrocautery instruments over floor standing towers. All equipments must be fully functional and in operating condition before any laparoscopic procedure is started. A separate tray with open laparotomy instruments must be ready for immediate use in the event of complications or problems necessitating open incisional surgery.

Patient Positioning and Draping

Positioning of the patient depends upon the laparoscopic procedure to be performed. Most pelvic laparoscopic procedures are performed with the patient in a supine, low-lithotomy position with the arms secured at the sides of the body. In contrast, upper tract laparoscopic procedures are performed with the patient in the flank position.

In the lateral position, all bony prominences must be carefully padded. The patient is securely fastened on the operating table by two to three circumferential wraps of a 6 inch cloth adhesive tape and a belt. In the lateral position, the bottom leg is flexed

approximately 45° while the upper leg is kept straight; two to three pillows are placed between the legs as a cushion and also to elevate the upper leg so that it is on the same level as the flank, thereby obviating any undue stretch on the sciatic nerve. Similarly, an axillary roll is positioned below the dependant axilla to prevent brachial plexus injury. The head and upper extremities are placed in a neutral position. We prefer the use of a double arm board for positioning the upper extremities. Application of active warming systems may prevent hypothermia should a lengthy laparoscopic procedure be anticipated. Similarly, use of pneumatic compression stockings is helpful in minimizing postoperative thromboembolic events. Previous incisions and scars and the surface anatomy is clearly marked prior to surgical preparation, and draping is commenced.

Before major laparoscopic procedures, a naso- or orogastric tube and a Foley catheter are usually placed to decompress the stomach and bladder, respectively, thereby decreasing the chance of injury of abdominal contents during insertion of the Veress needle and the initial trocar.

Placement of Operative Team and Equipment

Proper positioning of equipment and personnel is essential for the smooth performance of most laparoscopic procedures.

> Proper positioning of equipment and personnel is essential for the smooth performance of most laparoscopic procedures.

The monitor, insufflator, light source should be preferably placed on a ceiling-mounted boom. The monitors (preferably two) should be diagonally opposite to the primary surgeon and the assistant surgeon at the direct eye-level. The insufflator and light source should also be within the surgeon's field of view to keep a constant monitoring of the intra-abdominal pressure.

For upper tract laparoscopic surgery, the surgeon and first assistant (camera person) usually stands opposite the area of surgical interest and the second assistant stands on the contralateral side of the table. During pelvic laparoscopic procedures, the surgeon and second assistant stand on the left side of the patient and the first assistant on the right side of the patient. Incoming lines from insufflator, suction/irrigation, and electrosurgical devices are properly secured to a part of the surgical drape so that they do not entangle with each other and do not interfere with the free flow of laparoscopic instrument exchange. Optional technology (e.g., harmonic scalpel, argon beam coagulator) must be arranged in an orderly fashion using either preexisting or improvised pockets of the surgical drape. Additional technology (e.g., high-speed electrical tissue morcellator, laparoscopic ultrasound probe) may be moved to the operating table depending on the surgeon's needs and the availability of space.

Modern laparoscopic operating room systems now integrate all equipment (optics, insufflant) that can be centrally controlled by a touch screen or by voice activation and make operating room logistics smoother. These systems also integrate digital image and video capture and additional technology such as electrocautery, ultrasound energy, etc. Moreover, they involve the use of high-resolution flat screen liquid crystal display monitors that are ergonomically superior.

> A checklist ensuring that all essential equipments are present and operational should be completed just before initiating the pneumoperitoneum.

A checklist ensuring that all essential equipments are present and operational should be completed just before initiating the pneumoperitoneum. Specifically, this list should include (i) light cable on the table, connected to the light source and operational; (ii) laparoscope connected to the light cable and to the camera, with an image that is white balanced and focused on a gauze sponge; (iii) operational suction and irrigation functions of the irrigator/aspirator; (iv) insufflator tubing connected to the insufflator, which is turned on to allow the surgeon to see that there is proper flow of CO_2 through the tubing as kinking of the tubing would result in an immediate increase in the pressure recorded by the insufflator, with concomitant cessation of CO_2 flow; (v) an extra tank of CO_2 in the room; and (vi) a Veress needle, checked to ensure that its tip retracts properly and that, when it is connected to the insufflator tubing, the pressure recorded with 2-L/min CO_2 flow through the needle is less than 2 mmHg.

CONCLUSION

In recent years, urologic laparoscopy has breached new frontiers and has evolved into a specialized discipline in itself. Procedures that until recently were considered beyond the scope of laparoscopic surgery are now being increasingly performed safely and effectively by laparoscopic surgeons all over the world. The foundation of successful laparoscopic surgery lies in the strict adherence to age-old, established surgical principles, proper training of personnel in laparoscopic skills, and good equipment. In this

chapter we have covered the practical fundamentals of laparoscopic urology, which go a long way in ensuring a successful outcome for the patient and surgeon alike.

INTRODUCTION

> Exposure remains one of the keys to success in both open and laparoscopic surgery.

Exposure remains one of the keys to success in both open and laparoscopic surgery.

In open surgery, the incision and retraction dictates the quality of exposure. In laparoscopy, high-quality optics are absolutely essential to provide the necessary exposure for a successful surgical intervention. Imaging, with particular emphasis on newer digital cameras and monitor technology, will be discussed in this chapter.

Other key features of the operating room of the future include documentation, education, and training. The ability to readily capture both video and still images is essential to all of these goals. The current technology allows the surgeon to capture entire procedures or just still images in either digital or analog form. However, management and manipulation of the data can be quite cumbersome and complex. Future developments will certainly be instrumental in allowing for more user-friendly interfaces.

Most current operating rooms were designed targeting the open surgery needs. As minimally invasive endoscopic procedures have gained favor, adjustments were made to accommodate laparoscopic and minimally invasive technology. More recent operating room designs address the fundamental differences between open and laparoscopic surgery. As a result, specialized rooms are being developed and are much more conducive to consistent and trouble-free laparoscopy and endourology.

DIGITAL IMAGING

Analog vs. Digital Imaging

In the 1980s, when video endoscopy was first introduced, intraoperative video and still images were captured and recorded using conventional analog cameras.

> Despite universal availability and low cost, analog technology has several limitations and drawbacks when compared to the much improved digital systems commonly employed today.

Despite universal availability and low cost, analog technology has several limitations and drawbacks when compared to the much improved digital systems commonly employed today.

Besides inferior image quality, analog photos and video recordings tend to lose resolution and degrade over time. In addition, storage of these analog images, in the form of video libraries, occupies extensive space.

Analog images transmitted through individual fiberoptic bundles during various endourologic procedures are translated into continuous voltage waveforms to be viewed on an analog video monitor. Such analog image signals, susceptible to degradation during the translation process, typically lack the detail necessary to identify subtle pathologic processes. This limitation may be due to specific aspects of the signal being misinterpreted by the analog circuitry and results in the introduction of electronic noise (1,2). In some circumstances, subtle differences in exposure and visibility can also compromise recognition of important but delicate anatomical structures (Fig. 1).

Endoscopic Camera Systems and Charged Coupled Device

The current generation of endoscopic cameras employs the charge coupled device chip. The digital image is captured on a charge coupled device using either a digital still or a digital video camera. Photoreceptors, within the charge coupled device, rapidly assess the different light intensities that make up the endoscopic image. The charge coupled device generates pixels by converting unique light intensities within an image into corresponding electronic signals, which are then transmitted to a storage element on the chip (3).

Digital cameras are classified according to the amount of resolution determined by the number of pixels and the number of charge coupled device chips. The average charge coupled device resolution of single-chip camera ranges between 400,000 and 440,000 pixels, whereas three-chip cameras exceed 450,000 pixels. Display resolution of the cameras ranges between 350 to 450 and 700 horizontal lines for single-chip and three-chip cameras, respectively (4).

The development of the three-chip camera that contains three individual charge coupled device chips for the primary colors—red, green, and blue—represented a significant improvement in charge coupled device camera technology (Fig. 2).

In addition to composite super video home system and component signals, the three-chip cameras also provide an "uncoded" red, green, and blue signal. Color separation is achieved using a prism system overlying the chips (5). This three-chip camera design provides improved color fidelity and enhanced image resolution. Moreover, three-chip cameras produce less "noise" due to the pure red, green, and blue signals (6,7). A digital converter capturing each voltage signal as an image translates the voltage values into discrete numbers, either as 0 or 1. The encoded numbers for each image element or pixel include information on color, light intensity, and contrast. These variables can then be modified using image-processing software within the camera (8).

Theoretically, three-chip cameras produce better quality images than single-chip cameras. Despite the apparent advantages of three-chip cameras, some clinical comparisons have favored one-chip systems. Using normal video monitors, previous studies have implied that the resolution between the two cameras did not alter the visual perception of an image. For endoscopic imaging, digital contrast enhancement is a feature more important than the number of camera chips.

Three-chip cameras appeared to have no advantage over well-designed single-chip systems (1,5,9). However, this apparent limitation may change with the introduction of high-resolution digital monitors and high-definition television, because the amount of image information and the degree of perception are increased with these digital-imaging modalities (10).

> For endoscopic imaging, digital contrast enhancement is a feature more important than the number of camera chips.

FIGURE 1 ■ Schematic representation of analog vs. digital video systems. *Abbreviation*: CCD, charge coupled device.

VIDEO ENDOSCOPY (AKA "CHIP ON A STICK")

The development of the digital video endoscope has been a major advance in the endoscopic systems. As shown in Figure 3, miniaturization of chip technology, now allows a charge couple device chip to be incorporated at the distal end of the endoscope (chip on a stick or EndoEye™ [a]).

Instead of relaying optical images from the objective lens at the distal end of the scope to a camera attached to the eyepiece, the image is immediately captured by the charge couple device chip, digitized, and converted into electrical signals for transmission.

Digital video endoscopes have fewer interfaces. The digital information is directly transmitted to an image display unit, with minimal image loss, interference, and distortion (11,12).

The creation of true video endoscopes especially benefits the flexible laparoscope and the videoscope (Fig. 4).

For the first time in laparoscopy, the absence of internal optics in the long and flexible shafts of such instruments allows durable deflection mechanisms and increases the durability of flexible endoscopes (3,13,14). With no need to attach a camera head to the eyepiece of the scope, the videoscope cable can be secured to the light cord connecting to the video system. As a result, the setup is more lightweight and convenient. To date, this technology has been incorporated only into larger, rigid endoscopes (laparoscopes) and some flexible endoscopes (colonoscopes, bronchoscopes, and cystoscopes) (15–17). However, recent technological advances have now allowed miniaturization of charge couple device chips.

The replacement of smaller caliber laparoscopes with such an integrated digital video endoscope can be expected in the near future.

Another development in digital camera technology includes the use of a single-monochrome charge couple device chip using alternating red, green, or blue illumination to form a color image rather than using three chips with three separate color filters. This design reduces the volume of the instrument while taking advantage of established high-resolution monochrome charge couple device chip technology (11). This technology design, currently utilized in a digital videocystoscope, has been recently incorporated into digital laparoscopes as well.

Future Developments in Endoscopic Imaging

The reflected white light used to produce an endoscopic image can also be absorbed, scattered, or cause "autofluorescence." Such additional light–tissue interactions are being explored for advanced imaging technologies. Endoscopic imaging may be improved by incorporating an optical magnification lens system at the tip of the endoscope (magnification) or by utilizing other light–tissue interactions (spectroscopy). Magnifying or zoom endoscopes consist of a lens system built into the tip of instrument, which can be used to magnify small areas up to 100-fold. During optical spectroscopy, different spectra can be identified, depending on the wavelength of the light used, and various tissue properties.

> The development of the digial video endoscope has been a major advance in the endoscopic systems.

> Digital videoendoscopes have fewer interfaces. The digital information is directly transmitted to an image display unit, with minimal image loss, interference, and distortion.

> The replacement of smaller caliber laparoscopes with an integrated digital videoendoscope can be expected in the near future.

Highly tissue-specific spectra may be used to identify areas of ischemia, inflammation, and, most importantly, nonapparent malignancy.

Highly tissue-specific spectra may be used to identify areas of ischemia, inflammation, and, most importantly, nonapparent malignancy.

With this technique, multiple "optical biopsies" can be taken from suspicious areas, instead of conventional histological biopsies (11,18) Although still investigational, these techniques are attractive options for future laparoscopic and endourologic evaluation of the urinary tract.

DIGITAL IMAGING, VIDEO DOCUMENTATION, AND EDITING

Over the last few years, digital imaging has slowly revolutionized the field of video endoscopy.

Over the last few years, digital imaging has slowly revolutionized the field of video endoscopy.

Images captured initially in the analog format could later be converted digitally using a digital camera or scanner. However, the introduction of digital still cameras has taken image documentation and editing to a new level. Currently, the newest surgical video systems have integrated digital image capture system, allowing immediate capturing of still images from endoscopic procedures (Fig. 5) (3). Alternatively, a less-expensive digital still image capture adapter can be connected to endoscopic camera systems (6). Digital still images can usually be recorded in Joint Photographic Experts Group or JPEG, tagged image file format or TIFF, or bitmap formats. These digital images can be edited and optimized on the computer using various graphic software packages.

Incorporating medical images into the patient's record as well as creation of an image library can enhance urologic practice.

Incorporating medical images into the patient's record as well as creation of an image library can enhance urologic practice (19,20).

The quality of the digital image required depends upon its purpose. Low-resolution images, in the range of one to two megapixels, can be used for email attachments or Power Point™ presentations. However, a higher quality image, between three to four megapixels, is more useful if a printed image is required. In cases where storage is not an issue, the image should be obtained at its highest resolution, thereby allowing for future image manipulation.

Until recently, the majority of video recordings during endoscopic procedures could be performed with conventional analog video home system or SVHS formats, which could be digitally converted. The introduction of digital video-recording devices now allows direct recording of video footages into a digital format, such as digital video, Moving Picture Experts Group and audio video interlevel (Fig. 6). These video-capturing

FIGURE 5 ■ Still images and short video clips (depending on resolution) can be captured on a digital card. Direct digital video stream can be captured on a computer, digital camcorder, or digital recorder via an IEEE 1394 fire-wire connector on the back panel. *Source*: Courtesy of Olympus America.

FIGURE 6 ■ Digital capture is possible and increasingly flexible, offering the ability to store directly to DVD in all forms of Moving Picture Experts Group or AVI. Also offering ethernet connectivity providing video conferencing capability. Video capture directly to an 80-gigabyte hard drive is also possible or streaming to computer or video camera via SVIDEO, IEEE-1394, serial port, or parallel port is also possible. *Source*: Courtesy of Stryker Endoscopy.

systems can be part of an expensive commercial integrated video system, digital video camera, digital versatile disk recorder, or a low-cost personal computer with digital video capture card (21). digital video editing may be performed on a personal computer using various editing programs, e.g., Adobe® Premiere or Movie Maker.

Small still digital images can be stored on different digital storage media (SmartMedia, Compact Flash, Secure Digital, MultiMedia card, or Memory Stick) up to 1 gigabyte, depending on the media used. Zip disk (up to 750 megabytes), CD-ROM (700 MB), and, lately, digital veratile disk or DVD (17 GB) can be utilized for larger files, especially video clips.

> Storage of large numbers of digital files remains a big issue. Picture archiving and communication systems are under development to play an important role in "filmless" medical imaging in the near future.

Storage of large numbers of digital files remains a big issue. Picture archiving and communication systems are under development to ultimately play an important role in "filmless" medical imaging in the near future (22–24).

ILLUMINATION

Illumination of the operative field is an integral part of laparoscopic surgery. High-intensity light sources, usually halogen and xenon, are currently employed the most. However, halogen sources produce a slightly yellow light requiring compensation with white balancing of the endoscopic camera system. Xenon sources provide a more natural white light. Fiberoptic bundles contain either glass fiber or special fluid run through the endoscope and permit rapid transmission of light to the operative field and digital information in a small space. Although less efficient in light transmission due to a fiber mismatch at the junctions of the light cable and endoscope, the glass fiber bundles are more flexible, and therefore more widely used (12).

Modern light sources often have an automatic light-sensing feature, which quickly adjusts the light output as required by the camera. This automatic light adjust-

ment feature is particularly helpful during endoscopic procedures, as the endoscope may be rapidly moved throughout different parts of the urinary tract with variable levels of illumination. Light intensity is automatically adjusted to maintain a preset level. Similarly, some digital camera systems are equipped with an "automatic iris" system, which electronically increases or decreases the "aperture" of the camera shutter. Automatic intensity-adjusting light source is not required if the camera system is equipped with such a light-sensing feature (2). Newer charge couple device or image sensor–based endoscopic cameras feature electronic exposure. This system varies the effective exposure period (i.e., light gathering time) of the charge couple device as the live image is captured. Typical charge couple device exposure periods range from approximately 1/60 of a second to 1/10,000 of a second under very bright conditions. This electronic process can be used to maintain the brightness of the image. When the image brightness must be reduced to improve picture clarity, the image signal exposure period can be reduced electronically instead of adjusting the iris of the light source.

> Shadows play an important role in depth perception and spatial orientation. Endoscopic task performance significantly improves with video systems providing proper illumination and appropriate shadows in the operative field.

Shadows play an important role in depth perception and spatial orientation. Endoscopic task performance significantly improves with video systems providing proper illumination and appropriate shadows in the operative field (25).

Many of the current endoscopes employ a simple frontal illumination technique that produces an optically flat and shadowless image with resultant poor contrast. Using a single-point or multipoint illumination system, newer illumination and imaging technologies provide shadow-inducing systems. One of these techniques employs the use of two independent illumination fiber bundles, with one fiber bundle ending at the front lens, as designed in conventional endoscopes, and the other fiber bundle ending behind the tip of endoscope. This configuration results in an improved image with better contrast due to shadow formation. Spatial orientation and perception between anatomical structures are considerably enhanced (4).

IMAGE DISPLAY SYSTEMS AND HIGH-DEFINITION VIDEO SYSTEMS

> The development of high-quality image display systems has become essential during endoscopic surgery.

The development of high-quality image display systems has become essential during endoscopic surgery.

Previous studies have demonstrated that the inherent optical quality of most endoscopes and charge couple device camera exceeds the display resolution of standard television (26). Because of the limited resolution of current analog National Television Standards Committee, phase-alternation-by-line, and sequential color and memory monitors, there is a demand for higher resolution image display systems. One such digital display system is the high-definition television. The most common high-definition television formats used in the United States are 720p and 1080i. The "p" represents progressive scanning, meaning that each scan includes every line for a complete picture, whereas the "i" signifies interlaced scanning, with each scan including alternate lines for half a picture. These scan rates translate into a frame rate of up to 60 frames per second, doubling the frame rate of conventional television monitors. high-definition television offers greatly enhanced picture quality with improved image resolution. high-definition television pixel number ranges from one to two millions, compared to National Television Standards Committee, phase-alternation-by-line, or sequential color and memory's pixel number ranging from 300,000 to 1000,000 pixels (Table 1).

The other significant feature of the high-definition television format is its wider aspect ratio (the width-to-height ratio of the screen) of 16:9 as compared with National Television Standards Committee, phase-alternation-by-line, and sequential color and memory screens, which have an aspect ratio of 4:3. The wider aspect ration provides more information for the viewer, thereby enhancing both diagnostic and therapeutic interventions (6,27).

> Current applications of high-definition television in medicine include diagnostic and therapeutic maneuvers during endoscopic surgery. The increased resolution and clarity have been shown to greatly facilitate surgical performance.

Current applications of high-definition television in medicine include diagnostic and therapeutic maneuvers during endoscopic surgery. This increased resolution and clarity have been shown to greatly facilitate surgical performance (6).

The extremely high-resolution image afforded by high-definition television may resemble a three-dimensional (3-D) video image. Although not a true three-dimensional image, the increased video information provides the perception of depth.

The future application of high-definition imaging technology based on charge couple device chips would improve endoscopic image resolution. The European standard high-definition imagingchip resolution is 2,340,250 pixels, resulting in 1250 horizontal lines. high-definition imaging has the advantage of resolution enhancement for image brilliance and the augmentation of secondary depth clues such as shadows. Other techniques under development for image resolution enhancement include

TABLE 1 ■ Broadcast Formats

Format	Lines of resolution	Cycles/sec	Aspect ratio
National Television Standards Committee	525	60	4:3 (standard screen)
Phase-alternation-by-line/sequential color and memory	525	50	4:3
HDTV — United States	1125	60	16:9 (wide screen)
HDTV — Europe	1250	50	16:9

Abbreviation: HDTV, high-definition television.

the use of complementary metal oxide semiconductor technology to replace the charge couple device sensors (4). Both complementary metal oxide semiconductor and charge couple device imagers are manufactured in a silicon foundry; and the equipment used is similar. However, alternative manufacturing processes and device architectures make the imagers quite different in both capability and performance. Although not cost-effective, the use of a charge couple device processor to integrate other camera functions, like the clock driver and signal processing, is technically feasible. Such functions are normally implemented into secondary chips. Thus, most charge couple device cameras contain several chips. One of the major benefits of complementary metal oxide semiconductor cameras over the charge couple device design lies in the high level of product integration that can be achieved through virtually all of the electronic camera functions onto the same chips. Typically, complementary metal oxide semiconductor processor allows lower power usage and lower system cost.

Improved resolution and color separation of high-definition imaging provides better diagnosis and enhances the effect of secondary spatial cues, resulting in easier orientation, particularly if the images are combined with improved illumination.

Despite its current high cost, the price of high-definition television cameras and monitors will continue to decline as newer high-definition television products come onto the consumer market. With further optimization of size and weight of the camera system, high-definition television can become a standard feature for endoscopic imaging and display during endoscopic and laparoscopic procedures.

> Improved resolution and color separation of high-definition imaging provides better diagnosis and enhances the effect of secondary spatial cues, resulting in easier orientation, particularly if the images are combined with improved illumination.

THREE-DIMENSIONAL VIDEO ENDOSCOPIC/LAPAROSCOPIC SYSTEMS

> Stereoscopic vision is essential for precise surgical performance and operative safety during laparoscopic and endoscopic surgery.

Stereoscopic vision is essential for precise surgical performance and operative safety during laparoscopic and endoscopic surgery.

However, most current video endoscopic systems provide a two-dimensional, flat image. Recent advances in imaging technology allow the application of three-dimensional video techniques to laparoscopic surgery (Fig. 7). Most of the current three-dimensional video systems have four basic principles of stereoendoscopic image processing in common: (i) image capture, (ii) conversion of 60 to 120 Hz images, (iii) presentation of left and right images on a single monitor, and (iv) separation of the left and right eyes images (29,30). A three-dimensional video endoscopic system captures two slightly different images of the operative field, which are then transmitted to the monitor so that the images of the right and left cameras are alternatively displayed (sequential display procedure) with a frequency of 100/120 Hz. Several image-capturing methods have been employed, including the dual-lens system, single-lens systems, electronic video endoscopic system, and a system of single rod lenses with two beam paths. The three-dimensional imaging display may be achieved by two methods, either active liquid crystal display glasses or polarizing glasses. In both instances, the brain fuses the right- and left-sided images on the appropriate imaging site. This technology is based on the physiology of retinal image persistence and is quite different from normal stereoscopic imaging (5). The presentation of the two images independently to the left and right eye is an alternative to dual projection. This technology is currently available as part of the *da Vinci® Robotic System*[b]. Head-mounted display technology may offer another means of delivering separate images to each eye without dual projection.

---

[b]Intuitive Surgical, Sunnyvale, CA.

FIGURE 7 ■ Three-dimensional stereoendoscope. Schematic diagram of three-dimensional video imaging system. The two images are projected on a screen, and the glasses bring the two together, giving the impression of a three-dimensional image. Alternatively, the separate images can be presented separately to the left and right eye through a head set. This is currently available as a part of the *da Vinci*® robotic system and can theoretically be developed via a head-mounted display. *Abbreviation*: 3D, three-dimensional. *Source*: From Ref. 28.

Comparisons of two-dimensional and three-dimensional video systems have offered conflicting results in experimental and clinical practice. Despite the benefits of enhanced depth perception provided by three-dimensional systems demonstrated in various studies, three-dimensional endoscopic technology has not been widely used due to its high cost and relative lack of availability. Moreover, some studies have demonstrated no evidence of improved performance while using three-dimensional systems during endoscopy and suggest that a higher-resolution video system might be more advantageous than the three-dimensional endoscopic imaging (27,31,32). The three-dimensional imaging systems are currently used for true stereoscopic imaging during robot-assisted laparoscopic procedures (33–35).

VIRTUAL REALITY ENDOSCOPIC/LAPAROSCOPIC SIMULATION

Endourologic procedures require specific training to achieve competency.

Often, there are reduced training opportunities for residents due to a limited number of clinical cases. Moreover, ethical and cost issues may further limit the use of animal or cadaver models for training purposes (36–38). Hands-on training using bench models can successfully teach the novice laparoscopic skills, but lack the ability to simulate clinical conditions (39). Moreover, inanimate simulators lack the realistic feedback of living tissue.

Advances in virtual reality simulation offer a practical tool for urologists to practice various endourologic procedures from the basic to the most complex in an inanimate, but dynamic, life-like environment without risk for the patients or ethical issues.

A realistic virtual reality surgical simulation consists of accurate reproduction of anatomic structures, appropriate tactile feedback, and spatial cues.

Because endourologic procedures require little in the way of complex anatomic and tactile feedback, one of the earliest simulators in urology was a virtual reality ureteroscopy simulator[c] (36,37,40). This simulator allowed urologists to explore the ureter and kidney to identify pathologic processes, e.g., stones and tumors. However, this early simulator was limited by the lack of true anatomical representation and inadequacy in computer graphics. Virtual cystoscopy and ureteroscopy using either rigid or flexible endoscopes can be performed using a new endoscopic simulator[d] built, applying the most recent advances in computing power, virtual reality graphics, and physical modeling techniques.

Real-time fluoroscopy with simulation of C-arm control and viewing of fluoroscopic images of injected contrast can also be simultaneously combined with simulated endoscopic procedures. Several endourologic procedures including cystoscopy, retrograde pyelography, insertion of guide wire, ureteral stenting, ureteroscopy, stone fragmentation, and fragment removal using various tools can be realistically simulated.

Endourologic procedures require specific training to achieve competency.

Advances in virtual reality simulation offer a practical tool for urologists to practice various endourologic procedures from the basic to the most complex in an inanimate, but dynamic, life-like environment without risk for the patients or ethical issues.

---

[c]Immersion Medical, Gaithersburg, MD.
[d]URO Mentor System, Symbionix, Tel Aviv, Israel.

Recent studies have demonstrated that, using this virtual reality simulator, urologic trainees acquired ureteroscopic skills more rapidly (41–44).

In fact, the use of both laparoscopic and ureteroscopic simulators has led to a significant reduction in the learning curves of both routine and complex endoscopic procedures. Endourologic skills can also be validated using virtual reality simulation (38,45).

Due to further advances in computer and software technology, virtual reality simulation has become more realistic for the performance of laparoscopic procedures (46–49). Similar to the aviation industry, virtual reality simulation will likely be incorporated into the training, testing, and credentialing of endourologists and laparoscopic surgeons over the next 5 to 10 years.

INTERNET AND TELEMEDICINE

In recent years, telemedicine, defined as the use of electronic information and communication technologies to provide and support health care from a distance, has become an important aspect in patient care. Advances in digital imaging, high-speed computer connections, and the widespread availability of the Internet have allowed a steady growth of telemedicine within urology (50). Digital images obtained from various sources such as a digital still or video camera, scanner, computed tomography, and magnetic resonance imaging can be exchanged over the Internet at high speed. Current transmission modalities includes the integrated services digital network transmitting 128 kilobits per second, T1 lines transmitting 1.54 megabits per second (Mbps), coaxial cable (up to 6 Mbps), asymmetric digital subscriber line (1 to 3 Mbps) (6,8,19).

Two types of telemedicine systems are currently available. One is the synchronous, real-time video conferencing. In general, real-time motion requires that images are generated at a speed of 30 frames per second (51).

The advantage of "live" video teleconferencing consists of real-time interaction between physicians and patients with full motion audiovisual images, allowing a true physician–patient relationship.

In addition, several medical centers can be linked with the teleconferencing facility to promote tele-education and teleconsultation. With proper equipment, digital images including endoscopic pictures, pathologic slides, and radiogic images can also be transmitted in real time. The high cost of real-time telemedicine systems and communication networks has currently prevented the widespread use of this technology. For example, a teleconferencing system can cost more than US$80,000 and that does not include the connection fee which can be as high as US$800 per month (52). Recent studies have demonstrated that one could provide high-quality high-definition television image-orientated telemedicine via integrated services digital network lines or communication satellites. However, the minimum set-up cost, greater than US$1,000,000, is still prohibitive (53).

Alternatively, telemedicine can also be accomplished using an asynchronous or "store and forward" system, whereby the information is transmitted via email or the Internet. The recipients can review and respond to the information transmitted at their convenience, as the data are stored in a locally accessible, computerized data storage and retrieval system. Many surgical disciplines, including urology, are increasingly utilizing this technology. Current store and forward technology are also progressively improving with better software development and secure transmission of encrypted data over the Internet (19). Despite lack of real-time interaction, these systems remain very effective and useful tools for medical care and endourologic training (8).

Standardization of input devices for image data exchange is essential for telemedicine. There is an urgent need for future standardization and integration of telemedicine hardware (53).

Although the digital imaging and communications in medicine standard exists for radiological images, there is no standard for other digital images such as endoscopic still pictures or video clips.

The upcoming challenge for telemedicine lies within the decisions made as regards physician licensing requirements, regulation of telemedicine, reimbursement of consultations, and protection of patient confidentiality.

Laparoscopic Applications

Despite the shortcomings outlined above, telemedicine and even telesurgery have become a reality. Kavoussi and coworkers in 1994 demonstrated their initial laboratory experience in telerobotic-assisted laparoscopic surgery (54–59). Recently, urologic

laparoscopic telesurgery has been performed in a clinical setting. In this study, five patients in Rome, Italy, underwent laparoscopic procedures in a center where laparoscopy was only recently introduced (60). Nine thousand kilometers away in Baltimore, United States, a more experienced team oversaw the procedures in real time, offered advice, provided quality control, and even operated instruments remotely. The cases performed included a laparoscopic nephrectomy. This revolutionary approach to telemedicine has opened the door for more widespread applications of laparoscopic techniques, enhanced training, and improved patient care.

As one looks forward into the 21st century, the future of telemedicine looks brighter. Advances in digital imaging resolution and improvements in transmission bandwidth will make telesurgery and decision-making through telemedicine more accurate.

Technological improvements lowering the cost of imaging devices and the cost of utilizing specialized telecommunications lines will make telemedicine systems even more affordable than they are today and greatly enhance the performance of laparoscopic procedures in urology (54,59,61,62).

THE OPERATING ROOMS OF THE FUTURE—TODAY

Most current operating rooms were designed with open surgery needs in mind. As endourology and laparoscopy have gained favor, adjustments were made to accommodate advanced imaging techniques and additional minimally invasive technology. More recent operating room designs address the fundamental differences between open and laparoscopic surgery. Thus, specialized rooms were developed to be much more conducive to the consistent, trouble-free performance of laparoscopic and endourologic procedures.

The development of endoscopic carts containing video monitors, cameras, video recording equipment, insufflation devices, and carbon dioxide tanks facilitated laparoscopy. As mobile units, these carts may be transported from room to room, allowing for laparoscopic capabilities in rooms otherwise designed for open surgery. The quality of the component parts of these systems can be variable and subject to limitations introduced by any of the individual parts. In addition, the mobility of these complex systems introduces further potential for malfunction or inconsistent performance. The potential for carbon dioxide, and therefore surgical exposure, running out during key portions of procedures is another disadvantage of these systems.

Another issue relating to suboptimal operating room design is the effect of imperfect ergonomics on surgeon comfort from a musculoskeletal standpoint.

Several studies have identified significant stressors to the surgeon induced by laparoscopy, including monitor placement, camera holding, trocar placement, and table position and height (63–66).

Ceiling-mounted monitors and designs focused on the laparoscopic surgeon represent operating room updates, increasing versatility in the ergonomics surrounding laparoscopy (Fig. 8). Carbon dioxide delivered to the room constantly through a wall connector obviates the problem of tank turnover at vital points during procedures. Whether or not these specially designed operating rooms improve upon musculoskeletal complications in surgeons remains to be determined, even if some studies showed encouraging results in this regards and improved overall operating room efficiency (67,68).

Robotics and head-mounted displays are other recent advancements effecting surgeon comfort.

Robotics can take the form of either automating some portion of the operation or assisting during the entire operation. Automating the act of camera holding has been shown to be advantageous in terms of ergonomics and procedural efficiency. (69–71) The procedural advantages of robotic assistance to the surgeon are becoming more apparent as robotic surgery further penetrates the operating room. These advantages include three-dimensional stereoscopic vision totally controlled by the operating surgeon, increased instrument range of motion, and markedly improved comfort for both the surgeon and assistants. Immature published data show a potential translation of technical advantages into improved patient outcomes. Head-mounted display may represent an advance providing ergonomic advantages to the surgeon (Fig. 7). The introduction of three-dimensional vision available to the laparoscopic surgeon may bridge the gap between robotic and laparoscopic surgery. However, results regarding the true advantages of such technology are still conflicting (72,73).

The development of laparoscopic instruments with endowrist capabilities further bridging the gap between robotics and pure laparoscopy may be anticipated in the near future.

FIGURE 8 ■ Current (future) endo-scopic/laparoscopic operating room. Ceiling-mounted flat panel monitors. Built-in endoscopy table with adequate room for laparoscopic applications. Ceiling-mounted camera for external footage. Touch panel control allowing for routing of different source images on different monitors. Wall plug in for C-arm integration with room monitors. Wall panel–integrating operating room with audiovisual center allowing for video capture, integration with conference rooms, and teleconferencing.

A central concern in the operating room of the future will continue to be the adequate training necessary to surgeons to safely perform laparoscopy. Video conferencing technology has still several limitations, thereby leaving room for further improvements. As this technology becomes more reliable, remote surgical mentorship will become more feasible. Although scant studies addressed the feasibility of such a concept, the progressive growth of remote laparoscopic training accompanying technology improvements seems reasonable.

The reduction of patients morbidity associated with minimally invasive procedures will continue to drive improvements of endoscopic technology. Tremendous progress, especially in the realm of optics and digital image processing, has occurred in the past decade. It is also clear that over the next few years, high-definition digital processing and high-definition television monitor technology will almost certainly provide even further enhancements. The field of ergonomics and surgeon comfort has also recently become a focus as data accrues regarding musculoskeletal complications in surgeons. The future will certainly see the continued development of operating rooms equipped with instrumentation providing advantages to both surgeon and patient. Undoubtedly, these advantages will include further improvements in digital imaging technologies, more streamlined room design, and ergonomic optimization.

CONCLUSION

The introduction of technological advances such as high-definition television, three-dimensional laparoscopy, and further miniaturization of high-resolution digital video cameras should enhance laparoscopic surgical proficiency, and further broadening of laparoscopic applications in urology. These enhancements, coupled with the recent advances in telemedicine and surgical simulation, should also improve laparoscopic training and skill acquisition, decrease operative times and costs, minimize morbidity, and overall improve patient care. Furthermore, the integration of all of these technological advancements within specially designed operating rooms should maximize the application of each individual advance and allow for improved ergonomic performance of minimally invasive urologic procedures.

SUMMARY

- Exposure remains one of the keys to success in both open and laparoscopic surgery.
- In laparoscopy, high-quality optics are absolutely essential to provide the necessary exposure for a successful surgical intervention.
- The development of the digital video endoscope has been a major advance in the endoscopic systems.
- The replacement of smaller caliber laparoscopes with integrated digital video endoscope can be expected in the near future.
- Over the last few years, digital imaging has slowly revolutionized the field of video endoscopy.
- Incorporating medical images into the patient's record and creating an image library can enhance urologic practice.
- High-quality display systems are essential during endoscopic surgery.
- Advances in virtual reality simulation offer a practical tool to practice endourologic procedures in an inanimate but dynamic, life-like environment.
- Endourologic operative skills may be acquired more rapidly using virtual reality simulators.
- Technological improvements lowering the cost of imaging devices and the cost of utilizing specialized telecommunications lines will make telemedicine systems more affordable and greatly enhance the performance of laparoscopic procedures in urology.
- Robotics and head-mounted displays effect surgeon comfort.
- The integration of technologic advancements within specially designed operating rooms allow for improved ergonomic performance of minimally invasive urologic procedures.

INTRODUCTION

> The use of bioadhesive technology in laparoscopic urologic surgery dates back to the mid-1990s; however, Bergel first used dry plasma to establish hemostasis in 1909.

The use of bioadhesive technology in laparoscopic urologic surgery dates back to the mid-1990s (1); however, Bergel first used dry plasma to establish hemostasis in 1909 (2).

Fibrin patches to establish hemostasis during cerebral surgery (3) and to manage bleeding from battlefield parenchymal organ injuries were introduced subsequently. The adhesive properties of fibrin sealant were first recognized experimentally and then clinically in 1942, when investigators performed microsurgical peripheral nerve anastomoses (4). The quality of fibrin sealant during this time was poor because of low in vivo concentrations of fibrinogen and fibrin. A significant advance was made in 1944, when researchers attempted to accelerate the formation of fibrin clot by mixing fibrinogen with bovine thrombin (5). However, the adhesive properties remained inadequate because the fractionation techniques required to prepare concentrated fibrinogen were still not perfected. The use of fibrin sealant was therefore limited to applying dry fibrin to bleeding surfaces. In the 1970s, purification and fractionation techniques grew more sophisticated and high concentrations of freeze-dried fibrinogen became available. Gradually, high concentrations of fibrinogen and other components such as thrombin and factor VIII became commercially available. Europe saw the first commercial, multidonor fibrin-sealant products in the late 1970s, yet the United States was more reluctant to embrace a product that had the potential of viral contamination (6). In fact, licenses for the clinical use of fibrinogen substrates were revoked in the United States in 1978, and further purification and viral detection methods had to be developed before commercially available fibrin-sealant products could be employed clinically (7). Because of the potential benefits of fibrin sealant, American surgeons turned to fibrin preparations, either autologous or obtained from single-donor cryoprecipitates. Although the risk of disease transmission was theoretically prevented, the preparation of such products was time consuming and the fibrinogen concentration, critical to the sealant's tensile strength, was variable and unreliable. Despite the availability of several commercial

Today's fibrin sealants have excellent rheological properties that make them excellent additions to standard methods of tissue approximation and help secure hemostasis.

The hemostatic process depends upon the integrated activity of vascular, platelet, and plasma factors in combination with the regulatory mechanisms of anticoagulation, which are necessary to stabilize the fibrin clot and prevent accumulation of platelets and fibrin in areas of noninjury.

Regional vasoconstriction and extrinsic compression of damaged blood vessels by extravasated blood contribute to hemostasis on a purely mechanical level. Temporary arterial occlusion during laparoscopic partial nephrectomy can help achieve the same goal by intentionally decreasing the blood flow to the cut surface of the renal parenchyma.

fibrin-sealant preparations in Europe, Canada, and Japan, the U.S. Food and Drug Administration did not approve Tisseel™a until 1998.

Today's fibrin sealants have excellent rheological properties (elasticity, tensile strength, and adhesiveness) that make them excellent additions to standard methods of tissue approximation and help secure hemostasis.

Fibrin sealant is the only agent truly considered a "bioadhesive." However, gelatin matrix, thrombin, collagen, and cellulose products are available for enhancing hemostasis. All can be applied laparoscopically by either directly passing the agent through a laparoscopic port or using long applicator devices.

HEMOSTASIS

Hemostasis is achieved with the production of a fibrin clot that seals a site of injury, or a damaged blood vessel.

The hemostatic process depends upon the integrated activity of vascular, platelet, and plasma factors in combination with the regulatory mechanisms of anticoagulation, which are necessary to stabilize the fibrin clot and prevent accumulation of platelets and fibrin in areas of noninjury.

More specifically, the coagulation cascade can be activated by exposure of blood to foreign surfaces, tissue factors, or by platelet activation.

Vascular Factors

Regional vasoconstriction and extrinsic compression of damaged blood vessels by extravasated blood contribute to hemostasis on a purely mechanical level. Temporary arterial occlusion during laparoscopic partial nephrectomy can help achieve the same goal by intentionally decreasing the blood flow to the cut surface of the renal parenchyma.

This allows for better visualization that ultimately helps in achieving more permanent hemostasis after vascular clamp removal. Most likely, the extravasated blood helps hemostasis by a tamponade-like effect.

Platelets

Platelets are integral to efficient hemostasis because they adhere and aggregate to the sites where tissue factors is exposed by disruption of the vascular endothelial lining. After endothelial cell damage and loss, adhesive glycoproteins such as collagen, thrombin, and von Willebrand factor are exposed in the subendothelial tissue. Receptors on the platelets mediate binding to the glycoproteins, thus causing platelet adhesion to the particular area of vessel injury. An activation process leading to a conformational change in specific glycoproteins enables the platelets to bind multivalent adhesive proteins such as fibrinogen and von Willebrand factor (8). Platelet aggregation occurs through the interaction of adhesive glycoprotein cross-binding two different platelets. The aggregation process continues until the platelets create a hemostatic plug. Activation of platelets leads to (i) increased vasoconstriction through serotonin and thromboxane A2, (ii) vessel wall repair, and (iii) formation of enzyme/cofactor complexes by providing surface membranes upon which blood coagulation complexes can occur (8). Platelets also secrete platelet factor V, a key component of the enzyme/cofactor complex responsible for thrombin production. Thrombin activates more platelets and stimulates further coagulation by initiating fibrin deposition. The fibrin strand deposition reinforces the platelet plug and serves as a site for more von Willebrand factor deposition (9).

Plasma

The second crucial element of hemostasis—the fibrin clot—is the result of a complex interaction of many plasma proteins, proenzymes, and cofactors (10). The fibrin clot, the end product of the coagulation cascade, arises from and anchors the hemostatic plug. The cascade model of coagulation involves the activation of one of two pathways, the intrinsic pathway and the extrinsic pathway (Fig. 1). When these pathways were studied, it was thought that all the factors in the intrinsic pathway were within the vascular system, and that the tissue factors necessary to activate the extrinsic pathway were found outside the vascular space. Furthermore, it was believed that the two pathways were activated independently of one another. The current understanding of hemostasis helps appreciate that the intrinsic and extrinsic pathways are very much intertwined and that

FIGURE 1 ■ Cascade model for coagulation.

all clotting factors are in some way interrelated. Nevertheless, each pathway, including that initiated by platelets, results in the conversion of factor X to activated factor X. Factor Xa as well as activated factor V (Va) converts prothrombin to thrombin. Converting fibrinogen to fibrin, thrombin plays an extremely critical role in the process of fibrin clot development.

> Converting fibrinogen to fibrin, thrombin plays an extremely critical role in the process of fibrin clot development.

Fibrinogen, a soluble blood component, comprising 0.2% of whole blood volume is a glycoprotein comprising three pairs of polypeptide chains called Aα, Bβ and γ. The central domains of the fibrinopeptide A and B are cleaved from their respective Aα and Bβ chains by the serine protease thrombin. This enzymatic cleavage forms the fibrin monomers due to a change in the charge and conformation of fibrinogen (6). Hydrogen bonds and electrostatic reactions polymerize the fibrin monomers into unstable and soluble fibrin fibers.

> In the presence of ionized calcium, thrombin activates factor XIII to XIIIa. Factor XIIIa converts the noncovalent bonds between the fibrin fibers into covalent bonds and creates stable and insoluble fibrin clot by cross-linking the fibrin molecules.

In the presence of ionized calcium, thrombin activates factor XIII to XIIIa. Factor XIIIa converts the noncovalent bonds between the fibrin fibers into covalent bonds and creates stable and insoluble fibrin clot by cross-linking the fibrin molecules (11).

TOPICAL BIOLOGIC AGENTS: PHARMACOLOGIC

Fibrin Sealant

Fibrin sealant may be produced from pooled sources or a single donor. The use of pooled blood products is the current basis for the commercially available fibrin sealant. The single-donor blood can be allogenic or autologous.

> Fibrin sealant may be produced from pooled sources or a single donor. The use of pooled blood products is the current basis for the commercially available fibrin sealant. The single-donor blood can be allogenic or autologous.

Nine fibrin sealants are currently available to urologists worldwide: (i) Tisseel[TMb]; (ii) Crosseal[TMc]; (iii) Hemaseel[TMd]; (iv) Quixil[TMe]; (v) Beriplast P[TMf]; (vi) Bolheal[TMg]; (vii) Biocol[TMh]; (viii) VIGuard F.S[TMi].; and (ix) CoStasis[TMj]. Tisseel, Crosseal, Hemaseel, VIGuard F.S., and Costasis have Food and Drug Administration approval for sale in the United States.

The primary component of all synthetic fibrin sealants is highly concentrated human fibrinogen mixed with factor XIII and fibronectin. Human thrombin concentrate and an antifibrinolytic constitute the remaining components. Fibrinogen and thrombin are solubilized with antifibrinolytic and calcium chloride solutions, respectively (6).

Fibrin sealants do not rely on the intrinsic/extrinsic clotting pathways and actually function also in the presence of systemic coagulation defects.

When the two components are mixed in the presence of ionized calcium, the last step in the coagulation cascade is reproduced beginning with thrombin cleavage of fibrinopeptides A and B from the fibrinogen molecule. Thrombin also activates factor XIII, which stabilizes fibrin cross-linkage and promotes the formation of an insoluble, nonfriable clot. The addition of fibronectin helps to cross-link fibrin, and to stimulate cellular migration (12) and fibroblastic growth in the areas where the fibrin sealant was applied.

Fibrin sealants do not rely on the intrinsic/extrinsic clotting pathways and actually function also in the presence of systemic coagulation defects.

An antifibrinolytic, which is a variable ingredient in the fibrin-sealant preparation, is intended to slow the rate of fibrinolysis and thereby preserve the integrity of the fibrin clot. In Tisseel and Hemaseel, aprotinin is the antifibrinolytic agent. Alternatively, the antifibrinolytic in Crosseal is tranexamic acid. Aprotinin, derived from bovine lung, inhibits a number of serine proteases including trypsin, chymotrypsin, kallikrein, elastase, urokinase, thrombin, and plasmin (13). Tranexamic acid, a synthetic analogue of the amino acid lysine, prevents the binding of plasminogen and plasmin to fibrinogen and fibrin by competing with lysine for binding sites, and thus helps to suppress fibrinolysis (14). Tranexamic acid also offers a theoretical advantage because it is not bovine derived. In fact, anaphylactic reactions reported in bovine aprotinin did not occur with tranexamic acid (15–20). Crosseal eliminates the risk of bovine spongiform encephalopathy transmission and immunologically mediated coagulopathy.

Tranexamic acid has caused neurologic symptoms including trembling, involuntary head movements, and clonic contractions in rabbits.

Tranexamic acid has caused neurologic symptoms including trembling, involuntary head movements, and clonic contractions in rabbits (21,22).

Tisseel VH contains four separate vials and its preparation requires approximately 20 minutes prior to reconstitution—all four vials have to be warmed (37°C) using the Fibrinotherm heating and stirring device or a water bath. The bovine aprotinin is aspirated and injected into the fibrinogen vial. This solution is mixed in a magnetic stirring well for one to four minutes depending on the volume of the kit. The calcium chloride is added to the thrombin vial before agitation and further warming of the mixture. Once the preparation process is completed, the Tisseel is best used within four hours. The two components of the fibrin sealant may be applied sequentially or simultaneously. The most common method of application relies on a double-barreled Duploject™ Preparation and Application System[k] enabling simultaneous and equal application of the fibrinogen and thrombin solutions through a blunt-tipped needle. A laparoscopic applicator is also available. Conversely, Crosseal can be prepared in less than one minute and does not require a warming process provided the solutions have been previously thawed (21). Like Tisseel, Crosseal can be applied with a laparoscopic applicator. Both brands of fibrin sealant should be applied with individual drops to the target area. The drops should be allowed to separate from one another and from the applicator tip. Fibrin sealants also can be applied using a source of forced sterile gas (35–45 lb/inch^2) to spray equal portions of the solutions onto a desired surface.

- Proper application is essential for optimal adhesive function.
- After the sealant application, the two surfaces should be brought into contact prior to polymerization of the sealant.
- Once polymerization has occurred on one surface, it will act as an antiadhesive and prevent the two surfaces from adhering (23,24).
- Fibrin sealant is most effective in a "dry" operative field because it does not rely on the presence of blood to develop the fibrin clot.

This differs from other hemostatic agents such as Floseal™[k] or Gelfoam™[l], which require blood for optimal hemostasis.

To avoid the possibility of thromboembolic complications, fibrin sealant should be applied with caution and should not be injected directly into large blood vessels.

To avoid the possibility of thromboembolic complications, fibrin sealant should be applied with caution and should not be injected directly into large blood vessels (24).

Two additional preparations of fibrin, the absorbable fibrin adhesive bandage and the hemostatic fibrin-sealant powder have been described and utilized in a porcine model. Theabsorbable fibrin adhesive bandage[m] is made of a concentrated mixture of lyophilized fibrinogen and thrombin on an absorbable Vicryl backing (25). Cornum et al. (25) applied the absorbable fibrin adhesive bandage to porcine kidneys after lower-pole heminephrectomy; by comparing this method of hemostasis to conventional methods of partial nephrectomy bed repair, the authors found significantly less bleeding and

---

[k]Baxter Healthcare Corporation, Deerfield, IL.
[l]Pfizer, New York, NY.
[m]American Red Cross, Washington, D.C.

shorter operative and ischemia times in the absorbable fibrin adhesive bandage group. The same team employed the absorbable fibrin adhesive bandage for the management of grade-4 renal stab wounds in a porcine model and found that the bandage had a promising role in the renal trauma setting (26). However, such a fibrin preparation is not currently applicable to laparoscopy because the bulky nature of the bandage prohibits placement through laparoscopic ports. Furthermore, placement through a handport would be difficult because it will adhere to any moist surface that it comes into contact with. The other additional fibrin preparation, hemostatic fibrin-sealant powder,[n] consists of lyophilized human fibrinogen and thrombin. Bishoff et al. evaluated the ability of hemostatic fibrin-sealant powder to achieve hemostasis and seal the collecting system of porcine kidneys after laparoscopic heminephrectomy (27). In this study, hemostatic fibrin-sealant powder applied alone with regional ischemia was compared to conventional intracorporeal suturing with vascular control. Follow-up computed tomography was performed at 48 hours and six weeks. Although at 48 hours there were more urinomas in the hemostatic fibrin-sealant powder group, at six weeks there was no evidence of urinoma or hematoma in either group. Unlike the absorbable fibrin adhesive bandage preparation, the hemostatic fibrin-sealant powder preparation holds promise as a possible addition to the laparoscopic armamentarium of hemostatic agents.

Fibrin-Sealant Variant

Costasis, a fibrin-sealant variant that combines autologous fibrinogen with bovine thrombin and collagen, is prepared by drawing the patient's blood into a plasma-collecting system. The blood is centrifuged and the plasma is separated. The autologous plasma is mixed with thrombin using a dual syringe applicator. This product, unlike Tisseel or Crosseal, does not contain an antifibrinolytic such as aprotinin or tranexamic acid. Although Costasis has been used in cardiac, general, and orthopedic surgical fields, there are no reports in the urologic literature regarding its use or efficacy.

The primary advantage of Costasis is that the autologous source of fibrinogen eliminates the potential risks of viral transmission. However, both the risk of bovine spongiform encephalopathy and allergic reaction to bovine thrombin remain.

> The primary advantage of Costasis is that the autologous source of fibrinogen eliminates the potential risks of viral transmission. However, the risk of bovine spongiform encephalopathy and allergic reaction to bovine thrombin remain.

Gelatin Matrix and Thrombin

Floseal is a Food and Drug Administration-approved gelatin-matrix hemostatic sealant that has been well described in open cardiac, vascular, spine, and ear-nose-throat surgery (28–32).

> Floseal is a Food and Drug Administration-approved gelatin-matrix hemostatic sealant that has been well described in open cardiac, vascular, spine, and ear-nose-throat surgery.

Cross-linked gelatin granules comprise the gelatin matrix component of Floseal. The granules are manufactured after (i) extraction of collagen from bovine corium, (ii) gelatinization of the collagen, (iii) cross-linking and stabilization with glutaraldehyde, and (iv) grinding of the gelatin into 500 to 600 µm particles (33). Thrombin is bovine derived and similar to that used in the fibrin-sealant systems (Table 1). Hemostasis is achieved when the granules conform and swell by 10% to 20% upon contact with blood or body fluids (33). The outcome is blood flow restriction and a tamponade effect. Additionally, the presence of high concentrations of thrombin promotes long-term hemostasis by augmenting clot formation.

TABLE 1 ■ Characteristics of Pharmacologic and Physical Hemostatic Agents

Hemostatic agent	Manufacturer	Available preparations	Bovine derived	Intact coagulation pathway
Gelatin matrix and thrombin—*Floseal*	Baxter Healthcare Corp.	Matrix	Yes	Partially (circulating fibrinogen)
Microfibrillar collagen —*Avitene*	C.R. Bard, Inc.	Powder, sponge, and film	Yes	Yes
Oxidized cellulose —*Surgicel*	Johnson & Johnson	Fabric-like sheet	No (plant based)	Yes
Oxidized cellulose —*Oxycel*	Ethicon	Fabric-like sheet	No (plant based)	Yes
Gelatin—*Gelfoam*	Pfizer	Powder, sponge	Yes	Yes
Gelatin—*Surgifoam*	Johnson & Johnson	Powder, sponge	Yes	Yes

[n]American Red Cross, Washington, D.C.

■ In contrast to the fibrin sealants, Floseal relies on endogenous fibrinogen to supply fibrin for clot formation.
■ It is ineffective in fibrinogenemic patients.
■ Some degree of bleeding is necessary for Floseal to function, whereas fibrin sealants require a relatively dry surface.

The gelatin granules are manually mixed with the thrombin prior to delivery of the slurry with a laparoscopic applicator. The slurry is somewhat thick and requires an applicator with a sufficient diameter for deployment. Furthermore, the slurry ought to be mixed just prior to delivery to insure even viscosity and prevent applicator clogging. After slurry delivery, the slurry remaining caught in the "deadspace" of the applicator may be utilized by injecting air (one syringe) into the applicator. Once completely delivered, pressure should be gently applied for several minutes, to allow the formation of fibrin clot.

Floseal works in cases of fairly active bleeding, whereas fibrin sealants and physical agents are better suited for diffuse bleeding or oozing. This most likely accounts for the common use of Floseal in urologic laparoscopy as a hemostatic adjunct during laparoscopic partial nephrectomy (34–36).

Floseal, unlike fibrin sealants, is not an adhesive and therefore should not be used to seal the urinary collecting system.

> Floseal works in cases of fairly active bleeding, whereas fibrin sealants and physical agents are better suited for diffuse bleeding or oozing.

> Floseal, unlike fibrin sealants, is not an adhesive and therefore should not be used to seal the urinary collecting system.

Thrombin and Gelatin

The combination of thrombin and gelatin, either Gelfoam™[o] or Surgifoa™[p], is commonly used to establish hemostasis. To ultimately form a fibrin clot, the thrombin has to interact with an in vivo circulating fibrinogen, which is required for this method of hemostasis. In general, during laparoscopic surgery, the thrombin is delivered to the desired area by saturating gelatin sponges. By routinely using a thumb portion of a sterile surgical glove as a delivery bag to place the thrombin-soaked sponges through the laparoscopic ports, we prevent the fragmentation of the sponge and its premature contact with blood prior to final application. This method of hemostasis has been widely utilized during laparoscopic partial nephrectomy. In addition to a delivery mechanism for thrombin, the bulk of the gelatin within the parenchymal defect may provide compression on the surgical bed and aid in hemostasis.

TOPICAL BIOLOGIC AGENTS: PHYSICAL

Microfibrillar Collagen

Collagen is the main protein component of skin, tendon, bone, and blood vessels. Vascular injury exposes collagen fibrils in the subendothelial layer. Platelets bind to the exposed collagen either directly or via the von Willebrand factor. Manufactured collagen products, prepared as sheets or a loose fluffy powder, enhance platelet aggregation in the area of bleeding and clot formation by prompting localization of endogenous coagulation factors and by stimulating fibrin deposition. Collagen further adds to hemostasis by activating the intrinsic pathway.

Hemostatic action of collagen requires an intact coagulation system with functional platelets and clotting factors (Table 1). Therefore, collagen has little effect in patients with inactivated platelets (e.g., aspirin) or compromised clotting pathways (e.g., heparin and coumadin).

> Hemostatic action of collagen requires an intact coagulation system with functional platelets and clotting factors. Therefore, collagen has little effect in patients with inactivated platelets (e.g., aspirin) or compromised clotting pathways (e.g., heparin and coumadin).

Avitene sheets of bovine-derived collagen[q] are cumbersome laparoscopically because of being brittle and difficult to deliver into the insufflated abdomen. As such, the use of collagen sheets is limited. The powdered collagen preparation is more amenable laparoscopically because it can be blown through a large diameter catheter. EndoAvitene™[q] is a novel product specifically designed for laparoscopic use. The preloaded collagen can be applied through a 5 mm port and may be used in conjunction with thrombin, which can be dripped or sprayed over the deposited collagen.

Oxidized Cellulose

Oxidized cellulose, an absorbable knitted fabric prepared by the controlled oxidation of regenerated cellulose (Table 1), is free from risks associated with human/bovine

---

[o]Pfizer, New York, NY.
[p]Johnson & Johnson, New Brunswick, NJ.
[q]C.R. Bard, Inc., Murray Hill, NJ.

The hemostatic action of cellulose requires a functional clotting cascade and the presence of all clotting factors.

Cellulose has no adhesive properties and is only used to better establish hemostasis. In urologic laparoscopy, cellulose generally is applied after nephrectomy to control persistent bleeding from the raw edge of a spared adrenal gland or during partial nephrectomy for packing the newly created divot in the renal parenchyma.

Because the acidity of oxidized cellulose inactivates thrombin, thrombin and cellulose should not be used together.

Furthermore, gelatin will only enhance hemostasis if the clotting pathway is functional and if all the clotting factors are present.

The use of agents designed to augment standard methods for optimizing hemostasis is warranted during several urologic and laparoscopic procedures.

All sorts of hemostatic agents have been experimented with and documented during laparoscopic partial nephrectomy.

contaminant transmission and enhances hemostasis by contact activation of the intrinsic coagulation pathway. Also, its swollen gelatinous mass may hold clotting factors in the region of bleeding and augment clot formation. The cellulose is completely absorbed with time (7–14 days) without significant tissue reaction.

The hemostatic action of cellulose requires a functional clotting cascade and the presence of all clotting factors.

Surgicel™ᵣ and Oxycelˢ are available in varying-sized cloth-like sheets that can be passed easily through laparoscopic ports. Because cellulose will adhere strongly to any moist tissue, careful maneuvering is required to place it precisely on the desired location.

Cellulose has no adhesive properties and is only used to better establish hemostasis. In urologic laparoscopy, cellulose generally is applied after nephrectomy to control persistent bleeding from the raw edge of a spared adrenal gland or during partial nephrectomy for packing the newly created divot in the renal parenchyma (37).

When used as a bolster over which to suture the renal capsule, the cellulose can be rolled up and held in position with a 4.0 Vicryl suture at either end. The swelling of the cellulose upon contact with blood allows it to generate a tamponade effect similar to gelatin. Caution should be taken in situations where a confined space is involved. Several cases of neurologic injury, such as acute paraplegia, have been reported after application of cellulose. It was postulated that the migration of the cellulose into the epidural space caused spinal cord compression. Conceivably, overly enthusiastic application near the ureter or renal vessels could result in obstruction.

Because the acidity of oxidized cellulose inactivates thrombin, thrombin and cellulose should not be used together.

Gelatin

Gelatin, similar to collagen and cellulose, initiates the intrinsic pathway of the clotting cascade through contact activation. Gelfoam and Surgifoamᵣ are the two available bovine-derived gelatin products (Table 1). Generally, neither product is utilized alone but rather is combined with thrombin (see the section entitled "Thrombin and Gelatin").

Furthermore, gelatin will only enhance hemostasis if the clotting pathway is functional and if all the clotting factors are present.

UROLOGIC LAPAROSCOPIC APPLICATIONS

Hemostatic agents are routinely utilized in many areas of urologic surgery (24). Urologic laparoscopy has become more complex as procedures grow and evolve to duplicate their open-surgery counterparts. Increased complexity correlates with increased chances for complications due to inadequate hemostasis.

The use of agents designed to augment standard methods for optimizing hemostasis is warranted during several urologic and laparoscopic procedures.

Laparoscopic Nephrectomy

Hemostatic agents are not routinely used for laparoscopic radical nephrectomy for a number of reasons: (i) bleeding is usually kept to a minimum because of insufflation pressures; (ii) significant-sized blood vessels are controlled with vascular clips or staplers; and (iii) the urinary collecting system is routinely controlled at the level of the ureter. Nevertheless, hemostatic agents have been utilized for varying degrees of bleeding encountered during laparoscopic nephrectomy.

Laparoscopic Partial Nephrectomy

During laparoscopic partial nephrectomy transection of intra-renal blood vessels and violation of urinary collecting system account for the two major complications, e.g., delayed hemorrhage and urinoma. Even with hilar control, laparoscopic suturing of the interlobar arteries and opened calyces can be challenging due to suboptimal visualization and/or difficult angles. All sorts of hemostatic agents have been experimented with and documented during laparoscopic partial nephrectomy.

ᵣJohnson & Johnson, New Brunswick, NJ.
ˢEthicon, Somerville, NJ.

Initially, oxidized cellulose, gelatin, and collagen were used either alone or in conjunction with a hemostatic energy source such as an argon beam coagulator. Kletscher et al. evaluated the efficacy of both Gelfoam and Avitene to control parenchymal hemorrhage during laparoscopic anatrophic nephrolithotomy in a porcine model (38). Gelfoam and Surgicel were welded to the cut and outer surface of the kidney using an argon beam coagulator. Since this early report, cellulose, gelatin, and collagen have all been utilized for hemostasis in laparoscopic partial nephrectomy Stifelman et al. (37) performed 11 hand-assisted laparoscopic partial nephrectomies (mean tumor size 1.9 cm) and applied Surgical, Avitene, or fibrin-soaked Gelfoam activated by thrombin to the renal defects. Vascular hilar control was not obtained prior to excision of the renal lesion. The authors experienced no major complications and only two minor complications other than postoperative hemorrhage. Cellulose in conjunction with fibrin sealant for hemostasis has also been employed during laparoscopic partial nephrectomy Jeschke et al. (39) performed 51 laparoscopic partial nephrectomies for small (2.0 cm) exophytic renal tumors and covered the renal defect with oxidized cellulose and 2 mL fibrin sealant. Vascular hilar control was not performed and the integrity of the collecting system was not tested intraoperatively. One patient required reoperation for hemorrhage on postoperative day 1, and three developed urinary fistulas on postoperative days 3 to 4.

Floseal also has been used to enhance hemostasis during laparoscopic partial nephrectomy (34–36). Richter et al. (34) performed 10 laparoscopic partial nephrectomies for tumors (median tumor size 2.8 cm) and applied Floseal after tumor resection and before reperfusion of the kidney. Immediate hemostasis was obtained and maintained even after kidney reperfusion. No postoperative hemorrhage occurred and no significant perirenal hematoma was detected with follow-up ultrasonography at 24 hours and 10 days postoperatively. Bak et al. (35) reported similar results after six laparoscopic partial nephrectomies performed for 2 to 5 cm exophytic lesions (median size: 2.5 cm). Also in this study, hemostasis was achieved immediately upon application of Floseal on the moist surface of partial nephrectomy bed, and clinically evident postoperative hemorrhage did not occur.

During laparoscopic partial nephrectomy, we routinely obtain vascular control, and test the integrity of the collecting system with dilute methylene blue injected via a retrograde catheter. Any disruption of the collecting system is closed with intracorporeal figure-of-eight suturing. Tisseel is dripped over the areas of the collecting system and Floseal is applied on the moist surface of the cut renal parenchyma. Gelfoam bolsters are placed under the slightly tightened capsular sutures. Lastly, the remainder of the Tisseel is applied over the entire repair prior to removing the vascular clamp. No postoperative hemorrhage or urinary leak occurred in our experience.

Retroperitoneal Lymph-Node Dissection

During laparoscopic retroperitoneal lymph-node dissection, fibrin sealant can be applied to the lymph-node bed, in addition to the routine use of laparoscopic clips. However, lymphatic leaks may occur despite proper attempts to ligate all major lymphatic channels. Although no randomized, prospective trials evaluating the benefit of fibrin glue in this setting have been reported, fibrin glue has been used selectively during lymph-node dissections performed by European teams (40) and to aid the treatment of chylous ascites occurring after a donor nephrectomy (41).

Ureteral Anastomosis, Pyeloplasty, and Prostatectomy

Oxidized cellulose, gelatin, collagen, and gelatin matrix/thrombin combination are not considered sealants or adhesives and should not be used to close any part of the collecting system. Therefore, only fibrin sealant should be employed for controlling urinary leakage after planned or traumatic disruption (42) of the collecting system.

Several investigators have utilized porcine models to attempt closure of the urinary tract with fibrin sealant. After performing laparoscopic ureteral transection in five pigs, McKay et al. approximated the ureter with two transmural sutures and sealed the anastomosis with fibrin sealant. Outcomes were compared to those of conventional ureteral anastomosis. Although renal pelvis perfusion tests were higher (12.6 cm H_2O vs. 3 cm H_2O) in the fibrin-sealant group at eight weeks, the values were within normal range for the porcine model. The authors concluded that laparoscopic ureteral anastomosis using fibrin preparations was feasible (43).

Wolf et al., using a porcine model to compare the efficacy of fibrin sealant for closure of five linear ureterotomies with laser-assisted anastomosis, mechanical suturing

---

Oxidized cellulose, gelatin, collagen, and gelatin matrix/thrombin combination are not considered sealants or adhesives and should not be used to close any part of the collecting system. Therefore, only fibrin sealant should be employed for controlling urinary leakage after planned or traumatic disruption of the collecting system.

Wolf et al., using a porcine model to compare the efficacy of fibrin sealant for closure of five linear ureterotomies with laser-assisted anastomosis, mechanical suturing device, and conventional laparoscopic suturing, concluded that fibrin sealant yielded more favorable radiographic findings, flow characteristics, and histology.

device, and conventional laparoscopic suturing, concluded that fibrin sealant yielded more favorable radiographic findings, flow characteristics, and histology (44).

Anidjar et al. attempted to approximate porcine ureters using only fibrin sealant after laparoscopic segmental ureterectomy. The ureteral ends were held together for five minutes after the sealant was applied. No immediate anastomotic disruption occurred, and patency of all 10 anastomoses with no leakage in eight and minimal leakage in two was documented with fluoroscopy. Two pigs representing the chronic arm of the study died because of massive urinoma on postoperative days 6 and 8, respectively. Histologic examination revealed no significant coaptation of the ureteral ends.

> **Performing ureteral anastomoses with fibrin glue alone and no stay sutures is not recommended.**

Performing ureteral anastomoses with fibrin glue alone and no stay sutures is not recommended (45).

In another series, the combination of fibrin sealant and sutures applied in three patients with traumatic ureteral injuries was successful (42). To our knowledge, no other human studies of fibrin sealant for ureteral anastomosis are available.

> **Experimental and clinical data indicate that the sole use of fibrin sealant for ureteral anastomosis is unsafe. However, fibrin sealant applied with a limited number of approximating sutures may achieve results comparable to those of sutured anastomosis while decreasing operative time.**

Experimental and clinical data indicate that the sole use of fibrin sealant for ureteral anastomosis is unsafe. However, fibrin sealant applied with a limited number of approximating sutures may achieve results comparable to those of sutured anastomosis while decreasing operative time.

To determine the efficacy of fibrin-sealant–assisted ureteral anastomosis, additional clinical trials, with a larger number of patients, are awaited.

Fibrin sealant has been also used to complete the ureteropelvic anastomosis during a laparoscopic ureteropelvic junction obstruction repair (1). Eden et al. successfully performed eight retroperitoneal laparoscopic dismembered pyeloplasties by first approximating the ureteropelvic anastomosis with stay sutures, and subsequently sealing the anastomosis with fibrin glue. Patients were followed up with diuretic renography performed at three months and yearly thereafter. At one to two years follow-up, all patients had satisfactory upper-tract drainage. However, further clinical studies with larger numbers of patients are necessary to evaluate this technique.

We do not rely on the fibrin sealant for closure of the ureteropelvic anastomosis during laparoscopic junction obstruction repair. Rather, we perform running or interrupted suturing of the anastomosis and occasionally apply fibrin glue to suture lines. Although suturing is more time consuming than simply applying fibrin sealant, we still believe that the water-tightness of the anastomosis is better achieved with traditional closure.

> **Laparoscopic prostatectomy is another field of application for hemostatic agents even if the magnified visualization and the insufflation pressures already facilitate the control of the oozing frequently seen during open prostatectomy.**

Laparoscopic prostatectomy is another field of application for hemostatic agents even if the magnified visualization and the insufflation pressures already facilitate the control of the oozing frequently seen during open prostatectomy.

We do not routinely use any of the hemostatic agents and would likely use fibrin sealant if needed because of its potential to help seal the urethral anastomosis. To date, there are no reports describing the routine application of any of the hemostatic agents to laparoscopic prostatectomy, and we are unaware of any clinical trails upon which to base the efficacy of any of these agents in this particular setting.

Laparoscopic Injuries

Injuries to intestine, vascular structures, spleen, and diaphragm are known complications of laparoscopic urologic surgery. Hemostatic agents have been used to repair some of these injuries. During a right laparoscopic radical nephrectomy, Bhayani et al. applied gelatin matrix with thrombin (Floseal) to a 1 cm tear in the diaphragm (46). A Babcock clamp was used to approximate the diaphragm, and the omentum was used to cover the repair. While preferring formal suture repair for large diaphragmatic injuries, the authors recommended the use of Floseal to treat small diaphrag-matic injuries.

Fibrin sealant has also been used for repair of splenic injuries. Canby-Hagino et al. described utilizing fibrin sealant to manage conservatively a splenic laceration caused by upper-pole dissection during transperitoneal laparoscopic nephrectomy. Splenectomy was not necessary (47).

> ■ All hemostatic agents have the potential to be a useful adjunct to traditional means of controlling intraoperative laparoscopic complications.
> ■ Any complication should be managed with definitive measures that also prevent the development of additional complications.
> ■ There are no prospective trials specifically addressing the use of hemostatic agents for the management of complications occurring during urologic laparoscopic procedures. Bioadhesive/hemostatic agents may be used alone to manage a complication only in select cases.

POTENTIAL COMPLICATIONS

Allergic

The use of hemostatic agents implies potential risks of allergic reactions because bovine thrombin is immunogenic. Sudden and severe hypotension resulting in death has been reported after applying bovine thrombin to a deep hepatic wound (48), and immune-mediated coagulopathy from bovine thrombin is a well-recognized complication (49–51).

Exposure to bovine thrombin may result in the formation of antibovine thrombin immunoglobulin E antibodies. Upon reexposure, such antibodies may cross react with human thrombin and cause anaphylaxis, coagulopathy, or hypercoagulability (52,53).

> ■ Recent commercial preparations have replaced bovine thrombin with human thrombin (Tisseel and Crosseal).
> ■ Some products still contain bovine thrombin (Costasis, Floseal) or bovine-derived materials such as aprotinin (Tisseel) or collagen (Floseal).
> ■ To avoid adverse outcomes, products containing bovine protein should be contraindicated in patients with known allergy hypersensitivity reactions.

Infectious

> ■ Commercially available fibrin sealant carries a theoretical risk of viral contamination because it is manufactured from pooled human–plasma components.
> ■ Advances in viral inactivation technology have significantly reduced the risk of hepatitis A, B, and C, and HIV transmission.

Various viral inactivation techniques including vapor heating, steam treatment, pasteurization, irradiation, solvent detergent extraction, and nanofiltration have been utilized (6).

Careful donor selection strategies and screening plasma units intended for sealant production are another factors reducing the risk of viral transmission.

To avoid viral transmission, Tisseel is prepared from plasma donated from screened donors, and tested for viral contaminants. Furthermore, Tisseel manufacturing includes a two-step vapor-heated method for viral inactivation (Table 2) (54). In addition to donor screening and plasma testing human immuno defficiency virus, hepatitis A, B, and C, and parvovirus B19, both solvent detergent and pasteurization for viral inactivation can be used to produce Crosseal (Table 2) (21). Although Costasis prevents viral transmission altogether by collecting a patient's own blood as a source of autologous fibrinogen, it relies on bovine thrombin. Four cases of parvovirus B19 transmission have occurred in Japan (55,56). None of these preparations was approved by Food and Drug Administration and there are no reports of such a transmission in Europe or the United States so far.

Although no case of viral transmission using bovine thrombin has been reported, bovine spongiform encephalopathy is a theoretical risk (6). The risk of prion transmission is thought to be very low but cannot be entirely eliminated.

Margin notes:

The use of hemostatic agents implies potential risks of allergic reactions because bovine thrombin is immunogenic. Sudden and severe hypotension resulting in death has been reported after applying bovine thrombin to a deep hepatic wound, and immune-mediated coagulopathy from bovine thrombin is a well-recognized complication.

Careful donor selection strategies and screening plasma units intended for sealant production are another factors reducing the risk of viral transmission.

Although no case of viral transmission using bovine thrombin has been reported, bovine spongiform encephalopathy is a theoretical risk. The risk of prion transmission is thought to be very low but cannot be entirely eliminated.

TABLE 2 ■ Characteristics of Available Fibrin Sealants and a Fibrin-Sealant Variant

Fibrin sealant	Manufacturer	Viral inactivation method	Human derived	Bovine derived	Intact coagulation pathway required	Preparation time (min)
Tisseel	Baxter Healthcare Corporation	Two-step vapor heating	Yes	Yes	No	20
Crosseal	American Red Cross, Inc.	Solvent/detergent, pasteurization	Yes	No	No	1
Hemaseal	Haemacure Corp.	two-step vapor heating	Yes	Yes	No	20
VIGuard	Vitex: VI Technologies	Solvent/detergent, ultraviolet C light	Yes	Yes	No	
Biocol	LFB-Lille	Solvent/detergent	Yes	Yes	No	
Quixil	Omrix Biopharmaceuticals	Solvent/detergent, pasteurization/nanofiltration	Yes	Yes	No	
Beriplast	Aventis Behring	Pasteurization	Yes	Yes	No	
Bolheal	Kaketsuken Pharmaceutical	Dry heat	Yes	Yes	No	
Costasis	Angiotech Pharmaceuticals Inc.	Not available	Autologous	Yes	No	>20

Nanofiltration appears to be the best technique to improve the safety of fibrin-sealant components because the Creutzfeld-Jakob agent can be filtered from infected brain extracts of mice using a 35 nm pore size filter membrane (57).

TOPICAL SYNTHETIC AGENTS

Cyanoacrylate Sealants

Cyanoacrylates are synthetic monomers that have generally been applied externally for the closure of lacerations, wounds, and incisions. Although stronger than fibrin sealants, they are not bioabsorbable and, if not used topically, behave as any other foreign body causing inflammation, tissue necrosis, or infection.

Dermabond[t], a synthetic 2-octylcyanoacrylate adhesive approved in the United States, is for topical use only. It may be applied to small lacerations and surgical skin incisions, lasts 7 to 10 days, and requires no dressing because it is waterproof. Sebesta and Bishoff performed a randomized, prospective trial comparing Dermabond (118) to standard subcuticular skin closure (110) of laparoscopic port sites (58). Dermabond was not only rapid and effective but also yielded a decrease in cost and operative time. No other laparoscopic application for cyanoacrylates has been described.

Hydrogels (Polyethylene Glycol Polymers)

- Polyethylene glycol polymers are hydrogels that can be used for tissue sealing and adhesion.
- Polyethylene glycol polymers, completely synthetic and bioabsorbable, are particularly desirable as tissue sealants because inflammatory potential and risk of viral transmission are eliminated.
- Intact coagulation pathways or the presence of active bleeding are not required to achieve successful hemostasis or tissue sealing.

Two products are Food and Drug Administration approved. Focalseal-L[u] is a polyethylene glycol-lactide that requires photoactivation with xenon light. The eosin-polyethylene glycol-lactide mixture is first applied as a primer before a macromere of polyethylene glycol-lactide is applied. The latter is photoactivated with high-intensity xenon light. The only experience with the use of polyethylene glycol polymers in laparoscopic urology was a feasibility trial performed by Ramakumar et al. in a porcine laparoscopic partial nephrectomy model (59). After renal hilar control using a laparoscopic Satinsky clamp and wedge resection in either the upper or the lower pole, Focalseal-L was laparoscopically applied to five kidneys. After the removal of the vascular clamp, a control wedge resection was made in the opposite pole in order to confirm viability and perfusion. The authors found that (i) the polyethylene glycol polymer was adherent to the underlying tissue surface; (ii) the bleeding was significantly less in the polyethylene glycol-treated group; and (iii) no urinary leakage occurred during ex vivo retrograde perfusion studies performed at pressures as high as 100 mmHg.

Coseal[v] is another polyethylene glycol polymer combination that received Food and Drug Administration approval in 2003. Unlike Focalseal-L, Coseal does not require photoactivation and therefore makes its application potentially less cumbersome. The material forms a flexible, watertight seal that is reabsorbed within 30 days of its application (60).

Until prospective clinical trials are performed, the efficacy of Coseal and Focalseal-L in urologic laparoscopy remains uncertain. Nevertheless, synthetic sealants are advantageous because allergic and viral transmission risks are nonexistent and because intact clotting pathways are unnecessary.

CONCLUSION

Biologic and synthetic hemostatic agents have contributed and will continue to contribute significantly to all surgical fields. The hemostatic and sealing properties of bioadhesives make them particularly applicable to urology because nephrectomies, partial nephrectomies, and reconstructive renal surgeries are now the mainstays of urologic laparoscopy. The number of commercially available fibrin sealants has risen dramatically

> Ultimately, we are responsible to our patients and we must therefore navigate through the marketing machines and the latest trends to identify the products that are the safest, most effective, easiest to apply, and the most cost effective.

over the last several years and breakthroughs in bioengineering and recombinant technology will likely propel further development of bioadhesives that are safer, more effective, and easier to use. It is important to remember that in the realm of surgery, bioadhesive agents are still new. Likewise, compared to time-tested traditional means of establishing hemostasis and closure of the urinary collecting system, current and future bioadhesive agents will need further evaluation in large, prospective clinical trials.

Ultimately, we are responsible to our patients and we must therefore navigate through the marketing machines and the latest trends to identify the products that are the safest, most effective, easiest to apply, and the most cost effective.

SUMMARY

- Biologic hemostatic agents have the potential to be a useful adjunct to traditional means in controlling intraoperative laparoscopic complications.
- The use of hemostatic agents implies potential risks of allergic reactions because bovine thrombin is immunogenic. Products containing bovine protein should be contraindicated in patients with known allergy hypersensitivity reactions.
- Due to their excellent rheological properties (elasticity, tensile strength, and adhesiveness), fibrin sealants are excellent additions to standard methods of tissue approximation and help secure hemostasis.
- To avoid thromboembolic complications, fibrin sealant should not be injected directly into large blood vessels.
- Tranexamic acid is contraindicated during any surgical procedures with possible exposure to the cerebrospinal fluid or the dura mater because it can cause neurologic symptoms including trembling, involuntary head movements, and clonic contractions in rabbits.
- Fibrin-sealant variants combining autologous fibrinogen with bovine thrombin and collagen have no risk of viral transmission. However, risk of bovine spongiform encephalopathy and allergic reaction remains.
- Relying on endogenous fibrinogen, gelatin matrix hemostatic sealants are ineffective in fibrinogenemic patients. They are not adhesive and should be not used for collecting system sealing.
- Gelatin matrix hemostatic sealants can work in cases of fairly active bleeding, whereas fibrin sealants and physical agents are better suited for diffuse bleeding or oozing.
- Experimental and clinical data indicate that the sole use of fibrin sealant for ureteral anastomosis is unsafe.
- Synthetic sealants are advantageous because allergic and viral transmission risks are nonexistent and because intact clotting pathways are unnecessary.

INTRODUCTION

In the past century, advances in science and technology have brought dramatic changes that have transformed the practice of medicine and surgery.

In the past century, advances in science and technology have brought dramatic changes that have transformed the practice of medicine and surgery. Such advances have led to the development of more accurate diagnostics as well as more effective, less morbid, treatments that have been the highlight of modern medicine. The field of robotics has emerged as one such discipline with great potential to transform medicine. Although robotics has found common and useful applications in industry, agriculture, space, and aviation, robotics has been harnessed for application in the field of medicine only recently. Ranging from simplistic laboratory robots to highly complex surgical robots, which can aid a human surgeon or even execute operations by themselves, the robot has many potential roles in 21st century medicine. Manifold advantages including speed, accuracy, repeatability, and reliability may be gained from a robot.

HISTORY OF ROBOTICS

The Laws of Robotics:
- Law Zero: A robot may not injure humanity, or, through inaction, allow humanity to come to harm.
- Law One: A robot may not injure a human being, or, through inaction, allow a human being to come to harm, unless this would violate a higher-order Law.
- Law Two: A robot must obey the orders given to it by human beings except where such orders would conflict with a higher-order Law.
- Law Three: A robot must protect its own existence as long as such protection does not conflict with a higher-order Law.

The term robot, taken from the Czech word *robota*, meaning forced labor, was coined by the Czech playwright Karel Capek in 1921 in his play *Rossum's Universal Robots*. Since then, man has had a fascination with "the robot." The robot conjures up many, and often contradictory, images. The robot is at the same time a symbol of the future of technological advancement and limitless possibilities as well as the subservient machine performing menial, repetitive tasks. The robot alternatively liberates man, as worker and friend, or enslaves him, with the sinister possibility of robots rising up against their makers.

Such a conception of robots is reflected in the work of Isaac Asimov, first coining the phrase "robotics" in 1941 in a short story called "Runaround." As both a scientist and a writer of science fiction, he proposed three laws of robotics, to which he added a "zeroth" law later (1).

The Laws of Robotics:
- Law Zero: A robot may not injure humanity, or, through inaction, allow humanity to come to harm.

■ Law One: A robot may not injure a human being, or, through inaction, allow a human being to come to harm, unless this would violate a higher-order Law.
■ Law Two: A robot must obey the orders given to it by human beings except where such orders would conflict with a higher-order Law.
■ Law Three: A robot must protect its own existence as long as such protection does not conflict with a higher-order Law.

In contrast to this imaginative code of "ethics" of robotics, the robots of today possess three key attributes, which serve as a more useful definition. As currently defined, robots exhibit the following attributes:

Key attributes of current robots:

■ Programmability, implying computational or symbol-manipulative capabilities, which a designer can combine as desired (a robot is a computer);
■ Mechanical capability, enabling it to act on its environment rather than merely function as a data-processing or computational device (a robot is a machine); and
■ Flexibility, in that it can operate using a range of programs to manipulate and transport materials in a variety of ways.

With the merging of computers, telecommunications networks, robotics, distributed systems software, and the multiorganizational application of the hybrid technology, the distinction between computers and robots has become increasingly arbitrary.

Westinghouse first designed actual robots in 1940, with the creation of "Sparko," a motorized dog that barked and stood on its hind legs, and dancing to "Elektra." The first practical application of robots was during 1962, when General Motors used industrial robots for the first time. Since then, robotics has flourished. The benefits of modern robotics, including precision, reliability and speed of operation, have been widely employed to relieve humans of mundane work and dangerous tasks in industries and researches. Although robotics has been widely embraced outside of medicine, its acceptance in the field of medicine has been gradual.

ROBOTICS IN SURGERY

Why Employ Robots in Surgery?

Robots have many attributes that can aid the modern surgeon. Although humans are clearly superior to robots with regard to clinical judgment, decision making, and flexibility, robots offer precision, stamina, strength, lack of tremor, and reproducibility. This has led to a role for robots in a variety of surgical tasks including instrument positioning, trajectory planning, cutting, drilling, and milling. Robotic surgery also offers the well-described benefits of minimally invasive surgery and laparoscopy.

Like conventional laparoscopy, the incisions used during robotic surgery are smaller. This translates clinically to quicker convalescence, shorter hospital stays, diminished postoperative pain, and narcotic requirements, as well as a diminished risk of infections and better cosmesis (2,3). However, conventional laparoscopy has several limitations. These are largely technical and mechanical issues, stemming from the nature of standard laparoscopic equipment. The standard endoscope forces the surgeon to work looking at a video monitor instead of looking at his/her hands, thus disturbing the surgeon's hand–eye coordination. Conventional endoscopes use two-dimensional vision, thus limiting the depth of perception of normal binocular vision. In addition, there is loss of haptic feedback, referring to both the force feedback and tactile feedback used routinely in open surgery. Decreased haptic feedback makes tissue manipulation heavily dependent on visual feedback. Laparoscopic instruments work through ports placed within the body wall. With the port acting as a pivot, the direction of the instrument tip is reversed from that of the instrument handle, leading to counterintuitive motion. This also leads to a compromise in dexterity because the port at the body wall constrains the motion of the instrument in two directions. The result is that the tip of the conventional laparoscopic instrument has only four degrees of freedom, in contrast to the human hand having seven degrees of freedom. Finally, physiological tremors of the surgeon's hands are transmitted through the length of rigid instruments. These limitations make delicate dissection and the creation of complex anastomoses very challenging to the conventional laparoscopist.

Overcoming the disadvantages inherent to conventional laparoscopy, and expanding the benefits of minimally invasive surgery are major aims of surgical robotics.

Sidebar notes:

Key attributes of current robots:
■ Programmability, implying computational or symbol-manipulative capabilities, which a designer can combine as desired (a robot is a computer);
■ Mechanical capability, enabling it to act on its environment rather than merely function as a data-processing or computational device (a robot is a machine); and

Robots have many attributes that can aid the modern surgeon. Although humans are clearly superior to robots with regard to clinical judgment, decision making, and flexibility, robots offer precision, stamina, strength, lack of tremor, and reproducibility.

Robotic surgery also offers the well-described benefits of minimally invasive surgery and laparoscopy.

Overcoming the disadvantages inherent to conventional laparoscopy, and expanding the benefits of minimally invasive surgery are major aims of surgical robotics.

Robotic Surgical Applications

Surgical robotics was pioneered in the 1980s in the field of neurosurgery and later in the field of orthopedics (4,5). Robotic "registration," the ability of the robot to be oriented with respect to the anatomy of the patient, and to transform coordinates from one system, such as an imaging study, to the actual "coordinates" of a patient with perfect alignment is one of the challenges of robotic surgery. Registration is somewhat simplified in neurosurgery and orthopedics because of the relatively fixed anatomic landmarks and bony structures available.

Robots have been employed in the field of neurosurgery to facilitate such procedures as brain biopsy, tumor resection, and stereotactic surgery. For example, in 1985, Kwoh et al. employed the PUMA 560 robot[a] to perform neurosurgical biopsies with greater precision (6). Similarly, another robot, the Neuromate™, has a well-established track record in stereotactic functional neurosurgery. In the field of orthopedic surgery, robots have a growing role in such procedures as hip and knee arthroplasty. The ROBODOC® surgical system[b] is a modified industrial robot, which is used for several of orthopedic procedures. Designed to address potential human errors in performing cementless total-hip replacement, the ROBODOC surgical system employs a motorized arm with the capacity to drill a precise hole in the femur during hip-replacement surgery (7).

Additional pioneering work in the development of robotic-assisted surgery was the result of a joint collaboration in the United States between the National Aeronautics and Space Administration , the Jet Propulsion Laboratory, and MicroDexterity Systems, a private interest. As part of the Jet Propulsion Laboratory's Telerobotics Program, these interests formed the Robot-Assisted MicroSurgery project in the early 1990s. The purpose of this program was to build the technology and workstations necessary to improve robotic dexterity and enable microsurgical procedures to advance to the point where they could be applied to procedures of the eyes, ear, nose, throat, face, hand, and brain. By 1994, the Robot-Assisted MicroSurgery project had successfully developed a robotic arm measuring 2.5 cm in diameter and 25 cm in length, which was capable of six degrees of motion. In the following year, a system of kinematics and high-level control, which included an electronic safety system, was added. This technology was successfully tested at the Cleveland Clinic Foundation in the late 1990s during a simulated-eye microsurgery. Subsequent work produced a dual-arm telerobotic microsurgery workstation capable of microsurgical suturing.

The United States Army became interested in the possibility of "bringing the surgeon to the wounded soldier—through telepresence" (7). A system was thus devised whereby a wounded soldier could be transferred to the nearest Mobile-Activated Surgical Hospital, a vehicle with robotic surgical equipment, within which a wounded soldier could be operated on remotely by a surgeon. Although successfully tested in animal models, this system has yet to be implemented in an actual battlefield setting.

Robots designed to hold and manipulate instruments, such as cameras or retractors, have been a tremendous success. In 1994, Computer Motion, Inc.[c] developed the automated endoscopic system for optimal positioning (AESOP 1000). The AESOP 3000, which features a voice-activated robotic arm that holds the camera and endoscope assembly for the surgeon during an endoscopic procedure and moves it with seven degrees of freedom, was introduced in 1998.

Intuitive Surgical®[d] made an important advancement in robotic surgical instrumentation with the introduction of the *da Vinci*™ Surgical System, which received Food and Drug Administration approval in July 2000. Based on the same concept, Computer Motion, Inc. introduced the Zeus® surgical system soon after the *da Vinci* system. In both systems, the surgeon sits comfortably at a master console and controls the "slave" robotic instruments using a pair of master manipulators resembling joysticks. Separately, cameras are inserted into the patient's body to give a three-dimensional view of the body interior. Multiple specialties have employed these systems for a wide variety of operations.

ROBOTICS IN UROLOGY

Although not yet commonplace, robots are revolutionizing surgery, and urology is no exception. In fact, urologists have been leaders in the development and application of surgical robotics.

Genitourinary surgical procedures, including radical prostatectomy, cystoprostatectomy, and pyeloplasty are examples of the complex operations being performed and perfected with the aid of robotic systems.

Early work focused on utilizing robots to perform transurethral resection of the prostate as well as prostatic biopsies. Other applications involve percutaneous renal access and surgery. More recently, a surge of interest in "urobotics" has accompanied the introduction of the *da Vinci* and Zeus systems (5,8).

Challenging genitourinary surgical procedures, including radical prostatectomy, cystoprostatectomy, and pyeloplasty are examples of the complex operations that are being performed and perfected with the aid of robotic systems.

Transurethral Resection of Prostate

Robotic surgical systems used for soft-tissue operations, such as those performed in urology, require very sophisticated robotic responsiveness and computer control to adapt to the deformability and mobility of the organs. Procedures performed on fixed bony structures or within the skull have the advantage of having relatively fixed points of reference to aid in robot registration.

In 1988, Davies demonstrated the feasibility of the robotic transurethral resection of the prostate using the PUMA 560 (9). The Surgeon-Assistant Robot for Prostatectomy, consisting of a small cutting blade rotating at 40,000 r.p.m., was derived from a six-axis PUMA robot to perform transurethral resection of the prostate. After further development at the Imperial College from 1993 to 1995, the Surgeon-Assistant Robot for Prostatectomy was renamed PROBOT (a robot for prostatectomy) and specifically designed to perform transurethral resection of the prostate. Studies showed that the entire resection could be successfully completed with good hemostasis (10). The major limitation of this technique was the inaccuracy in determining prostatic dimensions using transrectal ultrasound (10).

Image-Guided Percutaneous Procedures

Needle access required for percutaneous renal surgery is a challenging art. A steep learning curve characterizes the acquisition of skill necessary to gain access safely and routinely.

Needle access required for percutaneous renal surgery is a challenging art. A steep learning curve characterizes the acquisition of skill necessary to gain access safely and routinely.

It is presently performed by manually inserting the needle under single-view fluoroscopic radiological guidance. To improve on this approach, several researchers have investigated the use of robotic systems in assisting in the needle placement.

Potaminos et al. have proposed a stereopair of two X-ray views registered to a common fiducial system with a five-degrees-of-freedom passive linkage that is equipped with position encoders to position a passive needle guide (11,12). Bzostek et al. used an active robot, LARS, for a similar application. Although these robotic systems successfully address the issues of image-to-robot registration and provide a very convenient means of defining target anatomy, they are expensive and their large size makes them cumbersome for routine use in the operating room. Stoianovici et al., from Johns Hopkins University, developed the simple, noncomputerized system—Percutaneous Access of the Kidney—for this purpose (13,14). Percutaneous Access of the Kidney is a radiolucent needle driver actuated by an electrical motor. The surgeon manually orients the driver and therefore the needle using the technique of "superimposed needle registration" (13). Percutaneous Access of the Kidney is then locked into the desired orientation and needle insertion is manually controlled by a joystick. Using the Percutaneous Access of the Kidney device in nine patients, percutaneous access to the desired calyx was attained in the first attempt in each case. Percutaneous Access of the Kidney appeared to be safe and effective, with no perioperative complications attributable to needle access, and even offered a reduction in procedure time (15). Encouraged by these preliminary results, the same group later reported the development of a remote center of motion actuator module called the "MINI-remote center of motion." This module is reported to integrate both with Percutaneous Access of the Kidney and a wide variety of additional end effectors, which are under development. The idea is to simplify the orientation procedure, increase accuracy, reduce radiation exposure, and to achieve Percutaneous Access of the Kidney's compatibility with computerized tomography. The MINI-remote center of motion is an extremely compact robot that utilizes the remote center of motion principle of the LARS robot (16).

Prostate Biopsy

An image-guided robot system has been developed and employed for transperineal prostate biopsies.

An image-guided robot system has been developed and employed for transperineal prostate biopsies.

The surgeon selects the biopsy site using transrectal ultrasound images and the robot obtains the sample from that location with a precision of 1 to 2 mm in needle position. This procedure was found to be quicker, more precise than the conventional

techniques, and very reliable as the robot maintains its own position (17). An SR 8438 Sankyo Scara robot is used to perform this operation. It is remote controlled, i.e., via telerobotics, and requires accurate positioning in known points of three-dimensional space with a high degree of precision (18).

Two alternative robotic projects enabling automated harvesting of prostate biopsy samples have been recently developed.

In the projects proposed by the group at Johns Hopkins University, prostate biopsies are taken using a modified Percutaneous Access of the Kidney robot. In fact, current Percutaneous Access of the Kidney drive system is not strong enough to drive the needle into prostatic tissue, and also requires instrumentation to provide feedback regarding the needle position. In the modified Percutaneous Access of the Kidney system, a computerized tomography-image set is used to target the prostate and register the robot, and the biopsy needle is inserted through the skin rather than through the rectum. A second approach has been pursued by a group at Politecnico di Milano, Italy, where an industrial robot is being used directly to insert biopsy needles through the skin using a telerobotic approach. Biopsy site may be localized by computerized tomography, stereotactic fluoroscopy, or ultrasound. However, the two systems described above are relatively expensive because they require additional computerized tomography-based imaging of the prostate.

Laparoscopy

As in all fields of surgery, laparoscopy/minimally invasive surgery has had a significant impact on urology. The manifold benefits of laparoscopy, including smaller incisions, diminished blood loss, lesser pain, quicker recovery, and shorter hospital stay, have been well substantiated by several studies (19,20). On the other hand, the technically demanding nature of laparoscopy, the lack of haptic feedback, and limited dexterity, among other issues, are significant obstacles. This is particularly true when performing complex pelvic surgery.

Certain urologic procedures are very challenging for conventional laparoscopic surgeons due to either complex anatomy or the need for extensive intracorporeal suturing. Examples include radical prostatectomy, radical cystectomy, and pyeloplasty.

Surgeon-Driven Robotic Systems

Several *surgeon-driven robots* are being used in performing urologic laparoscopy. In contrast to *image-guided robots*, which automatically manipulate instruments under the prescription of the physician based on digital imaging, surgeon-driven systems continuously take the surgeon's input and, in real time, translate it to corresponding instrument manipulation.

Surgeon-driven robots augment the manipulation capabilities of the physician above and beyond the surgeon's manual and visual capacity.

These systems can filter tremors and thus decrease them, scale motion, aid in manipulation of tissues in confined spaces, provide exceptional optics, and may even provide remote haptic feedback.

Automated Endoscopic System for Optimal Positioning

Designed by Computer Motion, Inc., AESOP is one of the simplest types of surgeon-driven systems. Its sole function is to hold and orient a laparoscopic camera under hand, foot, or voice control. The AESOP has six degrees of freedom, two of which are passive (positioned by hand and do not have motors actuating them). The robot has been used at several institutions and in many clinical areas, including urologic laparoscopy (21). Kavoussi et al. found that the camera was significantly steadier under robot versus direct human control, and neither operative setup nor breakdown time was increased with the use of the robotic assistant (22). The AESOP arm uses voice recognition software, which is prerecorded onto a voice card and inserted into the controller.

Computer Motion's National Aeronautics and Space Administration-funded research demonstrated that voice-controlled commands are preferable to alternatives such as eye tracking and head tracking, which control motion in response to movements of the surgeon's head.

For voice control, the surgeon must wear a microphone and prerecord a voice card that covers the set of movements possible with AESOP.

In 1994, the AESOP 1000 system became the world's first surgical robot certified by the Food and Drug Administration in the United States. AESOP 2000, with the enhancement of voice control, and AESOP 3000, with seven degrees of freedom followed, within 1996 and in 1998, respectively. The redundancy of the AESOP 3000 provides more flexibility in endoscope positioning. Being simple to operate, reliable, and

safe, AESOP soon gained popularity and by 1999 over 80,000 surgical procedures had been performed using AESOP technology (23–27).

Stanford Research Institute

The first surgeon-driven instrument manipulation system was developed for open surgical procedures at the Stanford Research Institute in Menlo Park, California. This system, which is operated from a console, includes a two-arm, high-mobilityrobot instrumented with grippers. Cornum and Bowersox used the system for in vivo porcine nephrectomies and the repair of bladder and urethral injuries (28).

Advanced Robotics and Telemanipulator System for Minimally Invasive Surgery

The Advanced Robotics and Telemanipulator System for Minimally Invasive Surgery system was designed at the Institute of Applied Informatics in Tubingen University, Germany in 1992. It was the first system that provided instrument mobility with six degrees of freedom.

It integrated the Fips endoarm with a conventional technical telemanipulator, mastered by a joystick (29,30). The prototype reached the experimental phase, but was unable to proceed to commercial production or clinical application (31). The "Kinematic Simulation, Monitoring and Off-Line Programming Environment for Telerobotics" software was used in the Advanced Robotics and Telemanipulator System for Minimally Invasive Surgery system as a three-dimensional real-time simulation support tool.

> Advanced Robotics and Telemanipulator System for Minimally Invasive Surgery was the first system that provided instrument mobility with six degrees of freedom.

da Vinci Surgical System

The *da Vinci* Surgical System is the most successful and most widely used surgeon-driven robot to date.

Since its introduction in Europe in 2000 by cardiovascular surgeons, its applications have been expanding to include a number of surgical procedures, such as Nissen fundoplication, cholecystectomy, hernia repair, gastroplasty, appendectomy, and hysterectomy. The use of the *da Vinci* Surgical System in urologic surgery, including radical prostatectomy, radical cystectomy, adrenalectomy, pyeloplasty, donor nephrectomy, partial nephrectomy, and vasovasostomy is also rapidly evolving (32–37).

The *da Vinci* system consists of three major components—the surgeon's console, the patient side cart, and the vision cart.

> The *da Vinci* Surgical System is the most successful and most widely used surgeon-driven robot to date.

■ *Surgeon's Console*: The surgeon's tool handles are serial link manipulators designated the masters. The masters act as (i) high-resolution input devices reading the position, orientation, and grip commands from the surgeon, and (ii) as haptic displays transmitting forces and torques to the surgeon in response to various measured and synthetic force cues. The console also consists of two medical grade cathode ray tube monitors that receive the image of the surgical site to display one image to each of the surgeon's eyes. The user interface at the surgeon's console consists of foot pedals and buttons, which allow the surgeon to control the system. This interface allows the surgeon to control the endoscope from the console itself, position the masters in the work space, focus the endoscope, control the cautery, and so on.

The surgeon's console also consists of an electronic controller. It is a custom-designed control computer, with a peak computational power of 384 Mflops and a sustained processing power of 128 and 256 Mflops. Redundant sensors, hardware watchdogs, and real-time error detection ensure fail-safe operation of the controller in all its states.

■ *Patient Side Cart*: The patient side cart consists of two instrument arms and a centrally located camera arm holding the endoscope. An optional fourth instrument arm has been recently added in an attempt to reduce one patient side assistant.

The instrument arms are designed to accurately deliver instruments with seven degrees of freedom into the body. Each instrument arm is fixed to the patient with the help of a cannula, which attaches to a cannula mount on the instrument arm with the help of cannula mount pins. To permit precise instrument tip movements, move the instrument arms position under the direction of the surgeon at the console. The surgeon's hand movements at the masters are precisely replicated at the instrument tips. A wide range of custom-made instruments (Endowrist) are available. These Endowrist instruments are fully sterilizable and are attached interchangeably to the two-tool manipulators.

The camera arm is also fixed to the patient through a cannula, which attaches to the cannula mount on the camera arm with the help of a cannula mount camera clamp. The camera arm controls the position and movement of the three-dimensional endoscope from outside the patient's body.

The set up joints hold the instrument arms and the camera arm, and are used to position the surgical cart arms to achieve optimal approach to patient's anatomy.

■ *Vision System*: Vision is provided by a high-resolution stereoendoscope that uses two independent optical channels, sampled by two independent three-chip charge-coupled device cameras. The image is relayed to the vision cart through a camera head attached to the endoscope. Left and right images are processed independently by the two camera control units, one each for the left and right optical paths. The vision cart also consists of two synchronizers, a focus controller, and a light source. The synchronizers process the operative image to maximize clarity and edge definition. The focus controller is operated via the foot switch on the surgeon console or two push buttons on the front panel of the focus controller. The light source provides the desired illumination during the operation and also heats the tip of the endoscope to minimize lens fogging during the operation. The distal tip of the endoscope may exceed 41°C when used, thus contact with skin and tissue may cause tissue damage.

The *da Vinci* system is designed to create an "immersive operating environment" for the surgeon by providing both high-quality stereovisualization and a man–machine interface, which directly connect the surgeon's hands to the motion of his surgical instrument tips inside the patient's body (38,39). The registration, or alignment, of the surgeon's hand motions to the motion of the surgical instrument tip is both visual and spatial. To restore hand–eye coordination and to provide a natural correspondence in motions, the system projects the image of the surgical site atop the surgeon's hands with the help of mirrored overlay optics. Moreover, the controller transforms the spatial motion of the tools into the camera frame of reference, so that the surgeon feels as if his hands were inside the patient's body. Lastly, the system restores the degrees of freedom lost in conventional laparoscopy by employing three degrees of freedom wrist, bringing a total of seven degrees of freedom to the movement of the instrument tip. The control system of the robot eliminates surgeon tremor, makes the instrument tip steadier than the unassisted hand, and allows for variable motion scaling from the masters to the slaves. Together with image magnification of 10X, motion scaling enables delicate motions easier to perform (40).

Zeus System

To introduce the AESOP robot, Computer Motion had already improved one element of minimally invasive surgery, namely support and positioning of endoscopic cameras. In the Zeus system, all the instruments were robotic. Similar to the *da Vinci*, the surgeon can sit comfortably at a master console and control the slave robotic instruments using a pair of master manipulators. Later, the Zeus system was integrated with the Hermes system[e], which is a platform for centralizing control of devices inside as well as resources outside the operating room. The system can be controlled by the surgeon using simple verbal commands or an interactive hand-held, touch screen pendant. Similar to the AESOP, the Hermes system recognizes the surgeon's voice through a prerecorded voice card that the surgeon inserts into the system prior to the start of surgery.

The instruments used in the Zeus system closely resemble conventional surgical instruments.

The camera, insufflator, light source, and other additional instruments are adjusted by voice or by a foot pedal. Three-dimensional vision is incorporated, but requires the use of goggles with shutter glasses.

The instruments used in the Zeus system closely resemble conventional surgical instruments.

TELESURGERY

Telesurgery involves a surgeon performing surgery from a remote location, be it a far away place or across the room.

In telesurgery, the actions of the robot are not predetermined, but controlled by the operating surgeon in real time through an interface.

Telesurgery involves a surgeon performing surgery from a remote location, be it a far away place or across the room.

---

[e]Stryker Endoscopy, San Jose, CA.

In telesurgery, the surgeon relies completely on the sensor data, which is transmitted by the robot at the remote location. The sensor data, therefore, must be very accurately transmitted.

Human–computer interface is one of the most complicated aspects of telesurgery. It has to be simple, intuitive, and efficient.

Because the surgeon is separated from the patient by distance, a robot, local to the patient, becomes the surgeon's hands, while an intricate interface helps the surgeon connect and communicate with the patient. Telesurgery is a part of robotic surgery because the robot is the one actually performing the surgery.

In telesurgery, the surgeon relies completely on the sensor data, which is transmitted by the robot at the remote location. The sensor data, therefore, must be very accurately transmitted.

Various schemes are used for this purpose. Fiducials are reference features, located on both the computer-based model and the anatomic object, and are used as a means of aligning the virtual image with the actual position of both the robot and the patient. In addition to that, infrared transmitters and receivers are used, as they offer very fast and very accurate registration.

Human–computer interface is one of the most complicated aspects of telesurgery. It has to be simple, intuitive, and efficient.

The virtual reality glove is one potential approach. The glove uses flex-controlled potentiometers or optical fibers, which can sense the position of the surgeon's hands with satisfactory speed and precision. This data is then transmitted to the robot, which follows the hand movement.

Telesurgery offers the advantages of minimally invasive surgery. In traditional surgery, hand size is a limiting factor when it comes to performing delicate movements or operating in hard-to-reach places. The robot can overcome this limitation because it can be as small as desired and can enter through a small opening and access any part of the body without the need for big incisions.

Additional potential benefits associated with telesurgery are:

- Reduced costs related to patients and specialist traveling.
- Remote treatment of patients by national and international specialists.
- Surgeon skills enhanced by a robotic interface.
- Robotic arms and controllers operating at an accuracy of approximately ±5 μm, computed with ±50 μm for the best microsurgeons (41).
- Motion scaling and tremor filtering allowing tasks impossible to perform otherwise.

In spite of these potential advantages, there are several concerns about telesurgery. The initial financial investment in acquiring a telesurgical system is considerable. Moreover, there are also medicolegal concerns regarding liability. Due to the fact that telesurgery would involve a number of specialists, hospitals, and countries, jurisdiction conflicts may occur (42). However, the major concern about telesurgery relates to its safety. Current robotic surgical systems have a variety of built-in safely features such as manual override (43) and "safety freeze" (16). However, problems such as loss of communication between the surgeon and the operating room or failure of the telesurgical system may occur and require someone on site to take charge.

VIRTUAL REALITY

Virtual reality is a highly evolved technology with the potential to allow people to interact in a computer-generated three-dimensional environment in real time using their natural senses and skills.

Virtual reality is a highly evolved technology with the potential to allow people to interact in a computer-generated three-dimensional environment in real time using their natural senses and skills.

Although virtual reality is closely related to computer simulation, it has many unique features. Whereas simulation is a method useful for education and training, virtual reality implies a computer-generated environment that is much more life like. With the help of an interface device, the user becomes a part of a virtual environment within which he/she can move and manipulate objects.

Although the term virtual reality was first introduced by Jaron Lanier in 1989, the concept of virtual reality emerged long before in 1963, when Ivan Sutherland developed the head-mounted display, which heralded the theories and themes of modern immersive science (44). In the 1970s, various industries began to see the applications and implications of virtual reality. One of the more obvious applications of virtual reality was in the making of films like *Star Wars* that were studded with special effects.

The three-dimensional mapping of genomes in deoxy ribonuclic acid research introduced virtual reality into medicine.

The three-dimensional mapping of genomes in deoxy ribonuclic acid research introduced virtual reality into medicine.

The introduction of virtual reality into surgery began in the 1980s. Surgical training is one of the key applications of this technology. For the purpose of surgical training, simulation and virtual reality do not have to rely on detailed graphics (unlike complex

professional flight simulators) and even moderately detailed surgical virtual reality systems could be effective in task training.

Surgical training is expensive, time consuming, and can be limited by the number of cases available at a particular institution. Ideally, surgical trainees would have the ability to sharpen their skills and broaden their experience by performing procedures repeatedly in a simulated environment outside the operating room. Virtual reality technology has the potential to provide surgeons with this type of optimal training environment.

A number of virtual reality training systems have been developed. For example, a venipuncture simulator proved to be effective in training health-care professionals. The system employs force feedback to simulate the feel of a cannula entering the skin and vein (45). There are a variety of more complex systems available for endoscopic procedures, including gastroscopy and colonoscopy to train gastroenterologists (45). Cardiac catheterization and angiography trainers are also available with real time modeling of physiological parameters and blood flow (45).

As computing power continues to advance, so will the capabilities of virtual reality systems. At present, virtual reality systems for surgery provide highly detailed models that are capable of fulfilling some of the training needs of surgeons. While still very expensive, it is estimated that with proper marketing and with the development of cheaper methods of production, the economics of virtual reality will become more favorable.

LIMITATIONS OF ROBOTIC SURGERY

Innovative and "cutting-edge" technology requires maturation and refinement, and inherently carries with it benefits and limitations. Robotic surgery is no exception. There is considerable room for improved kinematic configurations, as well as more compact and efficient actuator and transmission technologies. In terms of sensing and control, robots are driven by computers and share the same shortcomings, especially for autonomous operation. Robots follow instructions literally, and cannot use qualitative reasoning or exercise meaningful judgement. Increasing computational power may improve robot-control capabilities.

The loss of haptic feedback is a shortcoming of contemporary robotic systems. Haptic feedback comprises force feedback as well as texture, viscosity, temperature, and other characteristics, which provide the surgeon with much information. With further advancements in robotics, the technology necessary to provide haptic feedback may evolve.

Another obstacle to the widespread application of robotics is cost. Any new technology will fail unless there is a sufficient market to allow for the system to be mass produced, thereby reducing cost. The initial investment to acquire a robotic system may be prohibitive, and significant clinical benefit to patients needs to be demonstrated to justify this expenditure. Despite these challenges, surgical robotics is starting to thrive. In fact, medicine may prove to be one of the most fertile grounds for future robotic applications. Therefore, it is expected that as production and competition increase, the cost of robotics will go down significantly.

FUTURE ROBOTIC SURGERY SYSTEMS

As previously mentioned, one of the major points of criticism of robotic telemanipulators is the lack of haptic feedback from the operating instruments. While some surgeons using the current systems on a regular basis feel that this is partly compensated for by the superior three-dimensional visual feedback, others differ. Future robotic systems are likely to include improved haptic feedback data.

The enormous size of the systems compromises their proper positioning, thus either miniaturization or integration of the system into the design of the operating room by attachment to the ceiling may help in the future. The key to the future success of these systems lies in producing highly trained surgeons well versed with the robotic system. Because certain procedures are rarely performed, virtual reality training programs can be integrated into robotic systems for the purpose of "surgical-skills" training. The development of a telestrator may further help the experienced surgeon to instruct the trainee. The telestrator is a regular part of sports broadcasts and allows the announcer to draw lines and circles on screen showing how a play works and develops. Alternatively, a double-console concept would also serve the same purpose and would allow the experienced surgeon to adjust and correct the movements of the trainee. Similar to the concept of driving instructors, the second console would allow the tutor

Sidebar notes:

Surgical training is expensive, time consuming, and can be limited by the number of cases available at a particular institution. With virtual reality technology, surgical trainees would have the ability to sharpen their skills and broaden their experience by performing procedures repeatedly in a simulated environment outside the operating room.

The loss of haptic feedback is a shortcoming of contemporary robotic systems. Another obstacle to the widespread application of robotics is cost.

Future robotic systems are likely to include improved haptic feedback data.

As technology becomes more sophisticated, the concept of remote surgery will become more prevalent, extending the benefits of robotics to areas that lack similar services. This will allow the world's best surgeons to perform specialist procedures remotely using robotic control in any part of the world.

to take over the instruments when needed and demonstrate the correct maneuver, helping in the safe transfer of skills. This will also help in diminishing the learning curve in using the system.

As technology becomes more sophisticated, the concept of remote surgery will become more prevalent, extending the benefits of robotics to areas that lack similar services. This will allow the world's best surgeons to perform specialist procedures remotely using robotic control in any part of the world.

Moreover, the robotic systems of the future will be more cost effective and affordable, aiding in the dissemination of the technology.

Although the use of robotics in medicine and surgery is growing rapidly, the field is in its infancy. Just as laparoscopy represents a "revolution" in the art of surgery, the potential for robotics to transform surgical practice is enormous. Through continued technological innovation and human imagination, the robots of the future will help to improve the surgeon's precision and efficacy in and beyond the 21st century.

SUMMARY

- Although humans are clearly superior to robots with regard to clinical judgment, decision-making, and flexibility, robots offer precision, stamina, strength, lack of tremor, and reproducibility.
- Robotic surgery offers the benefit of minimally invasive surgery and laparoscopy.
- Robots are revolutionizing urology, and urologists have been leaders in the development of an application of surgical robotics.
- Robotic transurethral resection of the prostate is feasible.
- Robotic system can assist needle placement during percutaneous renal surgery.
- Robotic systems have been developed to overcome limitation and improve the benefits of conventional laparoscopy performed for challenging urologic procedures.
- Surgeon-driven robots augment the manipulation capabilities of the physician above and beyond the surgeon's manual and visual capacity.
- Voice-controlled commands are preferable to eye tracking or head tracking, which control motion in response to movements of the surgeon's head.
- The *da Vinci* Surgical System is the most successful and most widely used surgeon-driven robot.
- The robotic instruments used in the Zeus System closely resemble conventional surgical instruments.
- Reduction of some surgery-related costs, remote patient management, enhanced surgeon skills, accuracy, and capability to perform challenging procedures are advantages of telesurgery.
- Virtual reality might provide surgeons with optimal training environment.
- Loss of haptic feedback and cost are the major shortcoming of contemporary robotics. Continued technological innovation and increased market competition could overcome such limitations.

LAPAROSCOPY: GENERAL TECHNIQUES

BASICS OF RETROPERITONEAL LAPAROSCOPY

Monish Aron, Benjamin Chung, and Inderbir S. Gill

Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

The retroperitoneoscopic approach to renal and adrenal surgery is less popular than the transperitoneal laparoscopic approach, primarily because of its limited working space and surgeons' relative unfamiliarity with the optimal operative technique. Other perceived drawbacks of performing surgery in the retroperitoneum include the abundance of fat and the paucity of easily recognizable anatomical landmarks.

> The retroperitoneum is a potential, not an actual, space.

Unlike the peritoneal cavity, the retroperitoneum is a potential, not an actual, space. To create a viable working area, the retroperitoneal space needs to be deliberately expanded. It was not until Gaur (1) described an atraumatic balloon dilation technique to expand the retroperitoneum in 1992 that retroperitoneoscopy became a viable approach to treat urological pathology.

During the past decade, increasing experience at various centers has led to the refinement of laparoscopic techniques that take advantage of the strengths of theretroperitoneal approach while overcoming its perceived disadvantages (2–9). At our institution, retroperitoneoscopy is a common approach for most renal and adrenal pathology. Presented herein are our current techniques of retroperitoneal laparoscopy (10–14).

INDICATIONS

Retroperitoneoscopy has been used for a variety of renal and adrenal procedures (Table 1). In patients with morbid obesity or peritoneal scarring from prior transabdominal procedures, retroperitoneoscopy allows a superior and more direct approach to the renal hilum. The equipment usually required for retroperitoneoscopic surgery is summarized in Table 2.

Laparoscopic radical nephrectomy (15) and adrenalectomy (16) can be performed efficiently and effectively by either the transperitoneal or the retroperitoneal approach. Control of the renal hilum may be quicker and total operative time shorter with the retroperitoneoscopic approach. Operative morbidity, postoperative complications, and pathological characteristics of the intact extracted specimen are similar with both approaches. As such, in most instances, the choice of approach depends on the comfort level, training, and preference of the individual surgeon.

CONTRAINDICATIONS

General contraindications for laparoscopic surgery include severe cardiopulmonary compromise, uncorrected coagulopathy, and intra-abdominal sepsis. Specific to

TABLE 1 ■ Procedures Amenable to the Retroperitoneoscopic Approach

Adrenal
    Adrenalectomy
    Adrenal cyst decortication
Renal
    Simple nephrectomy
    Radical nephrectomy
    Nephroureterectomy
    Renal tumor cryoablation
    Pyeloplasty
    Renal biopsy
    Renal cyst deroofing
    Living donor nephrectomy
    Partial nephrectomy
    Pyelolithotomy and extended pyelolithotomy
    Anatrophic nephrolithotomy
Ureteral
    Ureterolithotomy
    Reconstruction for retrocaval ureter

S retractors (*2*)
Balloon dilator device
Laparoscopic trocars: Bluntip balloon port 10 mm (*1*), 12 mm (1–2),
   5 mm (*2*), 2 mm (*1*) (if required)
Laparoscope (10 mm, 30°: 5 mm, 30°)
Electrosurgical scissors (5 mm)
Electrosurgical hook (5 mm)
Laparoscopic right-angle dissecting forceps (5 mm, 10 mm)
Laparoscopic grasping forceps (short straight clamp, small bowel
   clamp, locking grasping clamp, Maryland clamp)
Laparoscopic irrigation/suction probe (5 mm)
Laparoscopic clip applicators, for metal and plastic clips
   (5 mm, 10 mm)
Laparoscopic stapler with vascular cartridge
Endocatch bag (10 mm shaft, 15 mm shaft)
Bipolar forceps (5 mm)—optional
Harmonic scalpel—optional
Laparoscopic staplers

retroperitoneoscopy, relative contraindications include intense perirenal fibrosis secondary to xanthogranulomatous pyelonephritis, genitourinary tuberculosis, or recent open surgery of the retroperitoneum. However, a history of percutaneous renal surgery or biopsy does not preclude successful retroperitoneoscopic laparoscopy.

PREOPERATIVE WORKUP

> Attention to the patient's cardiorespiratory status, bony or spinal abnormalities, coagulation studies, and history of prior surgery is imperative.

Attention to the patient's cardiorespiratory status, bony or spinal abnormalities, coagulation studies, and history of prior surgery is imperative. Preoperative bowel preparation includes two bottles of magnesium citrate on the afternoon before surgery, with clear liquids allowed until midnight.

A urinary catheter, compression stockings, and one dose of preoperative antibiotics are routine. An arterial line is mandatory in all patients with a pheochromocytoma.

Endocrine Preparation

Appropriate preparation from an endocrine standpoint is critical for successful adrenal surgical outcomes. At our institution, patients with a pheochromocytoma are pretreated with calcium-channel blockers and vigorous hydration, with alpha blockade being employed selectively. Patients with an aldosteroma are placed on the potassium-sparing diuretic spironolactone and oral potassium supplementation. Patients with Cushing's disease require perioperative stress doses of steroids.

SURGICAL TECHNIQUE

Patient Positioning

The patient is placed in the standard lateral decubitus (full flank) position. Currently, we do not elevate the kidney bridge on the table, and the table is flexed to the least degree that will allow adequate separation of the costal margin from the iliac crest, the "access corridor" for retroperitoneoscopic surgery (Fig. 1). The surgeon and the assistant stand facing the back of the patient. Prolonged flank position has the potential to result in significant postoperative neuromuscular complications. All extremities must be placed in neutral positions and all pressure points meticulously padded with egg crate foam: head and neck, axilla, hip joint, knee, and ankle. We firmly secure the patient to the table with 3-inch adhesive cloth tape and a safety belt.

Retroperitoneal Access

An open technique is employed. A horizontal 2-cm transverse skin incision is made just below the tip of the last (12th) rib. S retractors are employed to separate the flank muscle fibers. The retroperitoneum is accessed by piercing the dorsolumbar fascia with the index finger or a hemostat. Using the index finger, gentle dissection is performed to

FIGURE 1 ■ Port placement and patient positioning during right retroperitoneal laparoscopy.

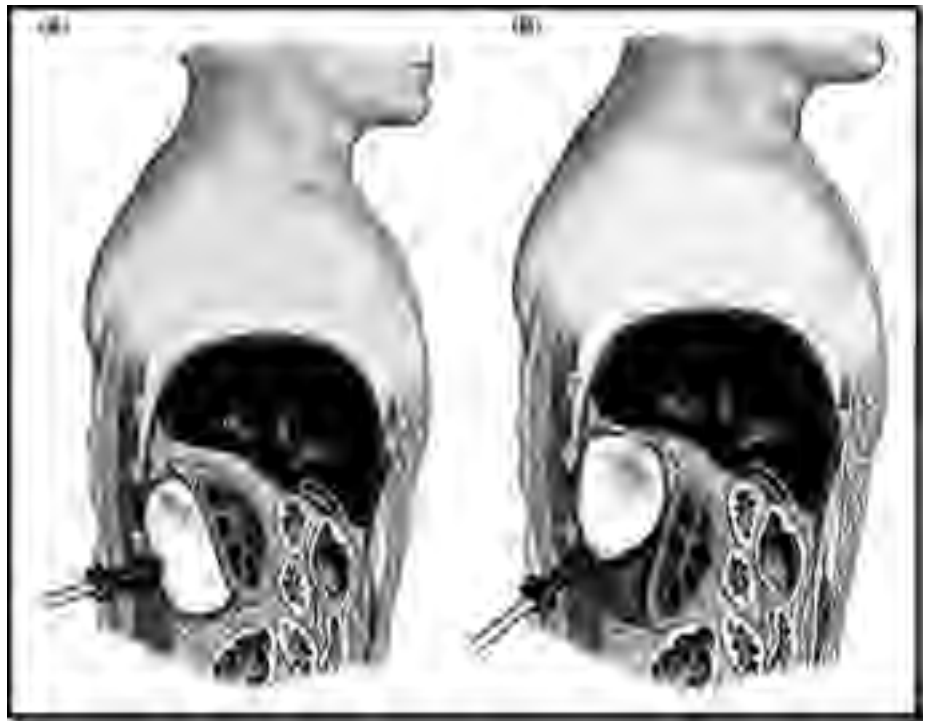
create a space for subsequent placement of the balloon dilator. It is important that the finger dissection be performed between the psoas muscle (and fascia) posteriorly and Gerota's fascia anteriorly. Proper entry into the retroperitoneum is important. The anterior surface of the psoas muscle is our primary anatomic landmark, during both the initial finger palpation and the subsequent intraoperative laparoscopic viewing. If the finger dissection is performed immediately along the anterior surface of the psoas muscle and fascia, it automatically stays posterior to, and outside of, Gerota's fascia.

Balloon Dilation

Additional working space in the retroperitoneum is created with a trocar-mounted balloon (Fig. 2) dilator. Initially, the balloon device is distended adjacent to the lower pole and mid-portion of the kidney (Fig. 3A). Approximately 800 cc of air (i.e., 40 pumps of the sphygmomanometer bulb device) are instilled to inflate the balloon. Thereafter, the balloon is deflated and manually advanced higher up along the psoas muscle into the retroperitoneum. The stiff shaft of the balloon dilator permits precise manual repositioning of the balloon dilator. This secondary cephalad balloon dilation of the upper retroperitoneum is performed in the vicinity of the adrenal gland and the undersurface of the diaphragm (Fig. 3B). Balloon dilation outside Gerota's fascia in the upper retroperitoneum effectively displaces the kidney anteromedially and opens up the potential retroperitoneal space, allowing access to the kidney and the adrenal, and exposes the entire anterior aspect of the psoas muscle, the primary anatomic landmark, during retroperitoneoscopy. The balloon is then deflated and removed. The dilation process can be monitored by inserting the laparoscope within the clear, transparent balloon to observe the following landmarks: psoas muscle (posteriorly), Gerota's fascia (anteriorly), and diaphragm (superiorly).

Port Placement

A 10 mm Bluntip trocar™ [a] is placed as the primary port. This trocar has a doughnut-shaped, internal fascial retention balloon and an external adjustable foam cuff, which, when cinched down, creates an airtight seal at the primary port site. Easy to use, this device is an important factor in minimizing air leak and subcutaneous emphysema during retroperitoneoscopic procedures. CO_2 pneumoretroperitoneum is now established

FIGURE 2 ■ Balloon dilation of retroperitoneum. Positioned between psoas fascia posteriorly and Gerota's fascia anteriorly, distended balloon (800 cc air) displaces Gerota's fascia-covered kidney anteromedially, allowing straightforward access to renal vessels.


(15 mmHg), and a 30° 10 mm laparoscope is inserted. Two or more retroperitoneal landmarks should be identifiable immediately: the psoas muscle, Gerota's fascia, lateral peritoneal reflection, ureter, renal artery pulsations, aortic pulsations (left side), and partially collapsed vena cava (right side). The psoas muscle and one or more of the following structures can be visualized with the following frequency: Gerota's fascia (100%), peritoneal reflection (83%), ureter and/or gonadal vein (61%), pulsations of the fat-covered renal artery (56%), aortic pulsations (left side; 90%), and the compressed, ribbon-like inferior vena cava (right side; 25%) (10). Usually two, and rarely three, secondary ports are placed. All ports are 12 mm for 3-port retroperitoneoscopy, although the port for the nondominant hand may be a 5 mm port. The anterior port is inserted near the anterior axillary line at least 3 cm cephalad to the iliac crest. A posterior port is inserted at the junction of the lateral border of the erector spinae muscle with the undersurface of the 12th rib. Commonly, this posterior port is inserted under laparoscopic control, although rarely, when this port is too close to the primary port to allow reliable endoscopic viewing, bimanual control may be employed. In the bimanual technique, the laparoscope and the Bluntip trocar are removed. For a right-handed surgeon, an S retractor, cradled by the surgeon's left index finger, is inserted within the retroperitoneum through the primary port site incision. The secondary port is inserted by the surgeon's right hand at the predesignated site at the lateral border of the erector spinae muscle and directed onto the S retractor. The S retractor protects the surgeon's left index finger from injury. Rarely, a fourth port (2 or 5 mm) may be required at the level of the primary port in the anterior axillary line for retraction of the adrenal gland and kidney anteriorly. This is sometimes required in the event of an inadvertent peritoneotomy, necessitating anteromedial retraction of the peritoneum. The three ports should be as far apart as possible. The anterior port should be 3 cm cephalad to the iliac crest; otherwise, the bone compromises its maneuverability. Clear laparoscopic observation during port placement is imperative to guard against injury to the peritoneum (anterior port), great vessels (posterior port), or pleura (the occasional fourth port).

Initial Dissection

With the kidney retracted or tented anterolaterally, a generous longitudinal incision is made in Gerota's fascia, parallel and close to the psoas muscle. This critical maneuver allows access to the renal hilar area. A search for vascular pulsations is initiated. Although gentle, undulating pulsations are characteristic of the inferior vena cava, sharp, well-defined pulsations reveal the location of the fat-covered renal artery or, on the left side, the aorta. Subsequent operative steps depend on the procedure being performed.

Technique for Radical Nephrectomy

Hilar Dissection

Hilar dissection commences with searching for renal arterial or aortic pulsations in the area of the renal hilum along the medial border of the psoas muscle. Blunt dissection in this area of loose areolar tissue is performed to identify renal arterial pulsations. The renal artery is circumferentially mobilized, clip occluded with locking plastic clips, and divided. The renal vein is mobilized and controlled with a gastrointestinal anastomosis vascular stapler (Fig. 4).

Adrenal Mobilization

Suprahilar dissection is performed along the medial aspect of the upper pole of the kidney and the adrenal vessels, including the main adrenal vein, precisely controlled. Dissection is next redirected towards the superolateral aspect of the specimen, including en bloc adrenal gland, which is readily mobilized from the underside of the diaphragm. In the areolar tissue in this location inferior phrenic vessels to the adrenal gland are often encountered and need to be controlled.

Specimen Mobilization

The anterior aspect of the specimen is mobilized from the undersurface of the peritoneal envelope. The ureter and gonadal vein are secured, and the specimen is completely freed by mobilizing the lower pole of the kidney. The entire dissection is performed outside Gerota's fascia, in keeping with standard oncological principles.

Entrapment and Exit

An Endocatch[b] device is introduced through the right-hand port incision, and the specimen is entrapped (Fig. 5). Smaller specimens are entrapped within the Endocatch (10 mm shaft), whereas larger specimens require the Endocatch II device which (15 mm shaft) which is introduced directly through the port-site incision. For larger specimens, an intentional peritoneotomy is occasionally created strictly for specimen entrapment. Intact specimen extraction is performed through an appropriate muscle-splitting incision (Gibson or Pfannensteil). Hemostasis is confirmed under lowered pneumoretroperitoneal pressure and ports are removed under direct vision. Fascial closure is performed for all 10 mm or larger port sites using a 0-Vicryl suture.

Technique for Adrenalectomy
Incision of Gerota's Fascia Between the Upper Pole of the Kidney and the Adrenal Gland

The posterior aspect of Gerota's fascia is incised transversely at the level of the upper pole of the kidney (Fig. 6). The aim of the ensuing dissection is to circumferentially mobilize the upper pole and mid-region of the kidney and the covering Gerota's fascia. The upper pole is now dropped posteriorly onto the psoas muscle away from the adrenal gland. This dissection proceeds immediately adjacent to the parenchyma of the upper pole of the kidney. Care must be taken not to injure any accessory vessel entering the upper pole of the kidney. At this juncture, the unmobilized adrenal gland is still located in its normal position, attached anteriorly to the parietal peritoneum.

Control of Main Adrenal Vein–Left Adrenalectomy

Careful blunt and sharp dissection is performed toward the renal hilum, between the upper pole of the kidney posterolaterally and the adrenal anteromedially. The caudal limit of this dissection is the renal hilar vessels, usually, the superior branch of the renal artery. Multiple small renal hilar vessels supplying the adrenal gland are encountered in this location, which are securely clipped and divided. Dissection is now transversely continued medially along the renal vein or artery, and the main left adrenal vein may be identified (Fig. 7A) at this juncture and clipped (5 mm clips) and transected. If the main left adrenal vein cannot be identified at this stage, dissection is redirected toward the undersurface of the diaphragm. The adrenal gland is mobilized along its cephalad aspect, controlling the inferior phrenic branches. Multiple aortic branches to the adrenal gland may need to be controlled in this area. Continued dissection along the medial and inferomedial aspect of the adrenal gland will identify the main left adrenal vein as its sole remaining attachment. The left adrenal vein is longer than the right, arises from the inferomedial aspect of the left adrenal gland, and courses obliquely in an inferomedial direction to drain into the proximal left renal vein. The vein is then clipped and transected (Fig. 7B).

Control of Main Adrenal Vein–Right Adrenalectomy

The right main adrenal vein is shorter, horizontally located along the superomedial edge of the adrenal gland, and drains directly into the inferior vena cava. Dissection is carried cephalad along the lateral aspect of the inferior vena cava, between it and the adrenal gland, until the right adrenal vein is seen, circumferentially mobilized, clipped, and divided (Fig. 8). The adrenal gland is then mobilized from the undersurface of the diaphragm. The main right adrenal vein usually arises from the superomedial aspect of the right adrenal gland. Although multiple small renal hilar arteries and veins enter the adrenal gland along its inferior and inferomedial edge, the larger, more well-defined main right adrenal vein usually resides in a more cephalad location, beneath and along the posterior edge of the right lobe of the liver.

FIGURE 6 ■ Transverse incision in Gerota's fascia, with the aim of separating the upper renal pole from adrenal gland.

FIGURE 7 ■ (**A**) Left adrenalectomy: Dissection proceeds caudally immediately adjacent to parenchymal surface of medial aspect of upper pole of left kidney, which is retracted posterolaterally (*curved arrows*). Adrenal gland, surrounded by periadrenal fat, is retracted superomedially (*straight arrow*). Caudal endpoint of this dissection is renal hilar vessels. Main left adrenal vein may or may not be visible at this point in dissection. Curved broken line indicates subsequent plane of mobilization of adrenal gland from the undersurface of the diaphragm. (**B**) Left adrenalectomy: Control of main adrenal vein. Upper pole of left kidney has been dropped posteriorly onto psoas muscle. Adrenal gland has now been circumferentially freed. Main adrenal vein, arising from inferomedial aspect of left adrenal gland, is now clip ligated (5 mm clips) and divided.

Alternative Strategy

Instead of incising Gerota's fascia to enter the plane between the adrenal and the upper pole of the kidney as described above, an alternative technical strategy can be employed. After port placement, the Gerota's fascia-covered kidney is retracted anteromedially, exactly as one would during a radical nephrectomy. Gerota's fascia is incised longitudinally parallel and 1 to 2 cm anterior to the psoas muscle. Renal artery pulsations are identified, and dissection is initiated immediately cephalad to it. This dissection is performed in the cephalad angle between the renal artery and the inferior vena cava on the right side and between the renal artery and the aorta on the left side. Dissection proceeds superiorly along the anterolateral aspect of the inferior vena cava or aorta. Inferior adrenal vessels originating from the renal artery and vein are clip-secured at this location. Continued cephalad dissection between the adrenal gland and the ipsilateral great vessel reveals small middle adrenal vessels, arising from the aorta and vena cava, which are secured. On the right side, the main adrenal vein, draining into the inferior vena cava, is the next structure to be dissected, clipped, and divided. On the left side, the main adrenal vein may not be identifiable at this juncture and may require circumferential mobilization of the adrenal gland before it comes into view.

Circumferential Specimen Mobilization

After control of the adrenal vasculature has been secured, sequential blunt and sharp dissection of the remaining attachments frees up the adrenal gland. Inferior phrenic vessels are often encountered along the undersurface of the diaphragm. During specimen mobilization, one should be careful not to create an unintentional peritoneotomy. Although a peritoneotomy does not significantly compromise operative

FIGURE 8 ■ Retroperitoneoscopic right adrenalectomy. Dissection between adrenal gland and inferior vena cava reveals short, horizontal main right adrenal vein, which is controlled and transected. Remainder of mobilization of right adrenal gland is similar to that on left side.

exposure during a retroperitoneoscopic radical nephrectomy, a peritoneotomy during retroperitoneoscopic adrenalectomy may decrease the operative field in the vicinity of the undersurface of the diaphragm. In this circumstance, placement of a fourth port may be necessary for anterior retraction. A 2 mm port suffices for this purpose.

Entrapment and Exit

An Endocatch bag is introduced through the right-hand port and the excised specimen is entrapped and extracted intact through the primary port site. Hemostasis is confirmed by lowering the pneumoretroperitoneum for five minutes. Ports are removed under laparoscopic vision. The larger (10–12 mm) port site(s) is closed in fascial layers, and the smaller (5 mm) ports are closed with subcuticular sutures.

INTRAOPERATIVE TROUBLESHOOTING

Proper Balloon Placement

Finger dissection is performed anterior to the psoas muscle and fascia; the anterior aspect of the psoas muscle must be clearly palpable by the finger. The balloon dilator is then gently and precisely inserted into this location, and inflated posterior to and outside of Gerota's fascia. Laparoscopic visualization through the clear, transparent balloon confirms proper balloon placement.

Problems with Orientation in the Retroperitoneum

The camera should be oriented such that the psoas muscle is always absolutely horizontal on the video monitor. The psoas muscle can be identified most easily caudal to the kidney. At this stage of the procedure, the retroperitoneal space is small. Posterolateral traction on the primary trocar to elevate the abdominal wall or anteromedial retraction of the kidney serves to increase the retroperitoneal space.

Inability to Locate the Renal Hilum

If the renal hilum cannot be located, Gerota's fascia should be incised longitudinally, along the psoas muscle. The kidney should then be retracted anteriorly, placing the hilum on stretch. The laparoscope is then slowly advanced across the anterior surface of the psoas muscle from lateral to medial in a cephalad direction. With the laparoscope held steady, a search is made for pulsations along the medial border of the psoas. Gentle dissection directly toward the pulsations should reveal the underlying vessel. Alternatively, the ureter can be followed cephalad to the hilum. Finally, the surface of the kidney can be identified and traced medially to its hilum.

Inadvertent Peritoneotomy

A peritoneotomy does not necessarily mandate routine conversion to transperitoneal laparoscopy. Most commonly, the peritoneotomy is inconsequential. However, if operative exposure is compromised, a fourth port can be inserted to provide additional retraction, and the procedure can be successfully completed retroperitoneoscopically.

TIME MANAGEMENT

Two concerns about retroperitoneal laparoscopy have been difficulty in identifying various anatomic landmarks and a lack of a clear understanding of the sequential operative steps toward this end. Sung and Gill (10) employed a uniform database to record predetermined intraoperative parameters prospectively in 16 patients who underwent 18 retroperitoneoscopic radical nephrectomies. They documented the anatomic landmarks seen immediately after balloon dilation prior to any laparoscopic manipulations (vide supra). Additionally, they recorded the time taken to complete each specific part of the operation to create a realistic framework of its sequential operative steps. They found that port placement time ranged from 6 to 20 minutes, decreasing with experience. Hilar dissection time was impacted by specimen weight and whether four or more retroperitoneal landmarks could be identified immediately after balloon dilation. When specimen weight was greater than the median value of 436 g, the hilar dissection time was 78 minutes, compared with 47 minutes for those specimens weighing less than 436 g. When the initial balloon dilation resulted in visibility of four or more anatomic landmarks, hilar dissection time was significantly shorter (47 as against 82 minutes). Adrenal mobilization added a mean of 49 minutes (range, 20–68) to the radical nephrectomy procedure. In the analysis of surgical time

for the entire operation, specimen weight was again significant. In patients with a specimen weight greater than 436 g, the surgical time averaged 230 minutes compared with 176 minutes for specimens weighing less than 436 g. Specimen entrapment of large tumors could be a technically cumbersome operative step, given the confines of the retroperitoneal working space. Entrapment could be completed retroperitoneo-scopically in 16 of 18 cases (89%). In two cases, for specimens weighing 867 g and 774 g, an intentional peritoneotomy had to be created at the end of the procedure solely for purposes of specimen entrapment (10).

COMPLICATIONS

At our center, vascular injuries were identified in 1.7% (7 of 404) and bowel injuries in 0.25% (1 of 404) of the patients undergoing major retroperitoneal laparoscopic renal and adrenal surgery between July 1997 and February 2001 (17). In five patients (63%), the injury could be controlled laparoscopically. Two patients required postoperative intensive care for one and three days, respectively. Of seven patients with vascular injuries, five required an average of 3.3 units of packed cells (range 1–8). Postoperatively ileus and atelectasis occurred in one patient and transient hypotension in another.

In an earlier multi-institutional review of 1043 retroperitoneoscopic/extraperitoneoscopic cases, Gill et al. (3) found that major complications occurred in 49 (4.7%) patients. Visceral injuries occurred in 26 (2.5%) patients and vascular injuries in 23 (2.2%). The commonest visceral injuries were pneumothorax ($n = 6$), pneumomediastinum ($n = 4$), and perforation of the urinary bladder ($n = 4$). Of note, of the 26 visceral injuries (2.5%), 7 (0.7%) were sustained by intraperitoneal organs: colon ($n = 3$), small bowel ($n = 2$), liver ($n = 1$), and spleen ($n = 1$). Of the vascular injuries (2.2%), the renal vein ($n = 6$) and inferior vena cava ($n = 4$) were the most frequently injured blood vessels. The retroperitoneoscopic/extraperitoneoscopic procedure was intraoperatively converted to transperitoneal laparoscopy in 56 (5.4%) patients. Conversion to open surgery was necessary in 69 patients (6.6%). Conversion to open surgery was performed in an elective manner in 41 patients (3.9%) and emergently in 28 patients (2.7%). Elective conversion to open surgery was most commonly indicated for significant adhesions or peritoneal tear ($n = 15$; 1.4%) or inadequate working space in the retroperitoneum ($n = 13$; 1.3%). Emergent open surgery was necessary to repair either visceral ($n = 16$; 1.5%) or vascular ($n = 12$; 1.2%) injuries.

CONCLUSION

Retroperitoneoscopy is our preferred technique for performing laparoscopic renal and adrenal surgery in most instances. The one exception is partial nephrectomy. Currently, our primary indications for transperitoneal laparoscopy include large renal and adrenal masses, cryoablation of anteriorly located renal tumors, partial nephrectomy for anterior and lateral tumors, pyeloplasty, and living donor nephrectomy. Compared with transperitoneal laparoscopy, retroperitoneoscopy is associated with a sharper learning curve. Meticulous attention during port placement is critical to ensure optimal positioning. Although the retroperitoneum initially affords a smaller working space than the peritoneal cavity, as the dissection proceeds, the retroperitoneal space can be readily enlarged and developed as necessary. Retroperitoneoscopy does offer potential advantages. Foremost is the facile exposure of the renal hilum. Because the bowel is not manipulated, paralytic ileus may be minimized. Inadvertent injury to peritoneal viscera is minimized, yet not eliminated, since intraperitoneal organs are separated only by the peritoneal membrane. The techniques discussed here have become an integral part of the training program in our department, and our experience to date indicates that the learning curve of retroperitoneoscopy will be significantly shorter for the subsequent generation of surgeons.

LAPAROSCOPIC SUTURING TECHNIQUES: GENERAL CONSIDERATIONS

Louis J. Giorgi, Jr.
Mercy Medical Group, Carmichael, California, U.S.A.

Michael E. Moran
Capital District Urologic Surgeons, Albany, New York, U.S.A.

INTRODUCTION

> Suturing and knot tying in the closed confines of the peritoneum or retroperitoneum take mastery of laparoscopic dexterity to its maximum extent and clearly separates those with experience from the novice.

Laparoscopic suturing has been previously regarded as the "master technique" in endoscopic surgery. Suturing and knot tying in the closed confines of the peritoneum or retroperitoneum take mastery of laparoscopic dexterity to its maximum extent and clearly separates those with experience from the novice.

But as time stands still for no man, technology and the advancements of instruments and, particularly, robot-assisted technologies are beginning to level the playing field in modern laparoscopic centers. In the past, we could have written solely about laparoscopic suturing instruments, techniques of extra- or intracorporeal suturing and knotting, and the various nuances of suture materials and needles that augment laparoscopic techniques. Some mention of skill acquisition has always been necessary as well. This no longer suffices, however, as advanced laparoscopic urologic reconstructive procedures are proliferating rapidly with fully intracorporeal sutures and knotting techniques.

It is now imperative to adequately cover methods of suturing skill acquisition. Some of the most intriguing basic research in surgery currently centers around the investigation of surgical skill acquisition, evaluating whether surgical skills can be learned better by some individuals versus others and the more adept individuals selected for training programs, or if all surgeons are potentially capable of obtaining a minimum degree of required competency. There is a growing base of knowledge regarding psychomotor skills, of which laparoscopic suturing is still considered the cornerstone.

> Laparoscopic training is evolving with the advent of sophisticated, high-end computer simulation equipment and these tools are just beginning to make inroads at academic centers.

Laparoscopic training is evolving with the advent of sophisticated, high-end computer simulation equipment and these tools are just beginning to make inroads at academic centers.

The potential magnitude of these questions will now be emphasized in this discussion on laparoscopic suturing. The need to measure and quantify laparoscopic skills has never been so acute. In this era of open public scrutiny, we must self-question our own methods. Competence in newly trained surgeons typically involves testing and attestation by his/her peers and mentors. Although laparoscopic skills do not readily correlate with performance of the open surgical counterpart, detailed investigations have shown promising results in our ability to standardize training programs. Also, surgery itself has a very lofty target to likewise mentor in regard to competency, similar to the aviation industry. Commercial airline pilots must have a first class medical certificate every six months, must check out with a flight simulator at least once a year, and submit to random tests for substance abuse. In addition, they have demonstrated a well-known loss of cognitive ability with age and, therefore, it is required that all commercial airline pilots retire at the age of 60.

The fourth or current phase of urologic laparoscopy is the re-emergence of more complex laparoscopic urologic procedures. Technology is the driving force behind this re-emergence and possibly represents the inherent appeal of minimally invasive surgery to patients.

Patients who are given an option of a less-invasive alternative will in many instances opt for it, regardless of sufficient evidence to support that decision.

There is growing basic scientific evidence that the patients are really benefiting from being less cut upon. The nay-saying philosophy of "why work through a keyhole when you can just walk through the door" is being eroded.

Sakti Das quipped recently that laparoscopic urology has passed through four phases of progress. First was the phase of initial exposure where diagnostic laparoscopy was used to identify undescended testes. Second was the phase of initial exploration heralded by Ralph Clayman's first laparoscopic nephrectomy. The third phase was the decline in laparoscopic urologic surgery, thought by many to be secondary to limited benefits of certain "high volume" procedures such as pelvic lymph node dissection and varicocelectomy.

The fourth or current phase of urologic laparoscopy is the re-emergence of more complex laparoscopic urologic procedures (1). Technology is the driving force behind this re-emergence and possibly represents the inherent appeal of minimally invasive surgery to patients (2).

Proceeding with advances in laparoscopic urologic reconstructive techniques, the technology is rapidly progressing, especially in surgical robotics. One must fight the tendency to view such series with skepticism. However, the exact opposite extreme is, likewise, not necessarily true. Technologic surgery in its infancy arouses justifiable concerns, but some simple facts remain. Patients who are given an option of a less-invasive alternative will in many instances opt for it, regardless of sufficient evidence to support that decision.

Next is the continual availability of newer technologies (i.e., telerobotic surgical systems) that potentially can make even the most arduous reconstructive techniques widely available. Third is the fact that a new generation of surgeons who have been exposed to these technologies and the laparoscopic environment for their entire careers is now available. There are now fourth-year residents at epicenter programs of advanced technologic laparoscopic teaching who have never seen an open radical prostatectomy. At other programs, there are residents who have seen virtually no open renal surgery. It is little wonder that this field is exploding.

There is growing basic scientific evidence that patients are really benefiting from being less cut upon. The nay-saying philosophy of "why work through a keyhole when you can just walk through the door" is being eroded.

There are an increasing number of studies indicating that minimally invasive laparoscopic surgeries cause less catecholamine response, less catabolic insult, and fewer intra-abdominal adhesions than open surgery. There are real reasons that this type of surgery will continue to advance and expand. With the advent of high-end, computer-enhanced robot-sutured reconstructions, it is seriously being questioned whether endoscopic sutured repairs may actually be better than their open counterparts with fewer long-term complications. Time will tell.

LAPAROSCOPIC SUTURING TIME LINE

"Thou shouldst draw together for him his gash with stitching," quotes the Edwin Smith surgical papyrus. Suturing has existed since prehistorical times.

"Thou shouldst draw together for him his gash with stitching," quotes the Edwin Smith surgical papyrus. Suturing has existed since prehistorical times.

Ancient suture materials included flax, hair, linen, pig bristles, grasses, cotton, silk, and gut from animals. Ant mandibles were used as needles to draw the sutures through wounds. By the 18th century, wire had begun to be used in holding together tissues. Currently, in the United States, the *U.S. Pharmacopeia* sets the standards that are used by suture manufacturers. Each needle has a point, a body, and a swage (the connection of the suture to the needle). Sutures themselves can be absorbable (most commonly used in the genitourinary tract), nonabsorbable, monofilament, or braided (3).

The early history of laparoscopic surgery is dominated by the diagnostic endeavors of those interested in hepatobiliary and gynecologic pathology. The instruments and procedures were necessarily limited. With the advent of more complex operative tasks, the gynecologists became increasingly interested in the capability of reproducing what were previously open surgical interventions as laparoscopic procedures. The need to suture was clear as long ago as 1972, when Clarke described a series of instruments and techniques applicable to gynecologic surgery (4). Extracorporeal knots and the search for methods of placing ligatures followed (5). The adaptation of an otolaryngologist's suture ligature for tonsillectomies was incorporated into the routine practices of innovative laparoscopic gynecologic surgeons (6). The Roeder knot, fashioned after an extracorporeal knot used by otolaryngologists for tonsillectomies, was probably the first of a series of extracorporeally tied knots that could be slipped tightly so as to achieve hemostasis or tissue realignment (Fig. 1). Weston described several other variations, which are derived from fishing and sailing knots (Fig. 2) (7). However, all of the extracorporeal knots do not improve the endoscopic surgeon's ability to place sutures or perform an

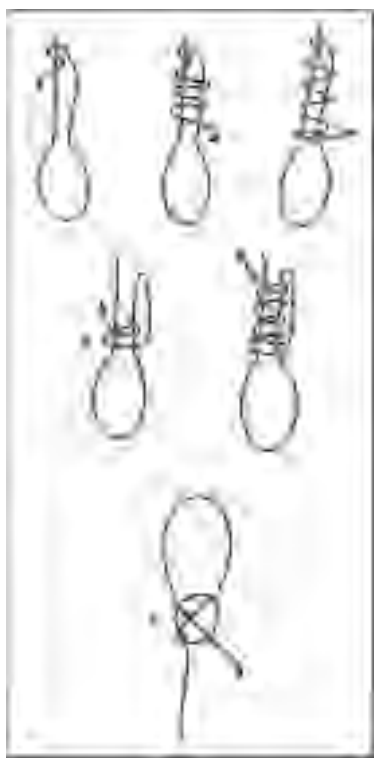
FIGURE 1 ■ Roeder loop knot.


FIGURE 2 ◾ Other types of extracorporeally tied slipknot configurations: (A) Roeder, (B) Duncan, (C) jamming loop knot.

entire anastomosis intracorporeally. Initially, following the general surgical adaptation to the laparoscopic cholecystectomy, urological and other advanced laparoscopic procedures associated with reconstruction were attempted. There were no specifically designed intracorporeal suturing instruments. The problem of making instruments designed to both gently reapproximate tissues and firmly grasp laparoscopic needles has been a difficult manufacturing goal. Such instruments are allowing endoscopic surgeons to rapidly reproduce even the most arduous urologic reconstructive procedures.

In the early 1990s, urologists at centers committed to advancing laparoscopic procedures persisted despite the "national decline" in urologic laparoscopy. Scheussler and Raboy pioneered reconstructive work on pyeloplasty and vesicourethral anastomoses, which laid the foundation for others to methodically begin investigations to improve instruments and methods. In 1991, our laboratories at University of California Davis began to systematically reevaluate all aspects of laparoscopic suturing, including needle design, suture types, suture colors, suturing techniques, knotting techniques, and instrument design. By 1993, we published the outcomes of some of these investigations in laparoscopic radical prostatectomy in a canine model (8). Rassweiler and coworkers have further augmented our knowledge of intracorporeal suturing and knotting, and continued to stress the need for "skill" development (9). Szabo and coworkers from the University of California San Francisco, began to develop instruments and methods of training endoscopic suturing. Their intent was to promote a wide range of endoscopic procedures. By the middle and late 1990s, instrument manufacturers were becoming increasingly aware that suturing instruments, in particular, needed to be designed to overcome the barriers limiting laparoscopic reconstructive surgery (10–14). Studies investigating the ergonomics of instruments and their effect on surgical performance were increasingly being published. Table height was evaluated and was shown to influence both the dexterity and efficiency of suturing (15). Finally, the methods themselves by which a surgeon learns have come under scientific scrutiny. How surgeons learn skills and how competence is measured has fostered many recent investigations of laparoscopic suturing. Perhaps some of the most exciting areas in all of surgical research currently are focusing upon methods of surgical skill acquisition (16).

Clinical series with advanced reconstructions include Kavoussi's pyeloplasty and Guillonneau and Vallencein's work on radical prostatectomy with sutured vesicourethral anastomosis. These techniques have had rapid proliferation in the urologic community, with a large number of secondary centers beginning to report on their own respective results. No longer are advanced laparoscopic techniques within the sole domain of the endourologists: urologic oncologists are rightly reclaiming some of these techniques as their own and fostering further clinical applications (17).

> Advancing technology, especially tele-robotic surgical systems are now poised to further diffuse these complex laparoscopic reconstructive methods into widespread application.

Advancing technology, especially tele-robotic surgical systems are now poised to further diffuse these complex laparoscopic reconstructive methods into widespread application (18).

In a recent review of the past decade's experience with laparoscopic surgical procedures from a single "cutting edge" institution, Costi et al. have noted that the quality of laparoscopic surgery has improved. They reviewed 3022 consecutive patients undergoing 99 different laparoscopic procedures at the Institut Mutualiste Montsouris in Paris over the past decade. A complex database included the types of laparoscopic procedures, conversion of access, duration of the surgery, complications, further hospitalizations and reoperations, and duration of the hospital stay. General trends confirm more difficult laparoscopic surgery performed in the latter half of the decade and fewer easier procedures. In addition, evolution of the surgery itself was demonstrated by the development of new procedures. All of this was noted without a significant increase in the number of complications (19).

ESSENTIALS OF LAPAROSCOPIC SUTURING

Basics

Surgical knot tying is one of the first skills every medical student delights in mastering. One- and two-handed throws are next developed throughout the surgical residency for controlling hemorrhage or reapproximating tissues. Typically, surgical application of stapling devices follows mastery of basic suturing skills.

> Laparoscopic urologic surgery is accomplishing the same fundamental operation as would an open incision, except with electronic imaging and small, fixed portals of access to the closed environment. The laparoscopic environment makes suturing and knotting a most difficult task.

Laparoscopic urologic surgery is accomplishing the same fundamental operation as would an open incision, except with electronic imaging and small, fixed portals of access to the closed environment. The laparoscopic environment makes suturing and knotting a most difficult task (8,20).

It is for this reason that urologic reconstructive surgeries were, initially, only sporadically reported, and relied upon automated stapling technologies or short cuts with such instruments as the EndoStitch™ᵃ. Now large series typically utilize fully intracorporeal suturing and knotting strategies.

It is doubtful that a urologist would perform any of the operations we do if told from the outset that suturing or knot tying could not be accomplished. It has been stated that laparoscopic urologic reconstruction can only be facilitated if there are developed stapling devices that can rapidly reapproximate tissue margins. These statements are made despite our continuing experience with metallic staples and the accompanying litany of complications when these are used within the genitourinary tract (21,22). Laparoscopic suturing is being performed throughout the world now for virtually every urologic reconstructive procedure. This review section will delve into the details of this most difficult of laparoscopic tasks. All aspects that have an impact upon suturing in this environment will be discussed. The focus will undoubtedly reflect the author's bias, centering on intracorporeal, two-handed, highly choreographed methods. In addition, detailed review of the literature of the most recent trends, especially in running suturing will be reviewed. Also the realm of robot-assisted reconstructions will also be considered.

Laparoscopic Hemostasis

Hemostasis in the closed environment imposed by minimal access surgery is one obstacle blocking progression to more complex intracorporeal techniques. The ability to maintain a clear surgical field allows complex tasks such as suturing to be performed (23).

Some of the instruments discussed in this chapter are essential components to the surgeon's hemostatic armamentaria. There are five basic modalities at the surgeon's disposal for the augmentation of local hemostasis (Table 1). These are in addition to the methods of systemically altering the physiologic clotting parameters that might facilitate hemostasis.

Vascular pedicles have been safely ligated and divided by autostaplers for two decades (24,25). The concern for arteriovenous fistula development is certainly worth consideration, especially if both structures are taken en bloc (26). The vascular autostapling devices are theoretically designed to separate the artery and the vein prior to fixing into the staple delivery mode. The laparoscopic autostaplers have little clinical data yet to support their widespread applicability. Laboratory studies indicate that it is crucial to anticipate the trajectory necessary for delivering the 12 mm device to the targeted pedicle vasculature. The wrong approach results in untoward tension on the vessels during the engagement process. During transperitoneal laparoscopic nephrectomies, anterior axillary line portals both cranially or caudad to the laparoscope portal were effective to autostaple the renal artery and vein (27). Clip application during pedicle dissection has been addressed in the general surgical literature (28,29).

There are proponents for loop ligation and for titanium clipping. Urologically, the laparoscopic nephrectomy animal model indicated that clips were associated with more blood loss than autostapling techniques (31).

One investigation of the two major manufacturers of laparoscopic clip appliers studied the pressures necessary to dislodge each type of clip in vitro and in vivo (2). In detailed measurements on both axial and horizontal displacement, the Ethicon clips held more effectively than the U.S. Surgical clips. Both types had an unusually high rate of distractibility during the in vivo studies (33). A second study quantifying the force necessary to dislodge the newer generation of U.S. Surgical clips, EndoClip II, found them to be much more difficult to dislodge (34). Each study was funded by the manufacturer whose clip was thought to be better, so conclusions must be weighed carefully. The surgeon should be aware that these clips can become dislodged during the course of subsequent dissection if either radial or horizontal traction is applied near or at the clip. Metallic clips, and automated staplers have been described to secure the renal pedicle during laparoscopic nephrectomy and nephroureterectomy (26). On comparing these two modalities to open suture ligation of the renal pedicle in a porcine animal model, all three methods were found to be equally efficacious in preventing arterial leakage at physiological pressures. At superphysiologic pressures (average 1364 mmHg), five of six pigs had leakage from renal arteries secured with an EndoGIA 30™ (26). This multifire vascular stapler cuts between two triple-staggered rows of 2.5-mm staples. Application of three 9-mm titanium clips and suture ligation with a 2-0 silk stitch as well as a 0-silk free tie prevented leakage even at renal artery burst pressures (average, 1821 mmHg). Moran similarly found renal artery branch vessel ligation with three clips transversely placed in opposing directions and linear stapling to be equally

efficacious in a porcine animal model (27). En masse occlusion of the renal pedicle without separating the artery and vein, using a 12 mm vascular stapler has also been examined in animals. One of three animals followed for six months demonstrated an arteriovenous fistula on aortography (26). The true risk of arteriovenous fistula formation from en masse renal pedicle ligation may be even higher given previous studies documenting their formation 5 months to 40 years after surgery (32–34).

Current practice recommendations are to use 9-mm titanium clips to secure renal vessels. A total of five clips, three placed proximally and two on the specimen side, placed transversely in opposing directions prior to vessel division is recommended.

Finally, a case where a partial nephrectomy was performed utilizing a linear cutting stapler has been described (35). Despite the widespread application of clipping and stapling technologies, there still exists a role for the use of suture in the management of the vascular pedicles during laparoscopic surgery. The most tried and true method of hemostasis remains the surgical ligature; it is cost effective and almost always readily available.

Laparoscopic Tissue Reapproximation and Healing

The ability of the laparoscopic surgeon to reconstruct the genitourinary tract is fundamentally the same in the closed versus the open abdomen.

The five techniques available for tissue reapproximation are listed in Table 2. More than one modality can be combined as in Dr. Avant's end-to-end anastomotic device and tissue laser welding techniques (36). The surgical literature is replete with arguments for and against suturing versus stapling for gastrointestinal reconstruction (37–40). Much research has been fostered into the mechanisms of tissue healing following various reconstruction techniques (38). Suffice it to say that the integrity of the intrinsic blood supply is paramount to the ability of mucosa-to-mucosa sealing (38).

Anastomosis and complex enteric-uroepithelial composite appositions are the rule for urologic reconstruction. A number of synthetic, autograft, and xenograft materials have been sought to further diminish the trauma of urologic reconstruction (41).

Methods to reapproximate these and native bowel segments to the bladder laparoscopically are being investigated. Stapled and sutured bladder resections and closures have been described (42–45). Bladder diverticula have been removed and partial cystectomies with and without nephroureterectomy have been described (Fig. 42) (46–48). Both clinical study and animal work on the use of metallic autostapling instruments suggest that this technique is successful (49). Delayed complications, specifically incrustation on the foreign body nidus, have not been observed to date. This probably reflects the investigator's careful apposition methods, trying to keep the staple line from direct contact with the urine. Upper tract reconstructions have also been reported. Dismembered pyeloplasties (49), anterior pyelocaliceal diverticulectomy (Fig. 40) with omental patch (50), and partial nephrectomies (51,52) have all been performed. The reconstructions to date have been hampered by constraints of limited instrument technology, lack of stereoscopic imaging, and closed, fixed, operative access to the urologic areas of interest, but the tide is changing. The numbers of diverse, sutured reconstructions have been increasingly reported as would be expected once mastery of this environment becomes coupled with technologies that facilitate rather than hinder progress.

Skill Development and Assessment

The field of laparoscopic urologic surgery has experienced a period of rapid regrowth in the past four years (1). Despite the initial skepticism that should generally be expected by such technologically demanding surgical procedures, this resurgence of interest has made popular demands upon training courses at the national meetings, local academic centers, and at international courses. The urologist must initially have an interest in laparoscopic surgery. All the nuances associated with instrumentation are significant. If one is not exposed early to laparoscopic instrumentation, the breadth of information necessary can seem staggering. Once the instrumentation has been mastered, the physiologic consequences of operating on patients must next be addressed. Safe utilization of electronic, high-speed insufflators and specific problems associated with pneumoperitoneum must be always understood during these cases. In addition to all this background material, the surgeon must also become adept at utilizing complex instruments in the laparoscopic environment. The laparoscopic environment consists of limited, fixed portals of access, longer than normal surgical instruments, and angles of access that at times must cross over one another to work within a brightly illuminated but small focal area within a live patient. Also there is complete reliance on the electronic image. That is to say, the movements within the operative field are within the surgeon's control, but there are activities often occurring outside of the surgeon's

view, such as retraction. Finally, add to this a lack of "true" stereotactic, three-dimensional vision and little ability to utilize the sense of touch (in the laparoscopic environment, the surgeon cannot palpate an organ or feel for the pulsations of a nearby artery) and you have summed up the potential limitations of working laparoscopically. But there are advantages as well or dedicated laparoscopic urologic centers would not have evolved. The brightly illuminated, magnified surgical field is an enticing environment to perform surgery, rather akin to microsurgery. The precision capable in such an environment is unparalleled. In addition, following the greatest traditions in urology, the technology fostered by laparoscopic surgery is by itself attractive.

Research currently focuses upon methods of learning, measuring, teaching, and modifying the mental and motor abilities to accomplish complex laparoscopic surgery (53). This is one of the most exciting areas of research in all of surgery currently. How do surgeons learn? What makes one person recognize pathways to practical motor problems quickly whereas others need to be shown? Should we be able to pick those potential urologic residents who will be able to master complex laparoscopic procedures by testing certain aptitudes? Are all urologic surgeons capable of adapting to the laparoscopic environment and mastering the techniques necessary to safely apply these in their practice? What skills are essential and can they be modeled and practiced to increase proficiency? These are some of the basic questions and clinical research currently being investigated on psychomotor skills necessary to perform complex laparoscopic surgery.

Psychomotor Skills

Surgical education to date has relied upon the formal apprenticeship model exemplified by the doctrine, "see one, do one, teach one" (54). Laparoscopic surgery has been defined by degrees of difficulty, with increasingly complex procedures resulting in "steep learning curves." These curves are usually, but not always, exemplified by the amount of time taken to accomplish the laparoscopic procedure, often comparing this to the open surgical equivalent (55). In addition, there are relatively few centers where advanced techniques are being used with regularity. On top of this, hospitals and regulatory agencies (particularly in the United States) are struggling with credentialing issues that surround "surgical proficiency." It is no wonder that the number of laparoscopic, urologic, intracorporeal-sutured reconstructions have not proliferated to any great extent. But the envelope continually expands and small groups of investigators such as Clayman, Janeschtek, Kavoussi, Gill, Gilloneou, Rassweiler, and others push us into rethinking the possibilities of this technology.

Paralleling the growing amount of research on laparoscopic suturing are investigations in the acquisition and development of psychomotor skills and skill evaluation. Derossis et al. from the McGill University evaluated 42 subjects to better understand how structured, objectively measured tasks could be utilized to improve performance during laparoscopic surgery. They demonstrated that the ability to develop suturing skills correlated with overall improvement in a wide variety of laparoscopic activities (56). Hanna et al. at the University of Dundee have investigated the differing abilities of right- and left-handed individuals to develop psychomotor skills for complex endoscopic manipulations. Utilizing a complex in vitro system, 10 right-handed and 10 left-handed individuals were evaluated for psychomotor aptitude, using both the dominant and nondominant hands.

> **Hanna et al. demonstrated that the right-handed surgeons performed fewer errors and exhibited better first-time accuracy than the left-handed individuals. In addition, accuracy definitely favored the dominant hand in both groups.**

They demonstrated that the right-handed surgeons performed fewer errors and exhibited better first-time accuracy than the left-handed individuals. In addition, accuracy definitely favored the dominant hand in both groups (57).

This same center reported upon the improvement of skill performance by optical axis manipulation. They noted that even small decreases in the viewing angle were attended by significant degradation in performance (58). Others have demonstrated this same phenomenon, such as Holden's group from The Hadassah Hebrew University Medical Center. They demonstrated that changes in the either the camera's position or the surgeon's position profoundly disrupted the surgeon's performance (59).

> **Serveral authors confirmed our observations that the closer the endoscope is to the targeted reconstruction site, the more magnified the field of view and the more difficult will be the performance of the suturing task.**

However, when the surgeon and camera positions were altered together, these detrimental effects could be altered and skilled performance could be regained. More specific to our topic at hand, endoscopic skills have been extensively evaluated by our group and others. Hanna again from Dundee evaluated the influence of direction of view, target-to-endoscope distance, and manipulation angles upon the efficiency of intracorporeal knot tying.

These authors confirmed our observations that the closer the endoscope is to the targeted reconstruction site, the more magnified the field of view and the more difficult will be the performance of the suturing task.

They specifically evaluated distances of 50, 75, 100, 125, and 150 mm from the targeted task. The 50-mm distance uniformly resulted in the longest times. In addition, the 60° manipulation angle had the shortest execution times compared to 30° and 90°. Finally, some recent investigations have sought how to minimize these problems utilizing a 90° laparoscope to achieve movement parallax. In this investigation, the authors report upon the theoretical advantages of manipulating the endoscopic image to the surgeon's advantage, essentially recapitulating all of the problems alluded to previously. By synchronizing a flexible laparoscope to the movement of a surgeon's head, movement parallax or compensated visual-enhanced movement is achieved (60). They note that a head-controlled flexible 90° laparoscope improves the surgeon's depth perception and hand–eye coordination. This has not been significantly reported for expensive three-dimensional imaging systems (61,62).

The primary problem with these types of investigations is that small study groups do not reflect the community of surgeons who will be attempting these procedures. In addition, the ability of a surgeon to perform a given task is a complex issue involving adaptive capacity, traits, and aptitudes that a person brings to any given situation. This is quite different from the skill of a surgeon. Skill is referred to when specific combinations of techniques are deftly employed to accomplish a given task (63). Numerous investigators have begun to focus the attention of their investigations on how surgical residents develop laparoscopic skills and on how best to foster this skill transfer? Reznick, at the University of Toronto, has written extensively regarding this issue. He summarizes the crucial nature of these research endeavors by stating that the teaching of technical skills is one of the most important tasks of surgical educators. He concludes by calling for adherence to simple principles: treat pupils as adult learners, set specific objectives, realize that operative skills are multidimensional, be there to observe, be patient, provide feedback, be positive, and seriously structure the assessment process (64). Many struggle with the notion that there are individuals who have an aptitude for performing innately difficult laparoscopic maneuvers deftly. This has found little documented validity and many cling to the notion that all interested surgeons who seek to be trained should avail themselves of advanced courses. In practice, however, there is increasing pressure on our specialty societies, hospitals, and governmental watchdogs that more scrutiny is warranted (65). Macmillan, also from the Dundee group, recently reported on a method of identifying individuals who appear to have an innate aptitude for performing complex dexterous laparoscopic tasks. They propose that if larger studies confirm these initial observations, selection of candidates for advanced laparoscopic training might be possible (66).

Laparoscopic Training

Theory

Surgical education has struggled with the methods to objectively scrutinize surgical performance of house staff for many years. The methods of formal education have had some limited application, but as the complexity of modern laparoscopic surgery has manifested itself, departments across the country and around the world have begun to evaluate how to assess competency, skill development, teaching methodologies, and communication skills (67). The complexity of this task has resulted in a surprising number of papers in the surgical literature on trends in education. Extensive lists are beginning to be generated on measurable psychomotor skills, but the ability of young surgeons to communicate is significantly important, especially for advanced laparoscopic procedures. Important aspects that deserve attention are psychomotor skills, cognitive decision making, incorporation of video-enhanced motor coordination, two-handed surgical maneuvering, and rhetorical ability. Students of advanced laparoscopic surgery are themselves independent learners. There are various approaches each will take to gaining laparoscopic skills. A whole host of research endeavors have begun to focus on the surgeon's ability to learn (68). At least four factors can be attributed to learning orientation: concrete experiences, abstract conceptualization, active experimentation, and reflective observation. D.A. Kolb is widely quoted in research regarding learning orientation. It is these orientations that help research investigators study learning. They identify four dominant learning styles: convergence, divergence, assimilation, and accommodation. The convergence learner stresses abstract conceptualization and active experimentation. These learners stress hypothetical-deductive reasoning to analyze their problems. Divergers rely upon contrasting orientations of concrete experience and reflective observation. Their information processing can thus be protracted and often do not feel impelled to act. Assimilators tend to use inductive

development of concepts such as unifying theories to explain their observations. They tend to focus on the soundness or fitness of ideas and thus are less concerned about the practical value of observations. Last are the accommodators who emphasize orientations of active experimentation and concrete experience (69).

Kolb's learning styles have been used successfully to evaluate medical students and evaluate the educational environment for medical learning.

In addition, this theory has also recently been applied to third-year medical students rotating on their general surgery clerkships at the University of Nebraska. They identified that the majority of the of third year students were convergers (45%), assimilators (26%), accommodators (21%), and divergers (8%). They were primarily interested in how best to evaluate the performance of the students and not to predict methods to better teach psychomotor skills. But applications of the modern learning theory are evident. They stated that clinical performance requires additional cognitive skills and abilities that need to be further quantified (69).

The ability to measure and impart laparoscopic psychomotor skills is another area undergoing intense scrutiny. The ability to ascertain those individuals who have innate ability should also be possible.

Factors recognized as crucial in laparoscopic surgery include muscle strength, speed, precision, dexterity, balance, spatial resolution, as well as poise and endurance. Kaufman et al. at the University of West Virginia have begun an active program focusing on three aspects of surgical education. First, can prospective surgeons be screened with regard to their psychomotor skills? Second, can the application of modern educational psychomotor concepts help in the development of advanced skills? Third, can evaluation methods of psychomotor skill proficiency adequately gauge the acquisition and performance of complex surgical tasks? Their methodology is complex, but applies a wide battery of psychomotor tests at the initiation of training, during training, and following training to better evaluate skill acquisition. Their tests include the following: McCarron assessment of neuromuscular development to measure motor function and fatigue, Purdue pegboard to assess fine motor control, Minnesota rate of manipulation test to measure speed and precision, Minnesota paper form board to measure spatial perception, haptic visual discrimination test to measure spatial perception, and California psychological inventory to measure poise, confidence, and relaxation. During preliminary evaluations, they have developed an equation that balances psychomotor ability with the acquisition of motor skill factoring in the time of training.

$$\text{Psychomotor ability} \times \text{Amount of practice} = \text{Motor skill proficiency (70)}$$

The United States Army represents another wealth of information regarding the ability to perform tasks and the ability to measure skill. Again, they have reported two major determinates for performance, length of time spent doing a given task, and aptitude. Using isoperformance curves, it is possible to explain the relationship between experience and aptitude mathematically. Now changes in the relationships can be measured and the effect of training can be calculated on isoperformance curves (71). As these studies continue, one can hope that directed methods of training will be possible for those interested in advanced laparoscopic surgery that will bring performance to a peak level and maintain it there (72–88).

Flight Simulators

The premise that the skill of the surgeons can be equated to the outcomes of the operations over time is a fundamental concept in modern surgery. Those surgeons who perform the most complex operations and have the lowest morbidity are encouraged. This concept is fundamental to other more intensively scrutinized professions as well, most notably commercial aviation. Flight simulation has a long and interesting history (89). Simulators have been attempted with surgical procedures such as laparoscopic cholecystectomy, laparoscopy-assisted vaginal hysterectomy, and laparoscopic inguinal hernia repair (Fig. 3) (73,77). But to date, they lack ability to function in the manner in which the aeronautics profession is capable. Current simulators are available in anesthesia, interventional radiology, and emergency medicine but these are far from clinical reality. Fidelity in haptic feedback has been an ongoing problem with surgical simulators. In addition, the ability of the computer to add nuances of human anatomical variability has not been achieved.

Computerized Education

The explosion in computer performance, hardware, and software has had profound effects on education, data management, communication, and entertainment. The impact

FIGURE 3 ■ Virtual reality laparoscopic reconstructive training (Karlsruhe Endoscopic Surgery Trainer).

of this modality on surgical education is just beginning to be felt (90). The "information age" has quietly crept into the surgical training programs throughout the country (91). It is no surprise to see that the house staff, familiar with computer technologies, gladly accept these methodologies. One recent study investigated the use of multimedia interactive computer programs to familiarize residents in laparoscopic skills. The comparative scales for the most effective method to familiarize and raise their knowledge regarding new laparoscopic procedures were as follows: textbook (4.7), lectures (5.1), videos (6.0), animal labs (7.3), and multimedia interactive computer programs (8.8). There are lots of problems with the more standard methods of surgical education when applied to laparoscopic surgery (91). First, with printed material such as this syllabus, there is no method of questioning the information unless those truly interested seek out references, read those, and synthesize their own opinions. Lectures provide the student with the possibility of real-time interaction through questioning and answering. The limitation of this modality is that it is entirely dependent upon the skill and knowledge of the lecturer. Couple with this the inherent problems of inhibitions in students in a large group, which can stifle potential educational interaction. Videos can be a very good reference but again, like textbooks, lack the ability to interact with questions and answers. Animal labs allow the student to experience live surgery, make mistakes, and correct them, and provide animate experience with such issues as tissue handling, bleeding, visual imaging problems, etc. These experiences are costly, limited in availability, and lack true educational values unless a skilled proctor is present continuously to provide feedback (92). Multimedia interactive computer programs can provide all of the aforementioned qualities necessary, and also provide interactive references to specific questions via "Help" commands. In addition, computer programs have been shown to increase retention of important facts and decrease the learning curves, can be scaled to individual performance abilities, are inexpensive compared to animal labs, and are mobile. The computer method of training can be self-directed, self-paced, as well as interactive. Rosser et al. at Yale University's

Minimally Invasive Surgery group have developed a CD-ROM tutorial to aid in the transfer of cognitive knowledge thought to be essential for establishing laparoscopic skills. The tutorial was designed to provide surgeons with the knowledge base thought to be essential for acquiring basic laparoscopy skills originally designed for an intense two-day course (Yale Laparoscopic Boot Camp). The main menu consisted of eight main menus that could be taken in any sequence. They were as follows: dexterity drills, laparoscopic equipment, strategy of positioning, operating procedures, troubleshooting, clinical applications, and post-test statistical analysis. The tutorial requires almost no reading with audio prompts to a layered, regimented program with abundant illustrations and embedded videos. Using the embedded post-test and statistics package, they were able to show no difference in the post-test scores for students taking the two-day course versus the multimedia computerized tutorial (91).

Virtual Reality

Jaron Lanier introduced the term "virtual reality" in 1989, but the concept that computers would have enough power to interface with a human's sensory perceptions formed the basis of Ivan Sutherland's doctoral thesis from Massachusetts Institute of Technology in 1963. As with most things in the computer world, the first head-mounted display became a reality and a young entrepreneur, Morton Heiling, tried to sell "Sensorama," a simulated computerized motorcycle ride through a virtual city. Computational capacity has been the only limiting factor in the advance of these technologies. Gordon Moore, Intel Corporation's cofounder, is now best known for Moore's law, stating that a computers power would double every 18 to 24 months. He has made this statement from observing trends for the past 35 years. In addition, the cost of that technology has almost halved in the same period of time. In other words, the supercomputer of 1990 that cost $100,000 is today available in a $150 Nintendo system. Randall Tobias, former vice-president of AT&T phone company is widely quoted as saying, "if we had similar progress in the automotive industry, a Lexus would cost $2, it would travel at the speed of sound, and go 600 miles on a thimble full of gas" (93).

One of the first major advances in the development of virtual reality surgical systems came with the Visible Human Project. Sponsored by the National Library of Medicine, 1 mm cross-sectional anatomy was stored on a computer for three-dimensional reconstructive purposes. This database became the first available human subset for computer virtual reality programs (94).

Virtual reality surgery overcomes several of the limitations of education in an operating room. First, the teaching session in the operating room cannot always be well designed or orchestrated. The prime focus remains upon the patient. The scheduled case may not be well suited for the resident at that given time. The corollary to this is that the technical nuances of the particular case may be above or below the skills of the student, making the educational potential limiting. The execution of the surgical procedure may not be altered to satisfy an educational goal. Likewise, the dissection and exposure cannot always proceed in a fashion best structured for educational potential. Finally, the steps of the surgical procedure cannot be repeated. Errors that occur can be corrected, but they cannot be repeated (95). All of these shortcomings are nonexistent in the virtual operating room. In addition, there is more evidence that learning complex tasks is significantly impaired by increasing the amount of stress in the environment (96). An operating room is inherently filled with stress. Factors contributing to the high stress environment of the operating room include time constraints, technical difficulties, concern for the patient, equipment failures, interpersonal issues, handling telephone calls, and lack of rest. Investigators now are sure that the greatest levels of learning and performance occur in environments with moderate stress. The psychomotor tasks are learned in three ways, all facilitated in the virtual environment. In the cognitive phase of learning, the student attains a degree of understanding of the task. The second phase is the associative process. During the associative phase, the student practices the task and compares performance with an expert. The differences are considered errors and mastery is achieved by minimizing these errors. Finally comes the autonomous phase, where skill is performed without cognitive awareness (97–99).

Telementoring and Remote Surgery

Several factors are associated with altering the rules of surgical education. The hospital inpatient population is becoming more complicated and surgical therapy is potentially becoming more technologically complex. Insurance payers and, in particular, government watchdogs are requiring more supervision and less autonomy of the residents. The residents are being asked to learn the same or more material in fewer working

hours. Practicing urologists are facing the same phenomena, which is increasingly taxing the endurance to stay current. This is the scenario that is poised for the combinations of all of the just discussed technologies to merge with telecommunications and allow guided preceptorships remotely. If you throw in robotic surgery, then telementoring is not even necessary. The expert at one location can perform the surgery at another without physically being present (100).

Telementoring has already been performed for multiple surgeries as well as urologic laparoscopic cases. Dr. Kavoussi's group at Johns Hopkins has gained significant notoriety for this pioneering effort. In their initial studies, the surgeon mentor was located in a control room more than 1000 feet from the operating room. Fourteen advanced and nine basic laparoscopic procedures were performed. Telementoring was accomplished using real-time computer video images, two-way audio communication links, and a robotic arm to control the videoendoscope. Success was achieved in 22/23 cases, without increased operative times or complications. They then extended their investigations and distances between the Johns Hopkins Bayview Medical Center and the Johns Hopkins Hospital (distance = 3.5 miles) for 27 more telementoring laparoscopic procedures utilizing public phone lines. Finally, they have extended their novel surgical instruction capabilities to the international arena with one case in Innsbruck, Austria, and two cases in Bangkok, Thailand (101). Others have reported upon the technology necessary for successful telementoring. The U.S. Navy recently studied the feasibility of laparoscopic hernia repairs aboard the USS Abraham Lincoln while cruising the Pacific Ocean. Telementoring was possible from remote locations in Maryland and California (102). In a recent research investigation, Broderick et al. at the Virginia Commonwealth University reported that decreasing transmission bandwidth does not significantly affect laparoscopic image clarity or color fidelity as long as the laparoscopes are positioned and maintained at their optimal working distance (103).

Now for the ultimate in technophilia, a recent Internet study on the attitudes and practices of general surgeons was performed. Over two months, 459 surgeons were enrolled in a study on the World Wide Web. Those polled stated that the Internet was used to expand their knowledge of surgery in 74.5%, more than half of them stated that they favored more advances in technology such as robotics in the operating room (53%), and most (78%) favored the technology necessary for telementoring to learn new laparoscopic procedures (104).

Technology and advances in urologic surgery are being paralleled by research interests in the methods of acquiring skills and teaching. There is no doubt that computer-assisted methods of education will proliferate and that the classic methods for keeping current will be transitioned into a high-tech data stream of information. Telementoring is already a reality at those institutions that have been on the forefront of laparoscopic surgery. It is only a matter of time when an "off the shelf" package will be added to an operating room in your locale for furthering the training of interested surgeons. There are centers cropping up around the globe interested in expanding the envelope of technology on laparoscopic surgical education. Most of these centers currently come with a high price tag. But as seen so clearly with computerized systems, this too should become an integral part of surgical education at any institution interested in less invasive surgical technology. One such center (Center for Minimal Access Surgery in London, Ontario) has recently published its first paper on the establishment of a "state-of-the-art" multidisciplinary technological education and research center for minimally invasive surgical techniques. The technologies available for skill acquisition include high-fidelity Minimal Access trainers, Body Form Simulators, a virtual reality system, a computerized laparoscopic skills workstation, and a multimedia library of laparoscopic procedures. In addition, the Center for Minimal Access Surgery has started a videoconferencing system to be integrated with its various components to enhance education via telementoring (105). Advanced endoscopic suturing and knotting should be easily mastered in such environments.

LAPAROSCOPIC EXTRACORPOREAL KNOTTING

Extracorporeal knotting techniques have evolved for a diverse variety of laparoscopic purposes. First, they can be utilized to secure hemostasis of the anterior abdominal wall (106). Best described as a "sling suture" technique, the utility in stopping active hemorrhage from trocar sites has been demonstrated by several authors. The technique of

FIGURE 4 ■ EndoClose™ needle carrier can be used to sling or lift structures out of the field of view, close fascial defects, or stop bleeding from anterior abdominal wall vessels. *Source*: U.S. Surgical Corp., Norwalk, CT.

sling suturing extracorporeally, includes both straight and curved needles of various sizes (107). For control of anterior abdominal wall hemorrhage, a transverse ligature is necessary to encompass the area of the vessel. The first stitch should be below the vessel if the culprit is from a lower abdominal trocar injury and above if the injury is upper abdominal. The trocar should be removed only after the control of hemorrhage. Alternative maneuvers may be necessary to control trocar site bleeding, including, but not limited to, percutaneous fulguration (resectoscope), transportal placement of a Foley catheter for direct pressure application, and others. This extracorporeal knot can also facilitate intra-abdominal visualization by "slinging" obstructing structures out of the visual pathway. Nathanson and Cushierie utilized just such an extracorporeal knot as a "falciform lift," and the same can be done with the urachus. Recently, several extracorporeal-assist mechanisms for passing these sling sutures have been marketed (Fig. 4). These instruments are primarily being marketed for use in visually-assisted fascial closures (Fig. 5).

Extracorporeal knotting has had its most common application with loop ligation techniques. A variety of loop knots are utilized and the laparoscopic surgeon can use pretied ligatures or tie one with standard sutures. Several knot configurations are also available and the surgeon can utilize fly-fishing knot variants or sailor's knots for the same purpose (5). Clinically, the most commonly utilized loop ligature still employs the Roeder knot (108). The Roeder knot can be applied pretied as a loop ligature or can be tied after needle ligature intracorporeal placement and then synched (Fig. 6) (35,53). The only investigation on the safety of vessel occlusion reported that dry gut Roeder knots provide vascular occlusion up to 3-mm arteries (107). The other knot configurations that have also been successfully employed include the Duncan knot (with or without a half hitch), Fisherman's clinch knot, jamming loop knot, and Weston's configurations (Fig. 7) (67,111,112). Loop ligatures by design can incorporate any of these aforementioned slipknot modalities. Several manufacturers offer prepackaged, slipknot loop ligatures. Common features include a variable length pusher (usually 80 cm) over monofilament or braided sutures. Application of pretied slipknot loop ligatures has been simplified by disposable applicators. Chromic gut, plain gut, polydioxanone (PDS™ and PDSII™), silk, polyglactin (Vicryl™, Dexon™, or Polysorb™), and dacron (Surgidac™) are all clinically available laparoscopic suture materials.

The endoscopic loop ligature is passed backward through a reducer sleeve (3 mm) and then into the appropriate trocar (Fig. 8). The pushrod is then advanced until the loop is fully opened within the abdomen. A grasping instrument is passed through the loop and the targeted tissue is grasped. The back-end of the plastic pushrod is snapped and the rod advanced to tighten the slipknot. The synching suture is cut at least 2 cm from the knot.

Finally, extracorporeal knotting can be utilized with intracorporeal suturing when knot pushers are available (112). Various reports indicate that, with practice, these knots

can be applied fairly quickly (less than five minutes) (109). Any available suture material can be utilized for these extracorporeal techniques, providing that adequate length is available to traverse the trocar (usually 80 cm). Various braided sutures do not slide as well as others if standard square knots are utilized, and should be avoided. Prepackaged endoscopic ligatures with variable needle configurations are available for this purpose from most manufacturers. One unique approach to this technique employs a specifically designed knotting instrument. Oko and Rosin report the ability to suture and place knots with almost any material and then adjust tension and knot position with their device (Fig. 9) (113). The same type of knotting technique was described by Puttick et al., utilizing a laparoscopic Babcock clamp (114). A multitude of manufacturers tout their knot pushers for ease of synching. The primary problem with all techniques of extracorporeal knotting includes the need to maintain long suture tails, multiple passages via trocars, no direct control of the sutures at the tissue while knots are being thrown, and the need to suture intracorporeally. Kennedy has shown that multiple extracorporeally tied knots can be sequentially thrown with the aid of a pusher, thus simplifying the reentry problems (115). Complex urinary reconstructions typically require end-to-end or layered closures, which are nearly impossible using extracorporeal techniques.

Prior to addressing intracorporeal suturing and knotting techniques, mention should be made to those who advocate clips to secure the intracorporeal suture or suture line. Although not an extracorporeal technique, the primary claims of those exploring this method of suture anchoring are avoiding the potential loosening of slipknot ties or the cumbersome multiple trocar passages required by extracorporeal knotting.

Choreography

Metallic and absorbable clips have been successfully used to secure intracorporeal sutures (116). Metallic sphere clips have likewise been devised to more securely maintain suture tension. There exists only one study evaluating the security of these differing modalities to secure a suture. Utilizing a tensiometer, distraction forces were measured following a standard three-throw knot versus titanium clips versus locking polyglactin clips versus malleable collars. No technique approximated the security of the standard three-throw knot. By doubly throwing the suture through the collar, the distraction force approached that of the knot [knot 4.9 kg (SD = 3.22) vs. doubly thrown collar 5.4 kg (SD = 3.22)] (116).

LAPAROSCOPIC INTRACORPOREAL SUTURING AND KNOTTING

Intracorporeal Suturing Difficulties

Laparoscopic urologic reconstruction continues to require intracorporeal suturing skills. Intracorporeal suturing and knotting represent the most difficult surgical techniques that the advanced laparoscopic surgeon can acquire. Reasons for the difficulty in performing intracorporeal suturing are multifactorial (Table 3). The closed operating environment represents the primary hindrance to mastering these techniques. Fixed portals of entrance limit the "approach" to the targeted suture site. The intra-abdominal viscera are rarely stationary and the ability to move a needle driver's approach is limited by these fixed entrance portals. Specifically designed assisting instruments (Fig. 10, bottom flamingos) can manipulate nonfixed tissues for correct alignment and overcome the problem of fixed portal positioning. In addition, the camera site and the surgeon's right and left hands also remain fixed. Adding an additional trocar is always possible, but it defeats the philosophical goal of minimal-access surgery. The camera position of choice when first attempting intracorporeal reconstructions should lie between the surgeon's right and left hands. For maximum efficiency, the right- and left-hand portals should not be over an acute angle with each other. The optimal angle to work with is 80° to 110° and each trocar should be separated more than 8 cm at the surface skin sites to allow the maximal ability for the tips to interact. Another important factor to control in this closed, fixed environment is image stability (117). A stable image is readily obtainable by replacing the human camera assistant with a robotic arm. A wide variety of choices are available, ranging in price and complexity from simple mechanical devices to computer-controlled, servo-assisted systems (Fig. 11). These instruments allow for maximally stable images, even with close zooming with the laparoscope. An added bonus of these robotic arms is the free lateral space at the side of the operating room table allowed by the low profile of some of these assist systems.

Rigid portals are another hindrance to rapidly adapting suturing skills. Surgeons are used to suturing with fluid wrist movements that accentuate needle-driving forces, forming loops in the suture to facilitate knotting, and keeping tension on the swaged-end portion for secure running stitches. Rigid portals eliminate these finesse skills and magnify the perceived difficulties of intracorporeal suturing. Flexible trocar portals have been recently marketed (Fig. 12, Karl Storz, Tubingen, Germany) that may permit some degree of fine movement assistance currently lacking in endoscopic suturing. More appropriate and well known to microsurgeons are the utility of curved needle graspers.

FIGURE 10 ■ Szabo-Berci flamingo tissue grasper and the parrot-jawed needle driver. These represent the first set of intracorporeal instruments specifically designed to overcome many of the difficulties outlined in this chapter.

FIGURE 11 ■ Robotic arm–assisted laparoscopic surgery using AESOP system. *Source*: The Computer Motion Inc., Goleta, CA.

FIGURE 12 ■ Flexible trocars may allow instruments with more degrees of freedom to be passed intracorporeally to facilitate reconstructions. *Source*: Karl Storz, Culver CA.

Primarily employed because the curved instrument allows continuous visualization of the needle and driver's tip during all aspects of suturing in microsurgery, the curved needle driver also has advantages to overcome problems of fixed portals in intracorporeal suturing. By changing the orientation and position of the needle along the curved needle driver the same fine alignments can be achieved for entrance and exit bites during needle driving without reliance upon flexibility at the trocar site. It takes hours of practice with handling the needle under videolaparoscopic conditions to master these new skills, but mastery facilitates fluid intracorporeal suturing. Another way around fixed trocars is to have access to the region of interest with part or all of the surgeon's hand (118). Conventional suturing instruments could be utilized if requirements for pneumoperitoneum are abandoned, such as with gasless laparoscopy (119). The surgeon's hand need not be introduced at all if mechanical systems that provide the degrees of freedom necessary to overcome fixed portal insertion site limitations can be developed (120,121). In fact, an Olympus prototype needle driver with six degrees of freedom has been investigated, but remains a research tool at present.

Another limiting factor preventing rapid acquisition of endoscopic suturing skills is the limited visual field. Open surgeons take for granted the ability to lift tissues so as to allow visualization during all phases of suturing. Although the concept of atraumatic tissue handling during suturing is a fundamental skill, the tissue handling represents the key to visually controlled needle placement. The laparoscope brightly illuminates the visual field but does not allow unlimited circumferential views without repositioning or changing to a different angle. A flexible or semiflexible laparoscope would make these angled adjustments, but the degree of interaction with the surgeon would have to be such that anticipated needle path trajectories could be followed. The only current method of overcoming this problem is to have an assistant tissue grasper manipulate the targeted suture site for correct visual alignment toward the laparoscope.

Next on the list of environmental limitations to intracorporeal suturing is the lack of stereoscopic vision. This is a result of current imaging technology. Videolaparoscopic images are magnified and two dimensional. With time and practice, the feedback from both surgeons' hands and the interaction with hand–eye coordination make even the most difficult intracorporeal maneuvers possible. In a study of videolaparoscopic suturing over standard suturing, the degree of difficulty was approximated to be eight times greater. Developing a memorized systematic method of tying with both hands cooperating to minimize the movements necessary to tie can overcome this problem (Fig. 13) (8). This results in "economy of motion." The right and left hand develop orchestrated interactions very much like in microsurgery (8). Small motions result in faster, more fluid, magnified suturing skills. Of course stereoscopic videolaparoscopes could decrease the difficulty of intracorporeal suturing. Such systems are available on robot-assisted, computer-controlled surgical systems such as *da Vinci*® (Fig. 14) (122).

FIGURE 13 ■ Two-handed intracorporeal suturing facilitating bilateral vesicopsoas hitches.

FIGURE 14 ■ Voiding cystogram following laparoscopic radical prostatectomy and microsurgical vesicourethroplasty in a canine model.

The major anticipated drawback of these stereoscopic imaging systems is the purchase price (estimates approximate $100,000) (122). As with any type of magnified endoscopy-assisted surgery, it is the surgeon who is highly trained and dexterous who performs flawlessly, even in difficult conditions. It may be expected, but is not proven, that the stereoscopic systems will benefit most those who have already mastered the difficulties of intracorporeal suturing. Better would be the utilization of less costly, but just as powerful, head-mounted 3-D displays. Such devices are already being utilized at nominal costs from the electronic gaming industry. High-end computerized head-mounted display systems eliminate the need for buying expensive high-definition monitors, allow the surgeon an almost unprecedented mobility, are increasingly lightweight and comfortable, and, most of all, are coming down in price. There should be no need for ceiling-mounted monitors, which often require structural reinforcement of the operating room ceiling. Head-mounted displays make each endoscopic operating room far more flexible and can be multitasked. The future imaging system would be a high-definition, lightweight, head-mounted system that is translucent and allows the surgeon to pick up "real" objects in his environment, as well as perceive the "virtual environment during the laparoscopy (123).

Finally, one last environmental limitation must be mentioned as a hindrance to intracorporeal suturing—hemorrhage. The closed environment of laparoscopic surgery imposes a formidable barrier to the maintenance of hemostasis. During intracorporeal suturing, bleeding even in small amounts can make identification of correct tissue planes an arduous or impossible task. Complex intracorporeal suturing requires a bloodless field to expedite the already difficult maneuvers mentioned previously. During the division of the viscera it is crucial to be able to achieve hemostasis without compromising the viability of the tissue to be reconstructed. In preliminary investigations, the argon beam coagulator demonstrated unique abilities for this specific purpose (Fig. 15) (23). Plasma from flowing argon gas molecules allows precise cauterization with very limited depth of penetration. The flowing gas also clears the targeted field, allowing the cautery to be more effective upon the bleeding vessels and decreases the time of thermal exposure. There are still risks of thermal necrosis from overzealous exposure to argon beam coagulators. This instrument probably has its greatest utility in its unique hemostatic effects for the reconstructive laparoscopist (124–139). Despite the potential merits and wide applicability of the argon beam coagulator, the downside should be mentioned. Argon gas is less soluble that carbon dioxide and fatal argon emboli have been reported (140,141).

Instrumentation and Skills

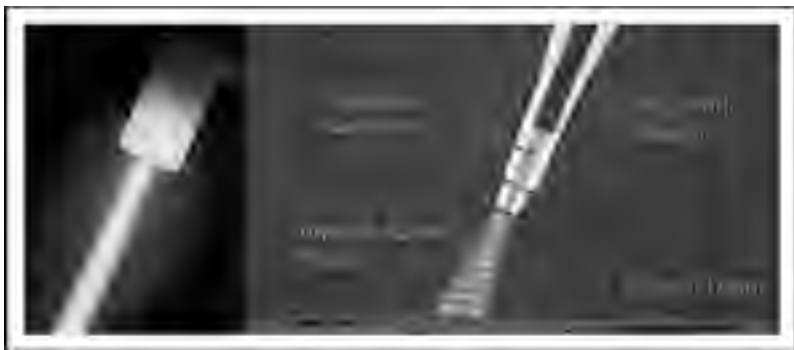
Closed environmental constraints aside, there are two other significant barriers limiting rapid mastery of intracorporeal suturing skills and instrumentation skills. Instrumentation initially relied upon adaptation of grasping instruments for the purpose of laparoscopic suturing. Limitations of general-purpose graspers are their inability to grasp and maintain the torque needed for driving needles through tissue. To overcome this problem, several manufacturers developed pin-vise–like needle drivers that would rapidly facilitate needle driving (Fig. 16). The torque problem was eliminated, but all the other problems discussed previously have not been addressed. The result is a perfectly good needle driver, but not a good intracorporeal suturing instrument.


FIGURE 15 ■ Argon beam coagulation may allow more effective hemostasis with less tissue necrosis. Both are essential features for advancing intracorporeal reconstruction. *Source*: Birtcher Medical Systems, Irvine, CA.

FIGURE 16 ■ Pin-vise laparoscopic suturing instruments. The design limits utilization of these needle drivers for few other purposes.

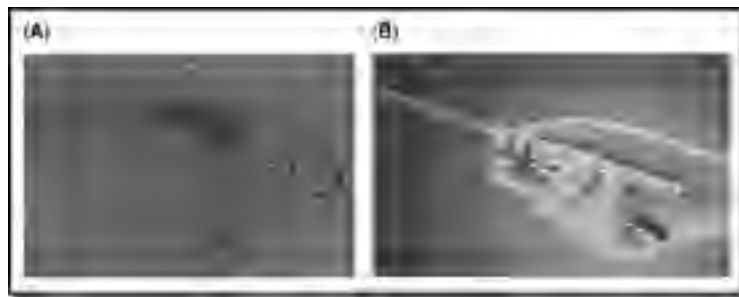
FIGURE 17 ■ Various types of intracorporeal needle drivers. Each represents a unique design modification. What is common to all is the lack of finger rings that limit laparoscopic surgical dexterity.


FIGURE 18 ■ (A) Classic finger-ringed instruments entrap the surgeon's hands. (B) Newer instruments allow fine manipulation of the instrument's tip without encumbering the hands.
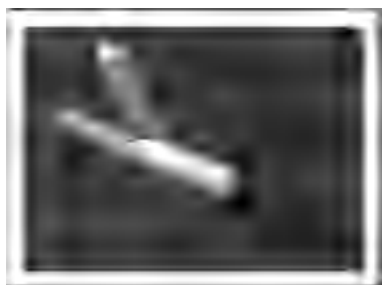

FIGURE 19 ■ A unique laparoscopic needle driver's jaws: Endolap™ Inc., contour tip with rack & pinion power drive.

FIGURE 20 ■ The Szabo-Berci™ parrot-jaw needle driver and flamingo tissue grasper close-up.

FIGURE 21 ■ Intracorporeal passage of needles.

There is no other function that the driver can accomplish and the second hand of the surgeon must multitask to facilitate just the needle driving.

Brute force by the needle driver does not necessarily create an improved suture reconstruction. By forcing the needle along an inappropriate trajectory through the tissues, irregular spaced intervals, bunching of tissues, and inability to catch mucosa are all possible. Forceful needle drivers should not be allowed to replace surgical finesse. In a study of seven different needle drivers, the ergonomics of laparoscopic suturing was recently studied (142). Wide variability in the torque and flexion forces are obtainable. Specifically designed intracorporeal suturing instruments have been developed addressing many of the problems outlined previously (Fig. 17). The shorter the needle driver, the less magnification of small movements at the tip from the surgeon's hands. By removing finger rings, the surgeon's hands are no longer entrapped. Fine movements with the palm or with the thumb and index finger can be accomplished (Fig. 18). In addition, because of the complexity of intracorporeal suturing, removal of the finger rings greatly eases the cramping and paresthesias that develop when the fingers and thumb are fixed within an instrument for hours. Finally, the needle driver's jaws are another essential feature affecting performance. Although most instruments rely upon the standard open diamond jaw configuration to firmly grasp the needle, other variations are just beginning to emerge as effective alternatives (Fig. 19). The only intracorporeal suturing set that provides an assistant tissue grasper and a dedicated needle driver are the Szabo-Berci™ flamingo and parrot-jawed instruments (Fig. 20). Curved-tip instruments allow the surgeon to identify cut edges, invert edges, identify both the entrance and exit bites with the needle and allow the surgeon to adjust the tension of the suture. Many individuals painfully aware of the limitations of current suturing instruments are beginning to develop "prototypic" devices. Agarwal et al. describe a simple 10-mm instrument with a fixed needle at the tip of the driver to facilitate intracorporeal suturing (143).

The last barrier for accomplishing intracorporeal suturing is skill. Defined as the ability to do something well, intracorporeal suturing skill requires remastery of tasks surgeons use daily, but with much more attention to detail. This was referenced at length during our discussion of laparoscopic training. Intracorporeal suturing can be divided into three distinct tasks that can be practiced and mastered separately. These are needle driving, suturing, and knot tying.

Needle Driving

Laparoscopic intracorporeal needle driving requires successful, safe introduction of the needle and suture material through a trocar or through the anterior abdominal wall. This requires the knowledge of which needles will pass through a specific-sized trocar (144). The safest method to avoid inadvertent injury to the trocar's flapper valve mechanism and the patient's underlying viscera is to grasp the suture 2 to 3 mm behind the swage, open the valve, and begin passing the needle driver and suture simultaneously (Fig. 21) (145). Second, the needle and suture must be grasped by the needle driver and correctly aligned prior to beginning. Here, the assisting instrument grasps either the suture close to the needle or the needle itself, and then the needle is turned by both instruments close to the laparoscope until proper alignment is achieved. Needles are best held perpendicular to the jaws of the driver and in line with the proposed suture line. A curved needle is best grasped halfway along its circumference, whereas the ski-types

FIGURE 22 ■ The principles of intracorporeal needle driving. Movements should be slowed to the point of control and an understanding of the forces at the entrance and exit bites can prevent frustrating needle deflections.

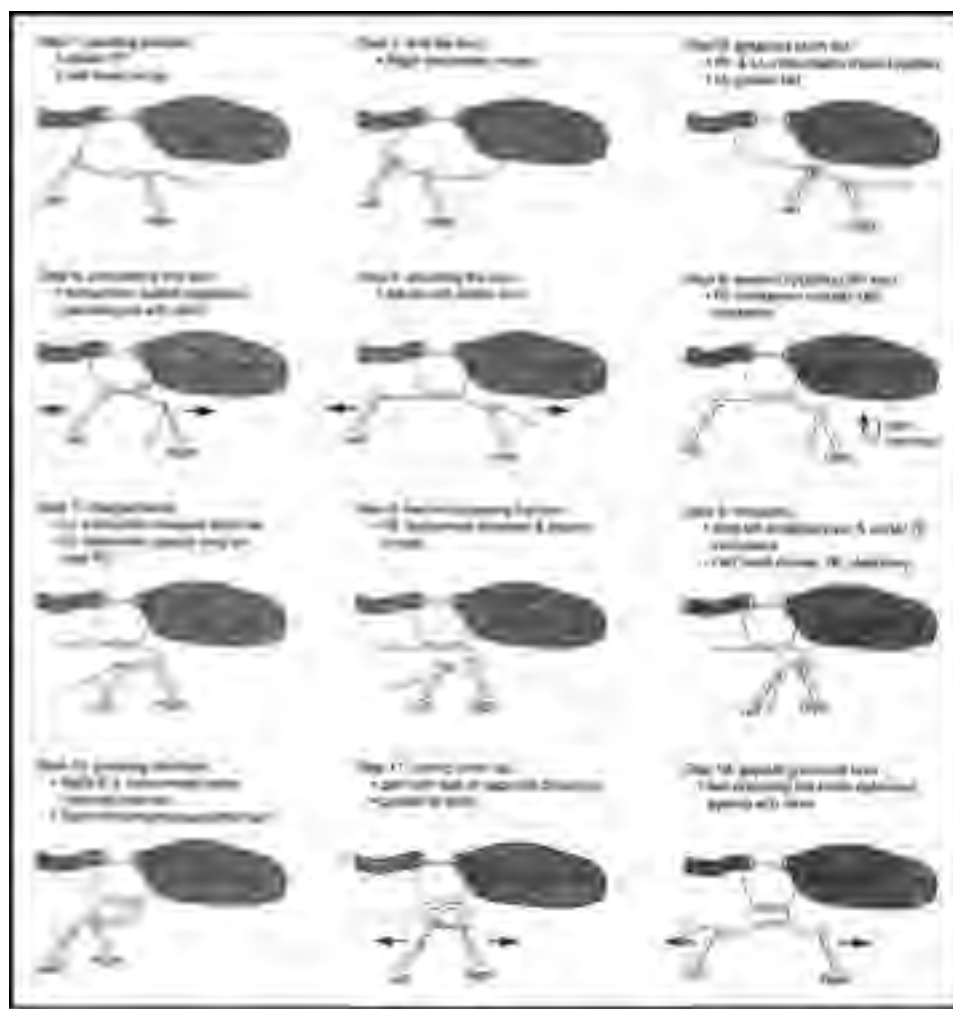
can be grasped along the straight shaft. An assisting instrument is utilized for tissue alignment and countertraction. Correct alignment and needle handling is crucial to preventing deflection of the needle within the driver's jaws as the needle point enters the tissue for the entrance bite. The most common problems encountered during initial experiences with intracorporeal suturing are frustrating deflections during the entrance bite, needle advancement, or the exit bite. It is recommended that while mastering this skill, the surgeon slows the motions down to the point of control and think about each step while maintaining alignment of needle, driver, countertraction, and tissues (Fig. 22). At the exit bite, the assistant instrument provides countertraction, and the needle is released by the driver and regrasped further back toward the swage and pushed through the tissues. At this point it can be regrasped by the driver (145).

Suturing

Suturing is the next skill to be relearned for intracorporeal reconstruction. Simple stitches require only one pass through the tissues and one knot to be synched. The goal of the laparoscopic surgeon should be to achieve a perfect stitch: equally apposed entrance and exit bite sizes to avoid tension on one side of the anastomosis or the other (146). Suture length should be kept to the absolute minimum required for this purpose (147). During microsurgical laparoscopic suturing, 13 cm is adequate for simple stitches. This allows ample room for the loops necessary for knotting even in thick muscular bladder reconstructions. Urologic reconstruction can require the utilization of simple running, or running locking sutures on the bladder. These stitches require more length of intracorporeal suture material and careful attention to tension along the repair. A good rule of thumb is that twice the length of a linear incision in suture material is required (148). Here as the needle is driven through the tissues at each exit bite, the assistant grasper is utilized to aid in pulling the running stitch through for the given length and the desired tension, while the needle driver with the reloaded needle is utilized to provide counter pressure. Because the intracorporeal suturing is arduous, it behooves the surgeon to make sure the suture line is perfect the first time; even if this takes time, it is still better than redoing it. Attention to detail is paramount to an ideal suture. The running suture should start 2 to 3 mm proximal to the incision and run up to 2 to 3 mm beyond, prior to tying the end knot (145). Locking is not particularly difficult but should also be carefully orchestrated and not started until the suture line's tension has been rechecked. It is far easier to tighten a running line of suture before, rather than after, it has been locked intracorporeally. The suture should run at least one needle-driven point beyond the end of the incision. Knotting a running intracorporeal stitch can be more difficult than a simple suture. This will be discussed in the next section.

Knotting

Knot tying represents the final hurdle for proficiency in intracorporeal suturing. Were suturing and needle driving not difficult in themselves, one might say that extracorporeal knotting would certainly be the method of choice. But because the skills necessary for complex endosurgical reconstruction are all linked, knotting represents the last, most difficult task (149). In addition, once mastered, intracorporeal knots can be manipulated to the endoscopic surgeon's advantage for complex anastomoses, very much like in microsurgery (more on this later) (150). The key to successfully mastering intracorporeal knotting has been careful, small, orchestrated movements of the instruments in both of the surgeon's hands.

FIGURE 23 ■ The 12 steps in choreographing the right and left hands for accomplishing fluid intracorporeal suturing and knotting.


The intracorporeal knot having the most utility is the simple square knot. A square knot is two apposed half hitches, one atop the other. To orchestrate the movements necessary to tie such a knot and eliminate wasted motion, each key movement must be identified and the entire sequence practiced. We have previously discussed the 12 steps in tying an intracorporeal square knot (Fig. 23) (151). *Step 1* is the starting position. A "C" shape is made in the suture with the right hand grasping the swaged end of the suture and the left stabilizing the tail. *Step 2*, the right hand only moves to create a loop around the tip of the left instrument. *Step 3*, the right and left hands move together as the left instrument grasps the tail of the suture. *Step 4*, the instruments are pulled in opposite directions paralleling the pull with the suture. *Step 5*, the knot is adjusted to center the first half hitch directly above the laceration by placing more tension on the right or left hand grasp of suture. *Step 6*, sets up throwing the second half hitch. The right grasps the swaged end and is rotated 180° clockwise. *Step 7*, the left instrument releases the short tail and grasps the swaged end near the right grasper. *Step 8*, the right instrument releases the suture and is placed on top, directly in front of the left grasper. *Step 9*, the left hand moves to create a loop around the right, which remains stationary. *Step 10*, the right and left instruments move together toward the short tail, which the right then grasps. *Step 11*, both instruments are pulled in opposite directions parallel to the stitch. *Step 12*, the two opposing half hitches are tightened against each other. This concludes the exercises necessary to orchestrate fluid interaction and minimize wasted motions, thus limiting the surgical frustration.

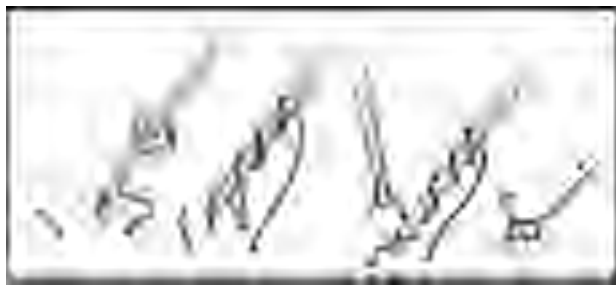
Methods other than that described above can be utilized for laparoscopic intracorporeal knotting: by prefacing these techniques with the reminder that intracorporeal suturing is difficult, but with time, patience, and practice it can be mastered. Utilizing microsurgical principles adapted for the laparoscopic environment, knots and sutures can be manipulated to the surgeon's advantage. This should be kept in mind when considering intracorporeal suturing techniques and taking short cuts (152).


FIGURE 24 ■ Pin-vise suturing technique.

FIGURE 25 ■ Pietrafitta's technique of stabilizing each half-hitch.

FIGURE 26 ■ Smiley face technique of intracorporeal knotting.

FIGURE 27 ■ Fly-casting method for intracorporeal knotting.

Depending upon the intracorporeal instruments utilized, a variety of intracorporeal knotting strategies can be performed. If a pin-vise needle driver is chosen, an intracorporeal "twist" technique can be performed (Fig. 24). Utilized by H.C. Topel[b] and L. Sharpe[c], a sequence of twists (usually 2–3 cm) on the needle wrap the suture around the assistant grasper, keeping the needle curve parallel to the introducer. The free grasper helps release the needle and swage from the jaws, carefully maintaining the loops. Then the looped grasper can grasp the tail and the instruments move in opposite directions to tighten the half hitch. This "twisting" technique can be utilized for both curved and straight needles. Straight needles can be utilized with conventional laparoscopic instruments. Here, the needle is used to wrap the swaged end about the assistant grasper, as long as the instrument is oriented toward the assistant. The tail can then be grasped from the now "looped" grasper. Another technique reported to simplify intracorporeal knotting describes grasping both ends, forming a loop above the repair (153). The needle driver can then loop through either side to facilitate formation of each half hitch (Fig. 25). This technique hopes to eliminate "complicated, dextrous, simultaneous two-handed motions." The "smiley face" technique is another method of promoting the intracorporeal formation of knots (Fig. 26). During intracorporeal suturing with this technique, emphasis is placed on manipulating both swage and tail segments with the needle. The needle is grasped midshaft with each end pointing upward, forming a "smiley face." Each half hitch is then facilitated by wrapping the needle around the assisting instrument to form loops. This technique results in fixed orientation and a stable continuing starting place. Kozminski and Richards have recently described a fly-casting technique to aid intracorporeal knotting with interrupted sutures (154). The tail is grasped and held up in space, and next the swage is passed over the tail and allowed to drop by gravity. The swage is retrieved from the underside for the first half hitch (Fig. 27). Mirror-image repeat of this sequence results in a square knot. Finally, a prelooped needle and suture is available for intracorporeal stitching[d]. Once introduced to the area of reconstruction, the needle is advanced and grasped by the driver. The needle is then passed through the preformed double loops and pulled in opposite directions. The applicator plunger is next pushed, pulling the tail and tightening the slipknot. A surgeon's knot can be incorporated by placing two loops around the left grasper during the first half hitch. A surgeon's knot adds to the security against slipping, especially with monofilament sutures such as polypropylene. If further modifications of the knot are required, then the surgeon's knot should not be deployed.

Running sutures may require special intracorporeal knotting techniques. Depending on the type of suture material utilized, there is the need to maintain the tension on the trailing segment of the stitch. Because of the fixed point of exit from the incision, the tail's end must be looped, causing a double-tailed segment that must

FIGURE 28 ■ Jamming loop knot (Dundee) shown previously can be used for extracorporeal knotting or starting a running stitch.

FIGURE 29 ■ Rollero's method of starting a running suture line.

FIGURE 30 ■ The Aberdeen knot (crochet) can be used to securely synch a running intracorporeal suture line if concern exists about crimping a monofilament suture.

be manipulated with the free swaged end. This double-stranded loop can result in increased demands upon the needle driver and assistant instrument to maintain tension on the suture line while performing intracorporeal knotting. Some monofilament sutures can fracture due to pressures applied by the instruments during knotting. Because of these problems, alternatives have been sought for running intracorporeal knotting. The jamming loop knot (Dundee jamming loop knot) can be thrown extra- or intracorporeally (Fig. 28). The running suture line can be initiated with the knot outside of the abdomen. The suture is then grasped along the swage and passed intracorporeally, usually with the aid of a reducing sleeve. The needle is then passed through the tissues and pulled until the loop approximates the tissues. The needle is then passed back through the loop, and the swage and tail ends are pulled in opposite directions jamming the knot (15,45). J.W. Rollero describes the use of a noose-like knot to start running intracorporeal suture lines (Fig. 29). The first two loops are made in a counter-clockwise fashion.

The tail crosses over the loop and is passed through the center. A third loop is formed by passing back through the center. The first running stitch is passed back through this third noose, anchoring it into place as the tension is applied. The Aberdeen (crochet) knot allows the intracorporeal completion of the running suture line (Fig. 30). Its major advantage over simple square knots is the avoidance of unequal lengths being manipulated intracorporeally and excessive force being applied to monofilament suture materials. Here the suture is first passed beneath the last running stitch before it is tightened to form a loop. A second loop through the first is fashioned, and then the swage with needle is passed through, tightening both the loop and synching the knot (155).

Recently, the interest in running sutured anastomosis has prompted resurgent interest in this technique, particularly, as it applies to the vesicourethral repair following laparoscopic radical prostatectomy. This running technique has attracted some significant research attention lately and will addressed separately in the section entitled Running Suturing.

Intracorporeal Needles

Laparoscopic intracorporeal needle configuration has received limited attention by manufacturers to date (156). Because of the limitations of the closed working environment and difficulty of intracorporeal suturing, it might be expected that needle configurations should approximate those of microsurgery. Needles should be high-quality stainless steel or carbon steel. Carbon steel needles are harder but are more brittle, and "on-table" adjustments could result in weakening or breaking of the shaft. Homogenous stainless steel is preferred but more costly. The needle profile of choice has

not been rigorously investigated (146). In our study of intracorporeal bladder neck reconstructions, we identified three configurations that facilitated intracorporeal suturing (151). A curved 3/8 needle, a ski configuration, and an "S"-shaped profile were most helpful (Fig. 31). Needle points can be taper point, cutting, spatulated, or taper cut depending upon the tissue and resistance expected in suturing.

The spatial constraints limit the needle size, shape, and suture lengths needed to most expeditiously accomplish intracorporeal suturing. For urologic pelvic work on the urethra or bladder neck, the deep recesses of the retropubic space permit only a small 1/2 or 3/8 needle (RB-1 or TF) taper point configured needle to allow eversion of knots when reconstruction is performed. Some investigators have advocated straight needles (SC-1 Ethicon, TS-20 Davis & Geck, Endosuture™ WISAP, or ELW U.S. Surgical). These have primary advantage on surface structures or when intracorporeal suturing with straight needle graspers.

Intracorporeal Sutures

Suturing under laparoscopic conditions also produces other influences on the choice of suture materials. Surgical knots must hold and the choice of a woven or monofilament, absorbable versus nonabsorbable suture must be carefully chosen with this constraint foremost. For urological applications, intracorporeal suturing with plain or chromic gut and polydioxanone has advantage of allowing secure half hitch throws. Unfortunately, the coloring of each of these suture materials is such that if blood is present at the laceration site, specifying the ends, crucial for the orchestrated movements already discussed, becomes impossible. Blood has a tendency to adhere to these suture materials and strict attention to hemostasis is warranted. In addition, the coloration absorbs the light in all these materials except for the blue PDS™ (157). Because multiple untied sutures are placed but not tied as is required for complex end-to-end anastomoses, swage and tail ends become indistinct (Fig. 32; *left*). Brightly colored, optically fluorescent colors are required to overcome this problem. Currently, dye materials that have been investigated to enhance visibility when exposed to xenon light have also demonstrated carcinogenic properties. Despite this, colors most efficacious for laparoscopic suturing include pink, yellow, green, and purple (Fig. 32; *right*) (151).

The next problem for intracorporeal suturing is introducing the correct length of suture material. Available endoscopic suture materials that come prepackaged have no conception as to the requirements of the surgeon for the given task. Therefore, the sutures are often long (greater than 80 cm). For a simple stitch, the length required should be no more than 13 cm for a surface knot or 15 cm for deep stitches (158). Running sutures are more difficult to approximate, but as previously mentioned, a rule-of-thumb is to utilize approximately twice the length of the incision (159). Keeping the length to the minimum required results in less surgical frustration in manipulating long tail segments.

Other Intracorporeal Suturing Techniques

An enormous effort has been placed upon developing innovative methods of intracorporeal suturing to obviate the difficulties we have spent so much time outlining above

FIGURE 31 ■ Useful needle configurations for intracorporeal urologic reconstruction. 1. swage, 2. point, and 3. body. (A) 3/8 curve, (B) ski configuration, and (C) "S" shaped needle.

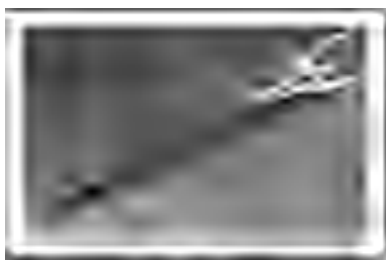

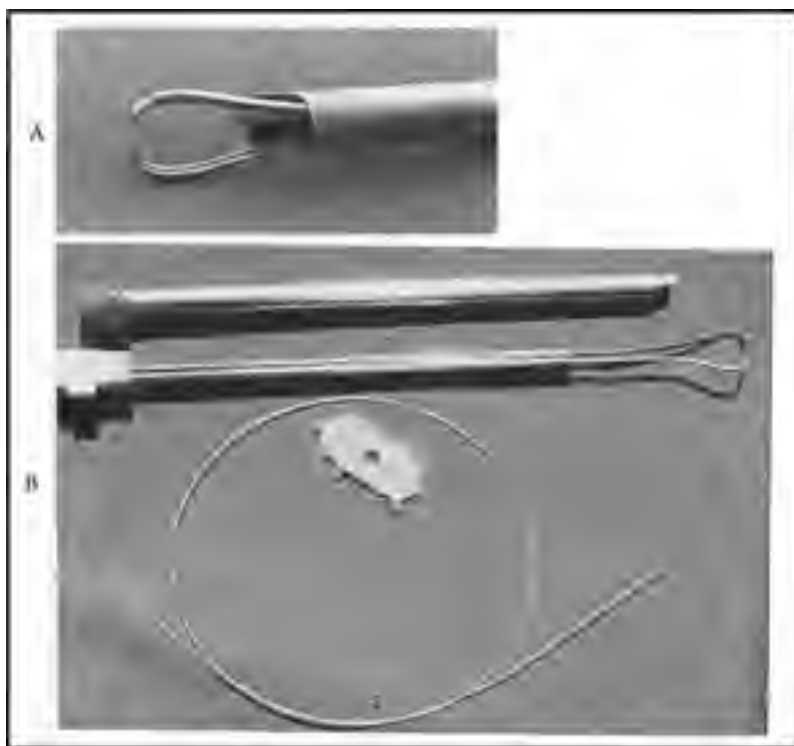

FIGURE 34 ■ EndoStitch™ is an automatic, loom-like, 10-mm intracorporeal suturing device. With practice knotting can also be facilitated with this instrument for simple and running sutures.

(158,160). Sheath systems that allow the needles and graspers to be positioned simultaneously have been described. Metal clips for replacing intracorporeal knots have been designed and marketed specifically for this purpose (24). Special techniques of tying that produce knots with straight pin-vise–type needle drivers have been reported (43). Mechanical devices are the latest devices that are attempting to reduce the difficulty of intracorporeal suturing and knotting. Stoller has described a simple device that will throw an intracorporeal knot automatically (161). A suturescope has also been invented with a mechanism for aligning tissues and driving a long needle through two opposing tubular structures (Fig. 33) (162). Utilizing this device, an endoscopic ureteroneocystostomy has already been performed. The ultimate mechanical suturing device would be an automatic endoscopic sewing machine. Current work with such a device has been investigated and utilized clinically via a large colonoscope, by Buess and coworkers (163). The Auto Suture Company has introduced its automated, single-handed, 10-mm suturing instrument, EndoStitch for clinical application (Fig. 34). This device utilizes a loom-like mechanism to pass a straight needle back-and-forth through tissues from either end of its jaws. Controllable with a single hand, the needle can simply be reversed and regrasped with a flick of the switch. Intended to be a single-patient use item, the EndoStitch device can be reloaded with the same or different suture materials. Suture materials are available currently in Polysorb (coated, braided, synthetic, polyglactin), Bralon™ (coated, braided nylon), Sofsilk™ (coated, braided silk), and Surgidac™ (coated, braided polyester). The lengths of these preloaded sutures are 18 and 120 cm, with their size being dependent upon the suture material but ranging from 4-0 to 0 (U.S. Pharmacopeia sizing).

Other systems for automating anastomoses are coming from advanced work on endoscopic beating-heart surgery. An enormous amount of research in this particular field will undoubtedly lead to many innovative devices to augment intracorporeal suturing (164). In addition, the ability to complete a complex anastomosis such as aortic-venous or aortic-arterial grafting automatically might have applicability to uroenteric anastomoses. This rather technical approach to intracorporeal suturing just might allow urologists to take advantage of the brightly illuminated, magnified image from the video systems and apply the reconstructive advantages of microsurgery (8,112,163). This of course, mandates bringing the laparoscope in close proximity to the area of interest. Each move of the laparoscopic instrument's tips speeds up in equal magnitude to the degree of magnification (8). All of the intracorporeal skills discussed earlier must be precisely applied or this becomes an impossible task. Hemostasis is

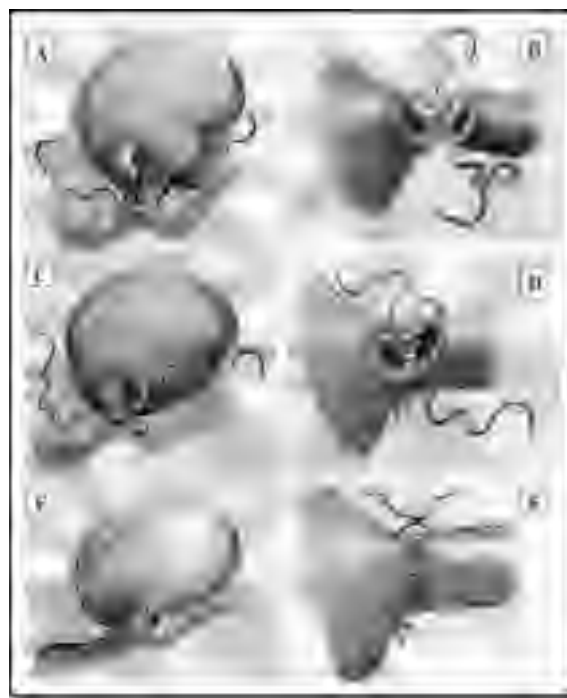
even more crucial during laparoscopic microsurgical suturing (160). The ability to observe small movements of the suture material through tissues is fundamental to smoothly facilitate needle driving, suturing, and knotting. Complex urologic anastomoses have been accomplished utilizing microsurgical techniques, including vesicourethral reanastomosis, augmentation cystoplasties, and others (153). The degree of difficulty of microsurgical intracorporeal suturing is twice again as difficult as regular laparoscopic suturing (153). The advantages of microsurgical reconstruction in urology include less need for long-term urinary diversion or drainage, less infiltration with scar tissue, and visually secure suture placement (153). In addition, because of the magnification, special suturing techniques can be performed that make end-to-end anastomoses nearly foolproof (150). Suspension suturing is the technique of converting a square knot into a slipknot and back again on demand (Fig. 35). This can only be accomplished if magnification allows careful suture manipulation. With these techniques, spatial constraints and limited visual fields do not prevent the surgeon from even small anastomoses.

Running Suturing

Despite considerable attention just given to suturing techniques, it is felt that one recent suturing method requires separate consideration. Initially Hoznek et al. described a simplified urethrovesical anastomosis using a two-hemicircle suture with three intracorporeal knots (165). Van Velthoven further simplified this technique by pretying two 6-inch, 3-0 polyglycolic acid sutures (one dyed and one undyed). Both needles are passed through the posterior bladder neck at the 6 o'clock position where the knot rests (Fig. 36). Sewing upward on either side of this results in a watertight closure. If a bladder discrepancy exists, the suture line can be run onto the anterior bladder neck forming a tennis-racket closure. Van Velthoven et al. report utilization in 122 laparoscopic and 8 robot-assisted radical prostatectomies with an average anastomotic time of 35 minutes. They have had no postoperative anastomotic leaks, and at short-term follow-up have reported no symptomatic bladder neck contractures (166). Menon's group has taken this technique and rapidly expanded its clinical application in the robot-assisted Vattakuti Institute Prostatechomy (Mani Menon, M.D.) series at Henry Ford Hospital. Now with over 500 consecutive cases presented, the mean operating time has dwindled to 150 minutes (167).

This technique is easily transposable to other urinary reconstructive procedures such as Anderson–Hynes dismembered pyeloplasty, ureteroureterostomy, ureteroneocystostomy, and ureteroenterostomy. Preliminary reports of this suturing methodology are beginning to accrue. Much has yet to be learned about this technique. But questions are numerous. Would a monofilament absorbable suture be better than the braided polyglycolic acid suture? Are two colors necessary? Are the two 6-inch lengths ideal? This sutured reconstruction technique appears to facilitate both free-hand as well as robot-assisted repairs and well may be a true advance in the technique of laparoscopic

FIGURE 35 ■ Suspension stitch technique for converting square knots to slipknots. Primary utility for end-to-end laparoscopic anastomoses. (A) Square knot opposing pulls to set. (B) Apposing tension to same side threads converts square knot to slipknot configuration. (C) Advancement of slip configuration. Finally, reconversion to square knot by apposing pulls as in top right. *Source*: Modified from Ref. 150.

FIGURE 36 ■ Van Velthouven's method of running vesicourethral anastomosis with a single intracorporeal knot. Two 6-inch lengths are tied together extracorporeally with two different-colored absorbable sutures.


reconstructive urology. Basic research may yet solve some of the dilemmas such as the ideal length of a running suture (168).

LAPAROSCOPIC UROLOGIC SUTURED RECONSTRUCTION

As this textbook will attest, the number and complexity of urologic reconstructions is rapidly expanding. In 2003, for instance, only about 700 robotic prostatectomies were performed worldwide. In 2004, this number is expected to rise above 7000, representing a log growth in the number of sutured vesicourethral anastomoses (1). Over 500 laparoscopic pyeloplasties have been reported with sutured repair. Also emerging with larger series are laparoscopic radical cystectomy with either orthotopic or heterotopic sutured/stapled urinary diversion. The implications and abilities for the urologist to intervene and reconstruct the urinary tract are now widely being applied. In this section, each urinary organ will be isolated and discussed with a review of the relevant literature. Every aspect of urologic reconstruction has been attempted upon the kidney, ureter, bladder, bladder neck, urethra, and genitalia. Even the inferior epigastric artery has been isolated and harvested for reconstruction of the penile vasculature for impotence using laparoscopic techniques (2). Laparoscopic ileal vaginal reconstruction has been accomplished in a young woman with Mayer-Rokitansky-Kuster syndrome (3). Virtually every intersexual condition has now been reported to be successfully treated with the aid of laparoscopic reconstructive measures (4). We have pursued an endoscopic model of gracilis muscle flap harvesting with intracorporeal transposition to the bladder neck and isolation of the neurovascular pedicle in rabbits. The following discussion of the most recent series of laparoscopic urologic reconstructive surgeries with historical references when relevent. Emphasis will be upon the sutured nuances within these reports.

Renal Reconstruction

Literally every open procedure performed upon the kidney has now been done laparoscopically. Procedures include the following: pyeloplasty, partial nephrectomy for malignancy, partial nephrectomy for duplication anomalies, partial nephrectomy for fusion anomalies, lower pole partial nephrectomy for stones, ureterocalicostomy, pyelolithotomy, anatrophic nephrolithotomy, pyelocaliceal diverticulectomy, renovascular surgery, autotransplant, donor transplantation, and nephropexy. Here, the literature will be viewed from the standpoint of the laparoscopic reconstruction efforts. Attention will be particularly paid to those methods that the investigators are utilizing to repair the genitourinary tract, and their postoperative management and outcomes.

Laparoscopic Pyeloplasty

Of all the renal procedures currently being done, the most commonly performed short of nephrectomy is reconstruction for primary or secondary ureteropelvic junction obstructions (Fig. 1). The laparoscopic approach to the repair of this condition is so successful at some institutions that it has become the "method of choice" for repairing all patients

FIGURE 1 ■ Laparoscopic pyeloplasty.

presenting with ureteropelvic junction obstruction. Others argue that less invasive endopyelotomy approaches remain viable alternatives in selected patients with a high probability of success. Markovich et al. (4) recently reported on trends from 37 endourologists in North America. They found that 41% were still performing endopyelotomy, 51% were performing laparoscopic pyeloplasty, and about 50% were still performing open pyeloplasty. Of note, about 20% of those polled would now choose a laparoscopic pyeloplasty as first-line therapy (5). A single institution's comparison of laparoscopic pyeloplasty, Acucise endopyelotomy, and open pyeloplasty showed success rates of 94%, 54%, and 86%, respectively (6). It is easy to understand that the trend among endourologists is to consider laparoscopic pyeloplasty as first-line therapy.

Schuessler has reported his first six cases of laparoscopic dismembered pyeloplasty (6). All were performed with running 4-0 polyglactin sutures, two had reduction pyeloplasties, and all were drained postoperatively. He has subsequently reported upon six additional cases with operative times ranging from 180 to 420 minutes. Two additional laparoscopic pyeloplasties are reported using a 4-0 absorbable suture material. The largest single series has come from Johns Hopkins with 100 reported cases. Seventy-one of these 100 cases were Anderson–Hynes–dismembered pyeloplasties with sutured reconstruction. Their average operative time was 252 minutes (range, 120–480 minutes). The success rate is reported to be 96% at a mean follow-up of 32.4 months (7). Gaur et al. (8) described eight patients who underwent laparoscopic pyelolithotomy without closure of the pyelotomy incision (9). They have subsequently described a homemade intracorporeal suturing instrument to solve the problem of open drainage in order to reconstruct the pyelotomy. Laparoscopic pyeloplasty has also been utilized to synchronously extract calculi and repair the obstructed ureteropelvic junction. In the single largest cohort, 19 patients with 20 renal units underwent simultaneous interventions. Varying methods of laparoscopic reconstruction were used including the Anderson–Hynes, Y–V plasty, and Heineke–Mikulicz. Stone free status was 90% (17/19) and 90% had no obstruction at three months follow-up. Two of these patients have recurrent stones at follow-up for an 80% stone free rate (16/20) (10). Laparoscopic pyeloplasty has been evaluated for the treatment of secondary ureteropelvic junction obstructions (11). In a multi-institutional evaluation of 36 patients with an average of 1.3 prior procedures (range 1–4), the reported patency rate for a laparoscopic pyeloplasty is 89% and the reasonable objective response was 94% (11). In addition to salvage for secondary ureteropelvic junction, other reconstructive urologic procedures may be necessary in patients that have had previous surgery and long segmental defects affecting the ureteropelvic junction. Kaouk et al. reported the use of a dismembered tabularized flap repair in a 73 years old lady with a solitary kidney who had failed multiple prior procedures (12). In addition, a laparoscopic ileal ureter reconstruction was described by the same group from the Cleveland Clinic. An 87 years old with a solitary left kidney had a solitary proximal ureteral tumor and underwent a total ureterectomy and an ileal ureteral interposition (13).

One recent review used a decision tree analysis to compare the costs of each method of ureteropelvic junction repair at a single institution (14). A retrograde ureteroscopic endopyelotomy was the least costly (US$3842). The Acucise endopyelotomy was next (US$4427) followed by antegrade endopyelotomy (US$5297), laparoscopic pyeloplasty (US$7026) and open pyeloplasty (US$7119) (14). The authors are quick to point out that the financial data are arbitrary to the decision, but in the current Health Care environment the failure to consider this is likewise unacceptable. In conclusion, patients with ureteropelvic junction obstructions, especially with crossing vessels, are increasingly being considered for laparoscopic pyeloplasty. The success of this operation is very good, rivaling those of its open alternative. The method of choice for the repair has yet to be answered, however, for patients with crossing vessels, the Anderson–Hynes–dismembered pyeloplasty appears to be the most reliable method with intracorporeally sutured anastomosis.

FIGURE 2 ■ Laparoscopic partial nephrectomy.

Partial Nephrectomy Reconstruction

As every other aspect of open renal surgery has been reproduced laparoscopically, it is important to consider the reconstructive aspects of partial nephrectomy (Fig. 2). Partial nephrectomies were previously anecdotal, now a MedLine™ search shows greater than 56 published articles on this primarily. Most partial nephrectomies are performed for malignancy. The largest series was reported at the 2003 American Urologic Association Meeting by Gill et al. They compared laparoscopic and open partial nephrectomies in 200 consecutive patients. Pyelocaliceal repair was performed in 63.9% of the laparoscopic cases versus 73.4% of the open cases ($p = 0.20$). Pyelocaliceal repair was performed utilizing suture-ligation of intrarenal vessels and renal parenchymal reconstruction (15). Another recent investigation of pure laparoscopic versus laparoscopic-assisted partial nephrectomy in a porcine animal model noted that surgeons rated suture placement and tying much easier in the pure laparoscopic technique over the assisted alternative (16). Most investigators have taken to covering their sutured repair with fibrin glue or modification with a Surgicel patch (fibrin glue–impregnated patch). A flap of extrarenal fat can likewise be swung and sutured for a layered covering. In addition, many papers reviewed also utilized stenting judiciously in order to decrease the risk of urinary leakage (17,18).

Laparoscopic Ureterocalicostomy

Two small series of investigations utilizing this technique have been reported, both in swine models. Cherullo et al. performed a laparoscopic lower pole nephrectomy by transverse amputation in 10 pigs. Next, a sutured ureterocalicostomy was carried out with interrupted absorbable sutures. All anastomoses were stented and the mean operative time was 165.3 minutes (range, 105–240 minutes) (19). The group at University of California Irvine is likewise investigating this complex reconstruction utilizing a similar porcine model but with a unique reconstructive twist. A novel nitinol tacker has been used for vascular anastomoses. Because previous reports by this same group have revealed little lithogenic potential for titanium during the use of an Endo-GIA™ for reduction of the renal pelvis during laparoscopic pyeloplasty, this device deserves further attention (20,21).

Laparoscopic Calicorrhaphy and Calicoplasty

Anatrophic nephrolithotomy has been the last bastion of open renal stone surgery (22). This has now been modeled in the porcine surgical research lab and brought into clinical practice at the Cleveland Clinic. Laparoscopic anatrophic nephrolithotomy was performed in 10 pigs and 11 kidneys using vascular pedicle clamping, contact surface kidney cooling, renal parenchymal incision laterally along the avascular plane, and sutured reconstruction. This group has reported upon the clinical application of this technique in two patients (23). Coupled with the methods of laparoscopic, intraoperative ultrasonography, it might be expected to expand to other applications such as the radial nephrotomy for obstructed calyces.

Laparoscopic Renal Vascular Surgery

Renal vascular surgery can be performed for nascent renovascular disease or during the reconstruction phase of renal transplantation and autotransplantation. In the former category, nascient renovascular disease, laparoscopic repair would of course have to compete with the less invasive alternative of percutaneous transluminal balloon catheter angioplasty with renal artery stenting (24). The Cleveland group has also evaluated laparoscopic renovascular reconstruction. In their preliminary animal series, five female swine underwent a seven-step renal artery repair (25). This group followed with a case report of a laparoscopic repair of a 3 cm sacular left renal artery aneurysm in a 57-year-old woman. A four-port transabdominal technique was utilized allowing circumferential

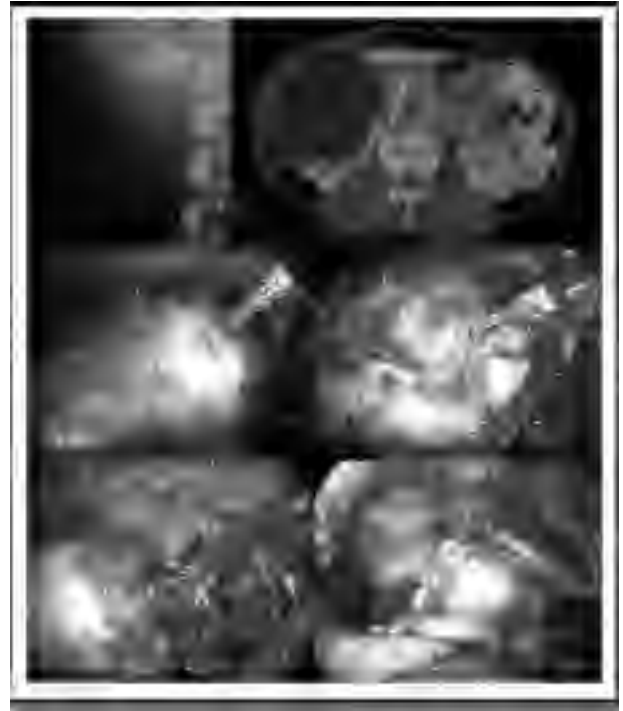
mobilization, Roummel tourniqueting of the main renal artery, bivalving of the aneurysm with excision, followed by 4-0 polypropylene sutured repair using an RB-1 needle. Total repair time was 31 minutes with an approximate 100 cc blood loss (26). Splenorenal bypass is another method for managing renal artery stenosis. This has been investigated in a canine model of six animals. In this laboratory model a spatulated, end-to-end anastomosis of the renal to the splenic artery was accomplished using 6-0 polypropylene sutures on an RB-2 needle. Mean anastomotic time was 71 minutes (SD = 8 minutes) (27). More distal vascular aneurysms are also approachable laparoscopically. This same group recently reported a 51-year-old male with a multilobulated intrarenal aneurysm from the upper pole branch of the renal artery. Laparoscopic Statinsky clamping controlled the renal hilum en bloc, the aneurysm was circumferentially mobilized, clipped and divided. They completed this using four ports with a total warm ischemia time of 39 minutes (28). Ming et al. have performed laparoscopic-assisted autotransplantation in patients with devastating ureteral and ureteropelvic junction injuries. The kidney is mobilized in much the same manner for a donor nephrectomy only a small separate lower quadrant incision is made for the autotransplant. Finally, the ultimate vascular reconstruction has been a robotic-assisted kidney transplantation where all anastomoses, both vascular and ureterovesical have been performed with the aid of the daVinci™ robot (29).

Pyelocaliceal Diverticulectomy

Gluckman first reported a laparoscopic ablation of a pyelocaliceal diverticulum by unroofing and ablation, but little was mentioned in the way of reconstruction (30). Two separate reports of pyelocaliceal diverticula ablations have been reported (31,32). In both cases, the anterior diverticula were incised and the linings marsupialized and fulgurated. Omentum was used in the first case and the colon in the second to isolate and cover the exposed raw surfaces. Since then, there have continued anecdotal reports of a case and one published small series representing five cases with detailed description of technique. In this series, a vertical incision was made over the thinnest avascular plane over the diverticulum. All stones or stone debris is removed into an endoscopic sack. Figure-of-8 3-0 polyglactin sutures were used to obliterate the ostium. An argon beam coagulator was used to obliterate the epithelial lining after thorough inspection to insure no inadvertent malignancies. Adjacent perirenal fat is mobilized and sutured into the diverticular defect. A Jackson-Pratt drain is placed prior to exiting. Stents were utilized routinely (32). A final series of four cases has been recently described on the management of type II pyelocaliceal diverticula (Fig. 3). Two of these four patients underwent laparoscopic repair in a similar fashion to that reported by Miller with excellent outcomes and functional recovery of the kidneys (33).

Nephropexy

Nephroptosis and the "floating kidney" are most commonly identified in thin, young females and preferentially involve the right side. It has an uncertain incidence in the modern era, but the correction of this condition resulted in large series published in the early modern surgical literature (34). With the advent of laparoscopic techniques, it is certainly possible to provide surgical fixation to these "floating kidneys." Urban first reported a laparoscopic nephropexy in 1993 using clip fixation techniques (35). Elashry et al. presented a group of six patients who underwent two methods of laparoscopic nephropexy: transperitoneal (4) and retroperitoneal (2). The nephropexy was performed using a vertical and horizontal row of 1-0 silk sutures through the renal capsule into the quadratus lumborum fascia. Mean operative time was four hours (range, 2.5–7 hours) (36). Larger series with longer follow-up is now available. Plas et al. (37) presented 30 patients who have had a transabdominal laparoscopic nephropexy since 1992; 17/30 have been followed for greater than five years and all are asymptomatic. In 10 completely evaluated patients, 8 have no nephroptosis but 2 (20%) have greater than 5 cm displacement. Their technique is decidedly different than the Washington University series. They describe fixation using a polypropylene mesh shaped like an ellipse to cover the sagittal aspect of the kidney during active cephalad displacement. Fascial staples are used to fix the mesh to the abdominal wall from the upper pole to the lower. The average operating time was 154 minutes (range 90–300 minutes) (37). A final series comes from Lubeck, reporting transperitoneal laparoscopic nephropexy in 22 women and 1 man. A round-bodied double-stranded No. 2 nonabsorbable polyester suture was passed via the abdominal wall and used to fixate the upper pole to the psoas or quadratus lumborum with a single simple stitch. A second suture is made to fix the convexity of the kidney laterally. They compared this procedure to 12 open nephropexies performed at their hospital showing previously.

FIGURE 3 ■ Laparoscopic type II pyelocaliceal diverticulum.


The mean operative time was 61 minutes (40–85) laparoscopic versus 49 minutes (28–70) for open nephropexy. Narcotic use, complications, hospital stay, and mean days to return to work all favored the laparoscopic approach. All patient in this series had correction of the nephroptosis by intravenous pyelogram at six weeks. There appears no definite method that reliably fixes the kidneys from these series, but the historical literature is replete with methods of renal fixation, well over 170 operative techniques. Szekely recently reported in a letter to the editor of the "Journal of Urology" that the same thing could be accomplished by placing a circle (U) nephrostomy tube for two weeks (38).

Ureteral Reconstruction

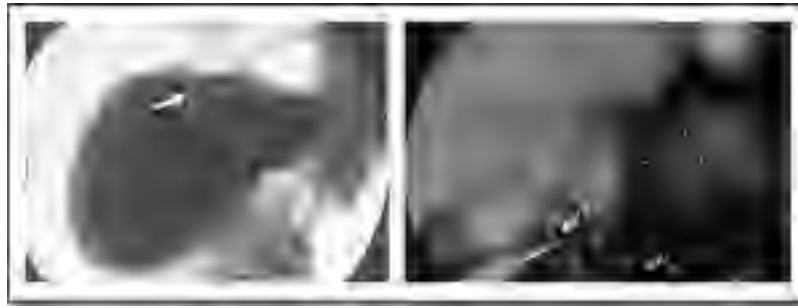
The ureter has been opened, repaired, or reconstructed predominately utilizing sutured techniques (39). Nezhat probably was the first to report a clinical application of intracorporeal-sutured reconstruction of a ureter obstructed by endometriosis. Excision of the involved segment and ureteroureterostomy was performed over 7 French catheter with four interrupted 4-0 absorbable sutures. A CO_2 laser was utilized for the bloodless dissection prior to reconstruction with an estimated surgical time of 117 minutes (40). Wichham explored and performed a laparoscopic ureterolithotomy without repair of the ureter in 1978 (41). Closure of the ureteral wall following ureterolithotomy was described utilizing a running 4-0 absorbable sutures® anchored on each end with absorbable clips (42). The procedure lasted approximately 180 minutes. We have recently resected a stenotic segment of ureter with an eroded proximal calculus and performed a Heinike-Mikulitz type of ureteroureterostomy with interrupted 4-0 chromic gut sutures intracorporeally tied over a stent (Fig. 4). A case of a right circumcaval ureter requiring transposition has also been reported (43). Retrograde dissection of the right ureter from the iliac vessels identified the post caval segment. Next, the middle third of the ureter was dissected until it passed behind the cava to the renal hilum. The renal pelvis was identified and dissected to the area of obstruction, divided, the distal ureter was spatulated and anastomosed with five 4-0 polyglactin interrupted sutures over a wire guide. This procedure was accomplished in 560 minutes and stented following the repair. Others have repeated the procedure of ureteral repair for retrocaval ureter, most now support a complete intracorporeal sutured repair (44). The laparoscopic approach and treatment of benign retroperitoneal fibrosis has been described (45). After mobilizing the ureter in a 15-year-old female, the ureter was secured within the abdomen with a biting clip applier. The correction of vesicoureteral reflux using laparoscopic biting clips to reapproximate the muscularis over the distal ureter and create a nonrefluxing tunnel has been described in the porcine model (46). There are now several series in which retroperitoneal fibrosis has

FIGURE 4 ■ Laparoscopic ureteral exploration for an eroded proximal left ureteral calculus. Use of an arthroscopic hooked-blade knife is shown (*above left*), and stone extraction (*above right*). Sutured reconstruction over a stent with interrupted 4-0 chromic intracorporeal stitches is shown below.

been explored, biopsied and peritonealization of the ureter has been accomplished. In fact, Puppo et al. have even reported upon the classic method of bilateral ureterolysis because of the risk of bilateral involvement (47). Finally, the ureter has been taken apart and reconstructed laparoscopically with intracorporeal suturing techniques for severe endometriosis in nine patients. Long-term follow-up for these laparoscopic ureter-oureterostomies is available between two months and seven years. Only one patient developed a mild ureteric stricture that required balloon dilation (48).

Bladder Reconstruction

Most laparoscopic bladder reconstructions to date have been performed with linear cutting staplers. A growing number of sutured reconstructions include diverticulectomy, closure of traumatic cystorrhaphies, ureteroneocystostomy, ureterocystoplasty, augmentation cystoplasty, seromyotomy (autoaugmentation), and partial cystectomy (49). The bladder neck has been suspended and bladder neck slings have been placed with the aid of laparoscopic sutures. Das reported resecting a large bladder diverticulum and suturing the ostium with 3-0 polyglycolic acid in a continuous, double-layered fashion (50). Intracorporeal knotting was utilized and the procedure took 288 minutes. Most bladder diverticuli are posterior and tend to be eccentrically located at or near a ureteral orifice. We have used simultaneous flexible cystoscopy and ureteral illumination to aid in the dissection and sutured reconstruction (Fig. 5) (51). Laparoscopic sutured cystorrhaphy following an iatrogenic intraperitoneal bladder laceration has been reported (52). A 75-year-old male with a large intraperitoneal bladder perforation required laparoscopic two-layered running suture repair. Using 3-0 polyglycolic acid suture (first layer mucosa and muscularis and second muscularis and parietal peritoneum) all knots were tied intracorporeally. The entire procedure of laparoscopic cystorrhaphy lasted 27 minutes. Two cases of vesicoureteroplasty have been reported (53). A two-year-old boy and a five-year-old girl with grades III and IV vesicoureteral reflux underwent laparoscopic mobilization of the distal ureter for 3 to 4 cm. A 3 cm straight horizontal myotomy was then created as a tunnel with the ureter sutured in situ by four 3-0 polyglactin, interrupted sutures. Extracorporeal knotting was used in the first case and intracorporeal knotting in the later. The mean time for vesicoureteroplasty was 182.5 minutes (range 170–195 minutes). Seromyotomy or bladder autoaugmentation has been performed laparoscopically at several centers (54,55). Very little reconstruction is necessary following excising a portion of the detrusor muscle. Detrusor flaps were sutured to the pelvic sidewall at Cooper's ligament utilizing 1-0 polyglactin secured intracorporeally with clips. The time of surgery ranged from 70 to 330 minutes. Augmentation cystoplasty utilizing xenograft human lyophilized dura mater and collagen-impregnated polyglactin mesh were accomplished laparoscopically in beagles (56). The bladders of four animals were opened after the fashion of Blaivas and bilateral vesicopsoas hitches were performed utilizing 3-0 polyglactin sutures with intracorporeal knotting. This type of bladder

FIGURE 5 ■ Laparoscopic bladder reconstruction of the large bladder diverticulum containing a stone. In the cystogram on the left, the bladder is the smaller contrast-filled cavity and the stone is filling defect within the diverticulum. Endoluminal assistance was provided by the use of a intravesical flexible cystoscope and a ureteral illuminator. *Source*: Cook Urologic, Spencer, IN.


opening allowed onlay of the xenograft such that two simple suture lines could accomplish the cystoplasty (Fig. 6). Running 4-0 polyglactin sutures synched with intracorporeal knots allowed the cystoplasties to be water tight with an average time of surgery of 134 minutes. One case of laparoscopically assisted continent catheterizable cutaneous appendicovesicostomy has been accomplished (57). A 15-year-old female with an obliterated bladder neck from multiple previous surgeries underwent mobilization of her appendix laparoscopically utilizing a 12 mm linear cutting stapler. The cecum was reattached to the side wall with absorbable sutures tied intracorporeally. The appendix was anastomosed isoperistaltically to the bladder via a trocar passed transvesically. The base of the appendix was delivered through a predetermined stoma site via a 10 to 11 mm trocar and the appendicovesicostomy was finished using the Mitrofannoff principle with a 4 cm subepithelial tunnel through a small open cystotomy. The total operating time was 360 minutes. Finally, Anderson et al. described an animal model for laparoscopic continent urinary diversion in swine (58). In nine male swines, in situ ureterosigmoidostomy in a 5 to 6 cm detubularized rectosigmoid pouch was performed. A Boari flap for reconstruction of the distal ureter has been described by several investigators. The first case was done because of distal ureteral involvement by endometriosis (59). A series has been presented by the Johns Hopkins group. There were two left and one right sided distal ureteral obstructions with 6 to 8 cm of distal ureteral involvement. An anterior bladder flap was harvested from the bladder after dividing the superior and middle vesical arteries with the Endo-GIA. The ureter was anastomosed to the flap using interrupted 4-0 polyglactin suture (60).

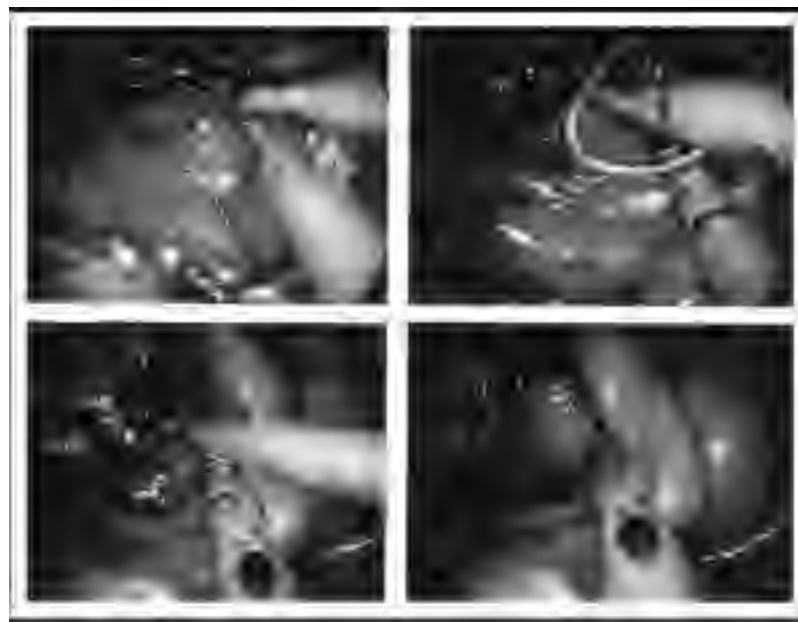
Visually guided transvaginal techniques have been employed in seven women with types I and II genuine stress urinary incontinence (61). A formal intracorporeal Burch and Marshall–Marchetti–Krantz suspension has been performed in over 92 incontinent patients with a mean operative time of 65 minutes. One to two 2-0 nylon sutures are placed on either side of the bladder neck and then into Cooper's ligament or the pubic periosteum (Fig. 7) (62,63). Bladder neck suspensions for genuine stress urinary

FIGURE 6 ■ Laparoscopic augmentation cystoplasty in a canine model.

incontinence were being widely performed, but long-term follow-up investigations have failed to adequately deomonstrate that laparoscopic colposuspension maintains continence (64,65). Some centers continue to persist in evaluating the potential for laparoscopy to treat stress urinary incontinence (66). Laparoscopic mesh fixations have been performed for severe pelvic prolapse syndromes in women. The "gold standard" sacrocolpopexy has now been performed laparoscopically. Of the vaginal restorative procedures, uteroscacral ligament vault suspension, iliococcygeous and sacrospinous fixation each have their proponents. There is marked utilization of mesh materials to reconstruct these prolapse syndromes requiring suturing to these anatomic structures. All types of prosthetic mesh materials are being investigated and utilized (67).

The urachus is an unusual site for urologic disease, but it too has been successfully approached by laparoscopic maneuvers. Most commonly, urachal sinuses and cysts have been laparoscopically resected and ligated. More common in children, these occasionally present in adulthood. A case of a 34-year-old male underwent a laparoscopic resection of a 4 cm cyst from the urachus using a voice-controlled laparoscope (68). One series of pediatric management of urachal anomalies has been published. Four children ranging in age from 4 to 10 underwent laparoscopic radical excision of the urachus (69). Four adults have also been managed laparoscopically in a report by Cadeddu et al. In these cases the urachus, and medial umbilical ligaments were detached just caudal to the umbilicus and dissected caudad to the bladder dome. In three-fourth cases, a bladder cuff was taken with the specimen because of fibrotic attachments. The bladder defect in these cases was sewn in two layers with 2-0 polysorbate loaded on an EndoStitch® device (70).

Laparoscopic cystectomy represents the ultimate surgical site for laparoscopic urologic reconstruction. For purposes here, the radical prostatectomy portion that requires reanastomosis to the urethra will be considered separately and discussed later. Now, attention will focus upon methods of laparoscopic cystectomy and urinary diversion. Brief mention will also be placed upon laparoscopic efforts at urinary undiversion. Initially however, the first attempts at laparoscopic bladder reconstructive surgery focused upon bladder diverticula resection and repair. Automated staplers have a wide application for laparoscopic procedures involving the bladder. The multifire linear cutting stapler has been used to divide the vascular pedicles and urethra during a laparoscopic cystectomy in 27-year-old female with recurrent pyocystis and previous urinary diversion (50). The endostapler has also been used to close bladder defects following diverticulectomy and distal ureterectomy for upper tract transitional cell carcinomas (71,72). Parra et al. reported the first laparoscopic bladder diverticulectomy in an 87-year-old man with a superiorly positioned, narrow-necked diverticulum and chronic urinary tract infections. Adequate healing without urinary extravasation was documented by cystography, eight days after surgery (73). In addition to expediting surgery, automated staplers may have an added benefit during excision of bladder diverticula containing urothelial malignancies by preventing potential spillage of tumor cells into the peri-

FIGURE 7 ■ Laparoscopic Burch colposuspension with 2-0 nylon sutures placed and tied intracorporeally.


toneum. Neoplastic changes in the lining of diverticula occur in approximately 0% to 13.5% of cases (74-77). Laparoscopic division of a bladder cuff during nephroureterectomy and ureterectomy in porcine experiments and humans has been described by Kerbl et al. (78). After cystoscopically incising the ureteral orifice and submucosal tunnel, a 2 cm juxtaureteral bladder cuff is dissected laparoscopically. A linear cutting, multifire stapler is then utilized to close and excise the cuff of bladder (79).

Parra was the first to perform a laparoscopic cystectomy in a patient with pyocystis. Porcine animal studies have been performed to evaluate methods of cystectomy and urinary diversion. Anderson and Clayman described a method of ureterosigmoidostomy (79). Kaouk et al. presented an animal model of orthotopic ileal neobladder (80). Baldwin described an attempt to simplify the laparoscopic reconstructive effort by using the "dunk" technique for ureteroileal anastomoses. In addition, they used Lapra-Ty suture clips[a] to facilitate intracorporeal knotting. Two-thirds of the "dunked" ureters were partially or completely strictured. In addition, the short cut method of knot substitution resulted in Lapra-Ty migration and subsequent urinary obstruction by the foreign body in two animals (81). Now, laparoscopic radical cystoprostatectomy is becoming increasingly performed. Large series are beginning to accrue patients into the laparoscopic group. Simonato recently reported their technique in 10 patients using a five-port technique. The urinary reconstructive aspects included the orthotopic ileal neobladder in six, sigmoid ureterostomies in two, and cutaneous ureterostomy in two. The mean operating room time was 166 minutes (range, 150–180). Two patients have diffuse metastatic disease with eight are free of disease at a mean 12.3 months (range 5–18) (82). Another method has been utilized by Abdel-Hakim et al. Laparoscopic radical cystoprostatectomy was performed in nine patients. Here the authors removed the laparoscopic specimen through a 3 to 5 cm right iliac fossa incision through which a detubularized modified Camey II orthotopic neobladder was performed (83). Matin and Gill from Cleveland have detailed their method of completely intracorporeal urinary diversion following laparoscopic radical cystectomy. Here the authors performed a completely hand-sewn anastomosis of the orthotopic neobladder and the ureteroileal anastomoses (84). They have summarized the application of this technique in two patients using six ports with an average time of 9.5 hours (85). This same group previously published a series of five patients who had undergone a laparoscopic radical cystectomy with ileal conduit urinary diversion using a six-port technique (86). Another group has performed 11 laparoscopic radical cystectomies with intracorporeal construction of a continent urinary diversion (Mainz pouch II). Their average operating time was 6.7 hours (87).

Segmental bowel excision and reconstruction using automated staplers has been practiced during open surgery for many years. Bohm et al. described the technique of laparoscopic intestinal resection and intraperitoneal reanastomosis (88). After mobilization of the selected intestinal segment and isolation of the vascular pedicle, the linear cutting stapler is inserted into enterotomies on the antimesenteric border of afferent and efferent limbs of the future anastomosis. Two consecutive firings of the 3 or 6 cm stapler creates a 5 to 11 cm anastomosis. A cotton umbilical tape encircling the bowel close to the anastomosis provides countertraction and prevents spillage of intestinal contents into the peritoneum. Firing the linear stapler across both loops of bowel near the corner of the anastomosis transects the specimen and completes the anastomosis. Kozminski reported the first urologic application of automated stapling for laparoscopic bowel resection and intracorporeal ileal conduit formation (89). His initial clinical case involved performing the palliative supravesical diversion in an 83-year-old male for unresectable fibrosarcoma of the prostate. Intracorporeal ureteral and bowel mobilization was accomplished through six 10 to 12 mm trocars. Bowel resection and reanastomosis were performed extracorporeally with linear stapling devices after evacuating the pneumoperitoneum and pulling the bowel through the 12 mm port site. Once the resected bowel segment was mobilized the mesentery is closed intracorporeally with biting clips and the ureteral anastomoses were accomplished extracorporeally by suturing techniques after mobilizing the ureters. Securing the conduit to the retroperitoneum was again accomplished by biting clips applied intracorporeally. Two subsequent patients have had ileal loop diversion with entirely intracorporeal bowel resections and reanastomosis using these staplers (89). In all three patients, the ureteroileal anastomoses were sutured extracorporeally. This same technique has been repeated by others (90). Other applications for these techniques would be urologic reconstructions utilizing other gastrointestinal segments. Augmentation cystoplasty can be performed with harvested gastric, small bowel, or large

---

[a]Ethicon Cincinnati, OH.

bowel segments. Ureteral interposition or replacement could theoretically be performed. Finally, supravesical diversions with ileal conduits represent only one of many methods of noncontinent and continent heterotopic or orthotopic bladder replacement techniques. Automatic, linear cutting staplers have the potential to make such urologic reconstructions possible. The lithogenic properties of metallic staples used for urinary tract reconstruction are well known. Stone formation attributed to exposed steel staples occurs in 3.2% to 4.2% of patients with ileal conduits and 4.9% to 10% of patients with Kock pouches (91–94). The lithogenic potential of titanium staples exposed to human urine is not known. Kerbl et al. have used a linear titanium stapling device to excise a bladder cuff during nephroureterectomy in six adult humans (78). Three patients have been followed more than a year without complication and/or endoscopic evidence of staple exposure. Endoscopic verification of the lack of exposed staples and over sewing the staple line are recommended by some authors. Prototypic automated staplers using dissolvable staples are currently under study. Julian and Ravitch compared stone formation on exposed stainless steel and Polysorb™ b absorbable staples used to close the bladder in dogs. Although staple exposure was much higher in bladders closed with absorbable staples (56% vs. 2%), crystal formation more commonly occurred on exposed stainless steel staples (25% vs. 7%) (95).

Laparoscopic augmentation cystoplasty has also been investigated. Early efforts attempted to use novel biomaterials such as intestinal submucosa (96). Others have utilized tissue expansion techniques to expand the native ureter and augment the bladder with this laparoscopically (97). The small bowel has been utilized during a transverse hemicystectomy with ileocystoplasty in the porcine model (98). Finally, Siqueria et al. described the synchronous correction of small bladder capacity by laparoscopically augmenting the bladder with ileum, but also performing a continent ileovesicostomy in the porcine model (99). The next step of course was clinical application. The first reported case of laparoscopic ileocystoplasty was Sanchez de Badajoz's case report of a patient with urinary tuberculosis. An isolated segment of ileum was taken using Endo-GIA staplers. The enterocystoplasty was performed with two firing of the Endo-GIA stapler plus the addition of holding sutures (100). Three patients were described by Gill et al. using different bowel segments in each of these cases. The functionally reduced bladder capacities were augmented using the ileum, the sigmoid, and the cecum and proximal ascending colon in these patients (101). In reporting the application of laparoscopic ileal cystoplasty, Elltiott et al. noted some important technical considerations. Important to this operation included (i) preoperative evaluation of compliance and videourodynamics; (ii) cystoscopic placement of externalized ureteral catheters; (iii) transperitoneal placement of trocars; (iv) identification of the cecum; (v) proximal mobilization of the ileum sufficient for pelvic placement; (vi) measurement of ileal length with segment of precut vessel loop; (vii) vertical cystostomy after incision of the peritoneum and entering the space of Retzius; (viii) ileal division and side-to-side anastomosis using Endo-GIA stapler; (ix) detubularization and freehand intracorporeal suturing into a U-shaped configuration; (x) fixing ileal patch at the 6 and 11 o'clock positions; (xi) completion of ileal-bladder anastomosis in quadrants with running sutures; (xii) irrigation of bladder and placement of a closed suction drain into the pelvis; and (xiii) cystogram at four weeks postoperatively (102). Because of the hazards associated with enterocystoplasty, the search for an ideal substitute continues even in the minimally invasive era. One recent investigation used a variety of different biodegradable grafts in an animal model. Thirty-one minipigs underwent transperitoneal laparoscopic partial cystectomy and augmentation cystoplasty using nothing (six controls), porcine bowel acellular tissue matrix (6), bovine pericardium (6), human placental membranes (6) or porcine small intestinal submucosa (6). All three grafts had only mucosal regeneration at 12 weeks postoperatively and all had contracted to between 60% and 75% of their original sizes (103).

The bladder has not only been the target of intense endourologic research interest, but it has finally been reconstructed in a variety of methods. This brings the discussion full circle, as is fitting. Wolf and Taheri have recently reported a laparoscopic undiversion. This was in a 25-year-old man who had undergone an open ileal conduit diversion and colostomy with mucous fistula for a gunshot wound 11 months prior to presentation. The colostomy and mucous fistula were taken down first and an extracorporeal bowel anastomosis was performed. Next laparoscopic trocars were positioned and the bladder dome and abdominal portion of the ileal conduit were mobilized. A single layered ileovesical anastomosis was performed using a 4-0 absorbable suture (104).

Vesicourethral Anastomosis

Laparoscopic reconstructive surgery has been applied to one of the most difficult repairs urologists perform, vesicourethral reanastomosis following radical prostatectomy. First attempted clinically in 1992, research work in animal models continues (105). In combined canine series of 20 animals, the radical retropubic prostatectomy and reconstruction was accomplished with a mean operative time of 294.5 minutes (106,107). In the study by Moran et al. the laparoscopic reconstruction was performed with the laparoscope closely approximated to the tissues for a microscopic repair. Six to eight fluorescently colored polyglactin intracorporeal sutures were placed utilizing microsurgical suspension techniques to convert square knots to slip configurations and back (Fig. 8) (106). No Foley catheters were positioned so as to evaluate the completeness of the microlaparoscopic repair (Fig. 9). One anastomotic leak occurred in six animals available for long-term follow-up. Minimal scarification was noted grossly or on trichrome stained sections in animals at necropsy (Fig. 10) (106).

Clinical application of laparoscopic repair of the vesicourethral anastomosis has been widely performed. There appears to be two basic approaches by review of the literature. There are those who favor an interrupted anastomosis and those who prefer a running anastomosis. There is no prospective randomized data to support either philosophy at present. Claims for almost any belief suggesting an advantage or disadvantage for each technique can be found. For instance, there are those who suggest that the running anastomosis simplifies and facilitates the repair. But there is a large series that argues the opposite (108). There are investigators that believe that the anastomosis capable laparoscopically is potentially better than its open counterpart. Large series are just beginning to be able to investigate this possibility. The complications from the vesicourethral anastomosis should be less. Urinary extravasation should be minimal. In one current series, Menon's group has now begun to leave no postoperative drains when they use a running anastomosis (109). Bladder neck contracture should likewise be lowered, but the exact incidence even in open series is not known (110). One such investigation noted contracture in 11% of radical prostatectomy patients (111). The data are not yet fully available, but there are groups suggesting that symptomatic bladder neck contractures are less following the laparoscopic repair. Is this due to the anastomotic technique or rather secondary to the method of prostatobladder neck division or to the method of mobilization of the bladder for performing a laparoscopic radical prostatectomy? Innovative investigations that might answer this question are beginning to emerge but follow-up remains short (112). A new semiautomatic suturing device has recently been reported from Yamada et al., called Maniceps. Using this device in 15 patients, the urethrovesical anastomosis was completed in 8.1 minutes (range 5–12). They report one bladder neck contracture at short followup (113). Another recent investigational method used 2-octyl cyanoacrylate adhesive for an in vivo canine study to glue the anastomosis in 12 dogs. Four anastomoses were performed with eight interrupted

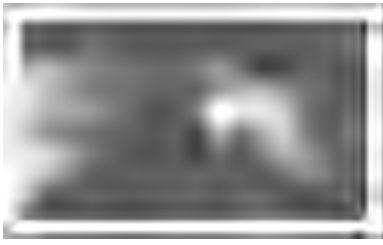
FIGURE 8 ■ Suspension stitch technique for converting square knots to slipknots.


FIGURE 9 ■ Voiding cystogram following laparoscopic radical prostatectomy and microsurgical vesicourethroplasty in a canine model.
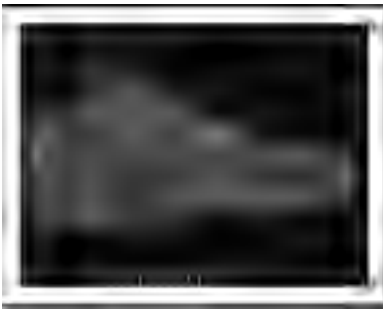

FIGURE 10 ■ Gross pathology of laparoscopic intracorporeal reconstruction eight weeks following radical prostatectomy.

sutures compared to eight using the adhesive. Only one of the adhesive animals anastomoses had leak pressures 70 mmHg or greater whereas all four control suture animals achieved this expected outcome (114). Laser welding has also been attempted in the canine model to facilitate this anastomosis. This was an open radical prostatectomy model, but four animals had a conventional eight interrupted suture technique while the experimental group had four support sutures followed by a diode laser welded anastomosis using a chromophore doped albumin solder. They noted superphysiologic leak pressures in all of these animals with no other differences in healing (115).

ROBOTIC RECONSTRUCTION

Introduction

The next generation of surgical robotics required the downsizing of mechanized instruments to reproduce the complex ability of the surgeon's arms and hands (116). Next, the surgical tools themselves needed to be added or subtracted from the devices so that surgical multitasking was possible. To control and coordinate the functions of the robot requires a computer. The computer is responsible for interpreting the surgeon's actions and transforming them into the movements of the robotic arms and hands. This requires incredible fidelity and incorporates a wide range of motion. The computer is translating the surgeon's movements into precise codes to smoothly and rapidly manipulate the robot (Fig. 11). Here the robot is in direct contact with the patient and the surgeon is removed to the controlling station. As with the laparoscopic surgery removing the surgeon from actually seeing the surgical field, the robotic hands are removing the laparoscopic instruments from actually touching and performing the surgery. The actual robotic tools, or end-effectors are located at the distal end of long instruments which are inserted into the patient through laparoscopic trocars. The movement of the instruments is controlled manually at the work station. To allow the end effector to be maximally effective at least six degrees of freedom are necessary.

A great deal of research effort has been applied to solve the problem of the actual surgical interface (117–119). That is what type of device is best for the surgeon to manipulate that will provide the computer with the information necessary to perform the surgery. Possibilities include scissor-like hand pieces that provide the computer with the data necessary to manipulate the end effector. Glove-like input devices have been proposed and view-directed controls utilizing the endoscopic image itself to be the frame of reference are being investigated. Some input devices are position controlled and others are direction controlled. In the former, the movement of the end-effector is coupled to the movement of the input device by the surgeon. A continuous movement of the input device is needed to achieve continuous movement of the end-effector. In the direction-controlled interface, the input device controls the velocity of the end-effector. Therefore, no continuous movement is necessary to achieve continuous movement of the end-effector. One study evaluating various input devices included a spacemouse, free-flying joystick, immersion probe, and head-tracking systems. Wapler suggested that for guiding the endoscope a head-tracking system would allow a more intuitive method of control (120). For manipulating the end-effector, the following requirement should be met: the manipulator must be compact enough to allow at least three systems to work independently without danger of collision, the patient should be manually accessible at all times, the insertion point must be kept invariant when moving the end-effector, allowance must be made for patient movements, all endoscopes and instruments must be manually controllable in case of manipulator failure, and the movement of the end-effector must not be self-locking. In addition, there are three options for supporting such a robotic system in the operating room, these include namely, a stand-alone system, a ceiling-mounted system, or a system that attaches to the operating room table. Both the stand-alone and ceiling mounted systems would require more room and have special precautions to ensure that no relative movement occur between the operating room table and the manipulator's base. At the beginning of surgery, the abdomen is prepped and draped in the same fashion for laparoscopic surgery. When the trocars have been positioned, the manipulators are attached to the operating room table. Each manipulator is manually brought into position such that the invariant point is exactly at the trocar. When all of the manipulators are in place, the actual surgical procedure is begun. Currently the surgeon has only visual feedback from the video-monitor. There are ongoing efforts to include force-feedback (i.e., haptic input) into the robotic manipulators so the surgeon can perceive subtle nuances of the laparoscopic environment (121).

FIGURE 11 ■ The *da Vinci*® Robotic Surgical Assist System.

There are two currently available laparoscopic robotic units in use, the Zeus® system and the *da Vinci*®ᶜ system, however others are in the works. The Zeus system has recently been acquired by Intuitive Surgical and the systems may possibly merge, but the *daVinci* system was approved in July, 2000 in the United States. The Zeus™ Robotic Surgical System has an ergonomic workstation with rather conventional appearing handles. The surgeon's movements are scalable to the surgeon's specifications. A ratio of 5:1 means that for every inch the surgeon moves the handles on the console, the robotic surgical instruments would move one-fifth of an inch. Tremors can be filtered out as well. The Zeus computer translates the surgeon's movements to the end effectors placed via trocars inside of the patient. The instruments themselves act similarly to conventional laparoscopic devices except that the surgeon does not actually touch them. The monitor on the Zeus system is a standard video image, the surgeon does have the option of wearing specialized binoculars to view the image in three-dimensional (3-D). The *da Vinci* company has the capability to add three-dimensional imaging full time without the need for the special glasses, but current research has not demonstrated a significant advantage for these image systems. The other robotic system is *da Vinci*. This robotic surgical system has an articulated wrist that allows six degrees of freedom during the performance of laparoscopic surgery (Fig. 11). This wrist addition allows for the two additional degrees of freedom and there is some basic evidence that that additional motion translates into more adaptive ability by skilled and nonskilled surgeons. The downside to the daVinci instrument tips would be that they are more complex, necessitating the 8 mm trocar portals. The *da Vinci* surgeon console

ᶜIntuitive, Sunnyvale, CA.

does not approximate anything like standard laparoscopic instruments. The surgeon's hands, wrists, and fingers manipulate a patented articulated Endowrist™. This type of system is necessary to take advantage of the laparoscopic instruments' dexterity. The other major difference of the two surgical robotic systems lies in the *da Vinci*™ ergonomic viewing console (Fig. 11). The surgeon sits at the console which is designed to support the surgeon's head while viewing the three dimensional image and has a separate adjustable surface on which the surgeon can rest his/her arms. The vision system is fully three-dimensional and integrated in the performance of the two robotic arms. The *da Vinci* system is a stand-alone device that moves in toward and over the patient whereas the Zeus system is component and attaches to the sides of the operating room table as does the separate and independent AESOP™ arm. In both robotic systems, the fidelity of movement is superb and the time delay from surgeon's movement to the robotic instrument movement is imperceptible. The cost of each system is above US$900,000 currently (121).

General Application

Numerous cardiothoracic, general surgical, gynecologic and urologic procedures have been attempted either in animate laboratories or clinically (Fig. 11) (122–133). Most of these studies have been case reports with series only available for evaluation of outcomes in cardiac surgery. A case report of computer-assisted robotic Heller myotomy in a 76-year-old female with progressive dysphagia was performed in Columbus, Ohio (123). The *da Vinci* system was utilized using four operative cannulas (5 mm liver retractor, two 10 mm working ports in the patient's midline and left midclavicular line, and one 5 mm port in the left anterior axillary line). An assistant surgeon stayed at the patient's bedside and controlled retraction and changed instruments on the robotic arm. The total operative time was 160 minutes and she was discharged the following day. Another case report again utilized the *da Vinci* system to perform a Nissen fundoplication on a 56-year-old female with longstanding gastroesophageal reflux (124). This was performed using five trocar ports; 12 mm supraumbilical 30° camera (used a robotic camera system), 10 mm right anterior axillary port for liver retraction (used a mobile table-mounted mechanical self-retaining device), and two 10 trocars for the right and left hands of the *da Vinci* robot. The patient's position was in low lithotomy position with the table in steep reverse Trendelenburg setting. The surgeon was approximately 10 ft away from the patient and the assistant was stationed between the patient's legs. The assistant performed the instrument changes and utilized a harmonic scalpel. There was no operative time listed but the patient was discharged from the hospital within 24 hours. The largest general surgical series has recently been reported from the group in Strasbourg, France on laparoscopic robotic cholecystectomy (125). These authors reported the laparoscopic, robotic cholecystectomy in 25 patients (16 women and 9 men) with a median age of 59 (range 28–81). They used the Zeus surgical robotic system with four laparoscopic trocar sites (one 10 mm umbilical camera port and three 5 mm ports for retraction and robotic surgery). The Zeus instruments were 3 mm in diameter and the surgeon was remote (4 m) from the patient and AESOP was used to voice control the camera. The assistant stayed at the operating room table to aid in retraction, clip application, and exchanging instruments. Completely robotic cholecystectomy was accomplished in 24/25 patients and one patient was completed with standard laparoscopic methods. The median time for the dissection was 25 minutes (range, 14–109 minutes). The median time to setup and take down the robotic system was 18 minutes (range, 13–27 minutes). An engineer was present in 22 of the cases making three minor technical adjustments (two nonfunctional graspers and one malfunctioning robotic arm sensor). Laparoscopic splenectomy, an extirpative surgical procedure has recently been accomplished with the *da Vinci* robot (126). A 69-year-old female was seen with idiopathic thrombocytopenia purpura. The patient was placed in steep reverse Trendelenburg position after placing one 11 mm camera port, two 8 mm robotic arm ports, and one 11 mm assistant port. The surgeon was 10 feet from the operating room table and used a hook dissector and Cadiere grasping forceps. Short gastric vessels were taken via the 10 mm trocar with an ultrasonic dissector. The spleen was 1000 g and was extracted via morcellation from the 10 mm site after entrapment. The procedure time was 65 minutes, operating room time was 90 minutes, and actual splenic dissection time was 31 minutes. Robotic setup and draping took just nine minutes. One final surgical case has also been reported, robotic pancreatic surgery (127). A 46-year-old female presented with a symptomatic 2.5 cm complex solid/cystic mass at the tail of her pancreas. The robotic surgery was performed in the modified lithotomy position using four laparoscopic ports. The total operating room time 275 minutes with the actual surgery

time of 185 minutes. The pathology was a benign neuroendocrine tumor and the patient left the hospital on postoperative day 2. Robotic bowel and vascular surgery is being investigated (128).

Gynecologic surgeons have also performed robotically assisted laparoscopic hysterectomies, adnexal surgeries, microsurgical tubal and uterine horn anastomosis. This gynecologic work has been performed at the Cleveland Clinic utilizing Zeus and AESOP in a series of porcine experiments (129–131). Both uterine and adnexal surgeries have been described including microscopic reanastomosis of the fallopian tubes (132). At the University of Texas Medical Branch in Galveston, 11 patients were enrolled into a laparoscopic, computer-enhanced robotic hysterectomy trial (133). Six patients had carcinoa in situ or well differentiated endometrial carcinoma, four had medically nonresponsive postmenopausal bleeding and one had unstaged ovarian cancer. The mean age was 55 (range, 27–77). Four trocars were utilized and operative times were 4/5 to 10 hours. Blood loss averaged 300 cc (range, 50–1500 cc). Hospital stay was two days (range, 1–3 days). There was one open conversion, the fifth patient in this series.

Just to push the envelope a little further, robotic surgery is beginning to be applied to pediatric surgery as well. Recent reports of robotic Nissan fundoplications have been published (134). Eleven children with a mean age of 12 (range, 7–16 years) presented with gastroesophageal reflux. The mean operating time for the robotic fundoplication was 136 minutes (range, 105–180 minutes). Four ports were utilized including a 12 mm optical trocar, two 8 mm robotic trocars, and a 5 mm assistant port. There have been two children who have had robotic cholecystectomies with an average time of 137 minutes. Finally, one child has had a robotic bilateral salpingo-oophorectomy for gonadoblastoma taking 95 minutes.

Urologic Applications

Urologic applications have also begun (135–146). In work by Kavoussi's group at Johns Hopkins University, AESOP has been utilized for telementoring and teleproctoring advanced laparoscopic procedures (135). In 1998, Bowersox and Cornum first used a robotic surgical telemanipulator to perform an open urological surgery in swine (136). Sung et al. in 1999 performed robotic-assisted laparoscopic pyeloplasties in a porcine model utilizing the Zeus system (138). Guillonneau's group in Paris began a program in utilizing the Zeus system in the animate laboratory and started to accrue patients into clinical applications performing laparoscopic pelvic lymphadenectomies in 20 consecutive patients with stage T3MO disease (139). They noted no need for open conversions and the average operative time was 2.1 hours, one full hour longer than their usual laparoscopic times. They noted that the time for robotic setup was 30 minutes. Abbou et al. from Creteil, France have also been exploring urologic applications (140). They recently reported the use of the *da Vinci* robotic system to perform a laparoscopic radical prostatectomy in a 63-year-old man with Gleason's sum score of six prostatic adenocarcinoma, clinically staged T1c and a prostate specific antigen of 7 ng/mL. They utilized five trocars (one 12 mm umbilical camera port, two 8 mm trocars located at the lateral rectus sheath, and two lateral 5 mm trocars at the iliac position for the assistant). Robotic instruments used were the Cadiere and DeBakey forceps, two needle drivers, long and round tip forceps, scalpel, electrocautery, and a prototype bipolar forceps. The operating time was 420 minutes, well in excess of their standard operative times of 240 minutes. Assembly of the robot took 30 minutes and disengaging the unit took 15 minutes. The vesicourethral running 3-0 polyglactin suture anastomosis took 30 minutes. These authors mention that the three-dimensional imaging system and the full six degrees of freedom of the daVinci robotic system made in vitro training on animals streamlined to the point that they could proceed to clinical applications quickly. Drawbacks of the system were pointed out to include, lack of tactile feedback, the high cost of the robotic equipment, the cost of disposables (US$1800) for this radical prostatectomy case), and the time lost to replace the surgical instruments. Guillonneau and the Montsouris group have recently published the first case of robot-assisted laparoscopic nephrectomy (304). They utilized their Zeus™ robotic system in a 77-year-old female with a nonfunctioning, hydronephrotic right kidney secondary to a ureteropelvic junction obstruction. They performed a transabdominal nephrectomy utilizing three robotic arms (Zeus™ and AESOP™). A 10 mm trocar was placed at the right pararectal line for the camera port and AESOP™. Two 5 mm trocars in the right flank in a triangular fashion for the robotic instruments (mainly a forceps in the left and monopolar scissors in the right). A 5 mm trocar was placed at the umbilicus and a 12 mm trocar was placed in the right subcostal region for suction/irrigation, retraction, and application of clips and/or

endovascular gastrointestinal stapler. The operative time was 200 minutes, anesthesia time was 245 minutes, blood loss was less than 100 mL and the patient's postoperative course was uneventful (141).

The probable proliferation of computer-enhanced robotic surgery is beginning to materialize in urologic practice. From robotic-assisted adrenalectomies, retroperitoneal lymphadenectomies, to robotic sacrocolpoplasty; all urologic applications are beginning to be reported (142–144). As with surgical applications these are mostly anecdotal case reports. One group's pioneering efforts deserves special attention, from Creteil France. Hoznek et al. have been attempting to use the daVinci robot to perform kidney transplant surgery (145). A 26-year-old male received a cadaver donor transplant performed with a hybrid open/robotic technique. The operative time was 178 minutes with a robotic vascular anastomosis time of 57 minutes. The authors present several interesting features of eliminating the surgeon from contact with the patient including reduction in the risk of infectious transmission to the surgeons.

There are two urologic surgeries that are begging the attention of the computer-enhanced robotic application, pyeloplasty and radical prostatectomy with urethrovesical reanastomosis. Guilloneau et al. first published on robotic techniques for pyeloplasty in 2000 (146). Currently series are beginning to be reported. Gettman et al. have presented preliminary work on nine patients using the *da Vinci* robotic system to perform four Anderson–Hynes and two Fengerplasty ureteropelvic junction repairs (147). The estimated blood loss was <50 cc, the mean overall operating room time was 140 minutes, and the mean suture times were 70 minutes. There were no open conversions. They have subsequently updated their Anderson–Hynes–dismembered pyeloplasty series to nine with a mean operating room time of 138.8 minutes (range, 80–215 minutes). The mean suturing time 62.4 minutes (range, 40–115 minutes) (148). Other groups with the available technology can be expected to rapidly follow with series (149). Radical prostatectomy with urethrovesical anastomosis is the next frontier. Abbou et al. first reported a case in 2001 as noted previously (140). They have expanded their series and have been performing the entire robotic surgery extraperitoneally. This prefaces the astounding data beginning to flow from the Vattikuti Urology Institute at Henry Ford Hospital in Detroit (150–152). The number of reported robotic radical prostatectomies is over 400 cases currently with rigid follow-up strategies for solving operative problems that are constantly associated with this surgery, incontinence, and impotence (152). The remarkable aspect of this experience is that innovations are already being reported that might enhance the operative technique even more, such as the single knot, two-color running suture (153). Ahlering et al. at University of California Irvine have shown that open surgical skills might be rapidly transferred into the laparoscopic environment with the use of the *da Vinci* robot (154). They report on 12 robotic radical prostatectomies all completed successfully with no open conversions and no blood transfusions. They have been able to equate this skill transfer to approximately the equivalent of a laparoscopic surgeon performing >100 laparoscopic radical prostatectomies. The questions remaining is how good can this operation be performed, what is the learning curve, can the complications of radical prostatectomy be minimized? All of these are approaching the event horizon. Menon's group has estimated that the operative time for a robotic radical prostatectomy is below 150 minutes (155). As their series expands and follow-up times accrue, data regarding impotence, incontinence, bladder neck contractions will all be reported. Others should be able to confirm these findings rapidly and the much anticipated results of brightly illuminated, magnified controlled environment will materialize (156). No one seriously should doubt these possibilities. It has been estimated that about 700 *da Vinci* robotic-assisted prostatectomies were performed in 2003. By the end of 2004, this number is anticipated to be 7000 or a logarithmic increase in the numbers of these cases.

Remote Telerobotic Surgery

It would appear from the previous discussion that most of the framework for operating on people with minimally invasive techniques could be accomplished from remote locations. The ethical, financial, and educational potential for this type of surgery is staggering. But as complex a scenario as this sounds, much basic groundwork is already being done for both research and clinical applications. The term telemedicine has become quite fashionable secondary to the world's rapid acceptance of computerized media and internet connectivity (157–165). Recall the significance of the year 1999, when computers outsold televisions in the United States. In fact, the U.S. government has been a strong supporter of pioneering efforts in the telemedicine field with research grants. The great potential for telecommunications is being realized in digital

radiology practices where the radiologist can view and comment upon clinical radiographs of patients at the hospital from his/her home. Robotic surgery as we have just seen is a technology based upon computer integration of a transducer station and the robotic instrument is the end-effector. The ability to combine these essentially digital computerized modalities is both obvious and possible (166–168). The first problem for interfacing telecommunications and robotic surgery is linking for real-time interaction. Several methods are possible including regular telephone lines, fiber optic cables, microwave transmission, satellite linkages, and broadband communication (integrated services digital network, local area networks, and dedicated T-1 lines). Recently the surgical group at Virginia Commonwealth University used regular internet connections to interact with surgeons in Ecuador and the Dominican Republic to perform six laparoscopic cholecystectomies (168). These surgeons used 33.6 to 64 kbps lines to transmit voice and video.

Telementoring has already been performed for multiple surgeries as well as urologic laparoscopic cases. Dr. Kavoussi's group at John's Hopkins has gained significant recognition for these pioneering efforts. In their initial studies, the surgeon mentor was located in a control room >1000 ft from the operating room; 14 advanced and 9 basic laparoscopic procedures were performed (135). Telementoring was accomplished using real-time computer video images, two-way audio communication links, and a robotic arm to control the videoendoscope. Success was achieved in 22/23 cases without increased operative times or complications. They then extended their investigations and distances between the Johns Hopkins Bayview Medical Center and the Johns Hopkins Hospital (distance, 3.5 miles) for 27 more telementoring laparoscopic procedures utilizing public phone lines. Finally, they have extended their novel surgical instruction capabilities to the international arena with cases in Austria, Italy, and Thailand. Others have reported upon the technology necessary for successful telementoring. The U.S. Navy recently studied the feasibility of laparoscopic hernia repairs aboard the USS Abraham Lincoln while cruising the Pacific Ocean (164). Telementoring was possible from remote locations in Maryland and California. In a recent research investigation, Broderick et al. at the Virginia Commonwealth University reported that decreasing transmission bandwidth does not significantly affect laparoscopic image clarity or color fidelity as long as the laparoscopes are positioned or maintained at their optimal working distance (169).

It was only a matter of time before the *da Vinci* or the Zeus systems, were linked to a remote surgical effector in another place and the actual surgery was performed with the aid of an assistant. The first laparoscopic cholecystectomy done remotely was down the hall in Montreal, Canada. Kavoussi was the first to perform a surgery remotely from another hospital in the same town. Finally, a surgeon in New York City successfully removed the gallbladder of a patient in Strasbourg, France with a 155 msec time lag. The operation took one hour and 16 minutes. The robotic machines can with little doubt accomplish complex surgical interventions and function without fatigue. Because the surgeon already has given up all visual information to the technology of laparoscopic surgery, the next great step is passing the surgical dissection to the machines.

CONCLUSION

Urologic laparoscopic reconstructive surgery is rapidly expanding at numerous centers around the world. The ability to reconstruct every urologic organ by laparoscopic methods have been reported. The technology to accomplish these dextrous maneuvers is changing rapidly with logarithmic rises in the number of cases. Suturing technology and techniques are the leading methods that are fostering these reconstructions, but the skills and talents of innovators in this field cannot be denied. Mechanical-assist technologies certainly offer the capacity to potentiate or facilitate the complex laparoscopic reconstructions necessary for laparoscopic urologic surgery. In one recent report, Antiphon et al. describe the use of AESOP and another mechanical arm to perform complete solo laparoscopic radical prostatectomy (170). Robotic surgery offers the potential to rapidly integrate these skills to a much broader range of urologists, perhaps even bringing these now sophisticated techniques into the hands of all urologists. In one recent investigation on skill, performance between standard instruments and two surgical robotic systems was compared. It was noted that general task performance utilizing standard laparoscopic instruments is faster but with similar precision with either the *da Vinci* or the Zeus robots. In performing the more sophisticated reconstructive task of suturing, neither robotic system improved the efficiency (as measured by time to

complete the task) as compared to a trained laparoscopic surgeon. However, precision was improved by the addition of the robotic interface. In addition, knot tying, which involves even more intricate intracavitary manipulations noted an improvement in both efficiency and precision with only the *da Vinci* robotic system. These authors conclude that current robotic systems are not "cost" justifiable when compared to skilled, highly trained endoscopic surgeons (171). It therefore seems obvious that laparoscopic suturing skills, no matter how difficult to master, have merit. Almost everything in the operating environment at present for the urologic laparoscopist can be considered a barrier to the rapid acquisition of the skills necessary to master suturing. Yet the brightly illuminated, magnified view beckons for microsurgical reconstruction that may be better than our open counterparts can achieve without the routine use of loupes (156). Recently the group from Cleveland has used the *da Vinci* to perform a sural nerve graft during a laparoscopic radical prostatectomy with a mean operative time of 6.5 hours in three patients (172).

Unique opportunities exist for further continued improvement in reconstructive technologies. Several intriguing technologies will be reviewed for their potential application in the future. Starting with suture technology, it now appears possible that an absorbable suture can be manufactured that does not require knots at all. Medical textiles research has become increasingly aware of the limitations imposed by minimally invasive surgery. In 1967, McKenzie published a little-known technique of a multiple-barbed nylon suture to repair tendons with greater strength and less inflammatory reaction (173). Ruff from Duke University began work in 1992 of an absorbable barbed suture for cosmetic repairs (174). A barbed suture, in theory removes tension from the apposing suture line decreasing the foreign-body reaction. Further evolution of this suture is reported by Dattilo et al. with a barbed bi-directional absorbable monofilament suture (175). In this investigation, the authors used a unique suture of monofilament polydioxanone containing 78 barbs in a spiral pattern around the circumference of the suture. The bi-directional barbed nature of this suture does not require knots for adequate tissue strength (Fig. 12). The barbed configuration anchors the suture into the tissue and provides adequate apposition while the wound heals with minimal tension and pressure. Preliminary work suggests that the knotless suture material may result in less scar tissue formation.

In this era of rapid technologic advances and sophisticated computer-enhanced robotics that a simpler solution would be to develop a dextrous suturing instrument. Indeed, this has already been accomplished and such a prototype is being investigated by Olympus Medical[g] (Fig. 13). With such a mechanical instrument, the dexterity lost by the fixed borders of the abdominal wall would be bypassed. The degrees of freedom lost by simple laparoscopic instruments would be restored by a "wrist-like" action. There would be no need for million dollar computer-enhanced master/slave robotic units when a $1000 or $1500 instrument could accomplish the exact same thing. Do not think that the future of complex surgery is not in the robotic realm. Just because the elimination of the current generation master/slave, computer-enhanced robotic systems could in theory be eliminated by a simpler mechanical system does not equate with the potential for a machine to outperform a human being. Rest assured in the fervent belief that the future robotic surgical systems will eclipse anything that we have seen thus far. The one thing that you can count on when it comes to the technologies of tomorrow is that change will occur at an ever accelerating pace. Robotic systems are just approaching their long-awaited capabilities secondary to the lack of computer horsepower. This shortcoming is just about to end, as the next generations of supercomputers are about to change the world in which we practice our craft. The best selling science writer, Gleick penned recently that "the last decade of the 20th century came as a surprise" in his book *What Just Happened* (176). In later sections of this textbook, several authors will more formally discuss advances in technology. But, suturing and reconstructive technologies are linked intimately with such progress and we have spent a great deal of time on these rapid changes. It is altogether fitting and proper that we should conclude with technology for technophiles. Entrepeneur, researcher, and inventor Kurzweil has become a major vocal proponent of the radical way that computer technologies will change the world in which we live and work (177). His web page introduces those who are fascinated by technology to trends that he has sought to follow-up on Moore's Law. Here he graphically demonstrates using data readily available that, by about 2009, there will probably be a computer on this planet smarter than a human being (178). What might we accomplish with such computing power. No longer would we be expecting the robot surgeon, controlled by this intellect to respond in a master/slave fashion but complete the task of restoring normalcy of its own accord.

PRACTICAL SKILLS ACQUISITION EXERCISES

Laparoscopic intracorporeal suturing represents a difficult task in experienced hands. How then can the average urologist hope to obtain these skills and apply them whenever the situation calls for intracorporeal placement of sutures? There are two alternatives. You can either practice utilization of laparoscopic suturing skills or utilize any of the included short cuts discussed in this chapter. If your goal is to obtain skills that can be used time and time again for increasingly complex laparoscopic intracorporeal reconstructions, your time is better spent learning how to suture without opting for short cuts. This can be accomplished by spending time and money at courses or you can utilize simple equipment and practice inanimately at home, the office, or in the operating room. It sounds ridiculous to memorize the 12 steps that we presented in the previous chapter. This only represents a starting place for you to master the choreographed utilization of both of your hands. To do this you will require a camcorder and tripod. A tennis ball will serve as the targeted "organ" for reconstruction. You may utilize any suturing instruments or a disposable grasper that is available, or contact your local manufacturer's representative to borrow one. Cut sutures to a prescribed length and you can precede. Slow down first and try to get a feel for the instrument's tips motions. Once you get proficient at handling the needle make things progressively more difficult by covering your camera and tennis ball with a blanket. Finally, add a pelvic trainer (again, obtainable from a manufacturer's representative), trocars, and a plastic human pelvis (scale models are obtainable from many biological supply houses for under US$35). Your best bet is to keep both hands on either side of the camera, but as skills advance you should move to the side as is required for most animate applications. I have taken still photographs from a video recorder during just such a home-study course to demonstrate each step again. Every time you get frustrated, take a rest. Each time you start things should get easier. The hand–eye coordination to function in the videolaparoscopic environment will develop.

Katz recently described a simple method of training for performing the vesicourethral anastomosis using chicken skin. A model urethra and bladder neck are prepared by folding and tabularizing a 5 × 4 cm piece of skin over a 14 French catheter. Training again is performed in a pelvic trainer. The single knot method of van Velthouven can be easily adapted to this training technique. As described by the authors, the initial attempts require the longest times for neophytes (residents and urologists with minimal laparoscopic experience). Needle passage was easier, followed by knotting and suturing in terms of skill acquisition. They noted in 10 neophytes who followed their five-step regimen, that all were able to advance and perform complete, accurate urethrovesical anastomoses (179).

Good luck!

LAPAROSCOPIC ADRENALECTOMY: TECHNIQUE

T. R. J. Gianduzzo and C. G. Eden

Department of Urology, The North Hampshire Hospital,
Basingstoke, Hampshire, U.K.

INTRODUCTION AND BACKGROUND

Laparoscopic adrenalectomy has become the standard surgical approach for most surgically correctable benign disorders of the adrenal gland.

Laparoscopic adrenalectomy was initially performed, in 1991, for a case of adrenal hematoma (1). Gagner et al. first reported the procedure for neoplasia in October 1992 (2); however, Go et al. had begun a series of laparoscopic adrenalectomies in patients with primary aldosteronism in January 1992 (3), followed by Suzuki et al., who had also commenced a series in February the same year (4).

Laparoscopic adrenalectomy has become the standard surgical approach for most surgically correctable benign disorders of the adrenal gland.

No randomized controlled trials have been undertaken to compare laparoscopic adrenalectomy with traditional open surgery. However, on the basis of comparative studies, laparoscopic adrenalectomy has demonstrated superiority in terms of analgesic requirements, recovery, convalescence, length of stay, and cosmesis, whilst maintaining equivalent long-term operative efficacy (5–8).

Laparoscopic approaches to the adrenal gland may be performed via either transperitoneal or retroperitoneal routes and may be either unilateral or bilateral. Initially, the transperitoneal route was used, predominantly because of the familiarity of this approach with open surgery (9,10). However, following the development of retroperitoneal techniques by Gaur in 1992, lateral and posterior retroperitoneal approaches have also been adopted (11).

Further modifications have since been developed including the transthoracic approach (12), the supragastric approach for left-sided lesions (13,14), hand-assisted laparoscopic adrenalectomy (15), the use of needlescopic instruments (16,17), and, most recently, robotic laparoscopic adrenalectomy (18–20).

This chapter will describe the authors' preferred approach of transperitoneal laparoscopic adrenalectomy and also provide a review of the alternative methods that have been described.

Aldosteronomas may be considered as lesions of choice for surgeons early in the operative learning curve.

TABLE 1 ■ Indications for Laparoscopic Adrenalectomy

Functioning lesions	Aldosteronoma
	Adreno corticotrophic hormone-independent Cushing's syndrome (adenoma and hyperplasia)
	Adreno corticotrophic hormone-dependent Cushing's syndrome (pituitary adenoma refractory to treatment and nonlocalized ectopic adreno corticotrophic hormone source)
	Pheochromocytoma—benign/malignant
	Congenital adrenal hyperplasia[a]
	Cortical adenoma
Possible malignancy	Primary adrenal carcinoma[a]
	3–5 cm lesions with suspicious imaging characteristics or progressive growth on serial imaging
	>5 cm lesion
	Metastasis[b]
Benign symptomatic lesions	Cyst
	Myelolipoma[c]

[a]Role of laparoscopic adrenalectomy controversial.
[b]Remove if primary controllable or if symptomatic.
[c]Laparoscopic adrenalectomy indicated if lesions are greater than 4 cm in size or features suspicious of malignancy are present.

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

Indications

As shown in Table 1, the indications for laparoscopic adrenalectomy can be categorized as:

1. Functioning lesions,
2. Suspicious malignant lesions of small size, and
3. Nonfunctioning benign lesions that are either symptomatic or have the potential to become symptomatic.

Functioning Lesions

The resection of aldosteronomas was one of the initial indications for laparoscopic adrenalectomy. These lesions are often small and the patient's body habitus favorable; therefore, they are particularly suited to the laparoscopic approach.

Aldosteronomas may be considered as lesions of choice for surgeons early in the operative learning curve (21).

Unilateral laparoscopic adrenalectomy is the treatment of choice for patients with Cushing's syndrome due to unilateral adrenal adenomas (22).

The preponderance of periadrenal fat in Cushing's syndrome cases may make adrenalectomy initially more difficult, particularly via retroperitoneal approaches (21,23). Cushing's disease refractory to primary pituitary treatment or cases of ectopic adreno corticotrophic hormone-dependent Cushing's syndrome where the ectopic source of adreno corticotrophic hormone production cannot be localized may require bilateral adrenalectomy (24). Bilateral laparoscopic adrenalectomy has also been proposed as an alternative treatment for select cases of congenital adrenal hyperplasia (25).

Subclinical Cushing's syndrome is present in up to 20% of cortical adenomas (26). It is characterized by loss of the normal cortisol circadian rhythm and resists suppression with dexamethasone, but may have normal 24-hour urinary cortisol levels (26,27). Such lesions may progress to clinical Cushing's syndrome or present with postoperative adrenal crises from unrecognized suppression and may therefore be better removed rather than monitored (24).

After initial controversy, laparoscopic adrenalectomy for pheochromocytoma is now well accepted as a standard indication for unilateral or bilateral disease (24,28–30).

Laparoscopic adrenalectomy for pheochromocytoma produces similar or milder hemodynamic effects, less surgical trauma, and is superior in terms of convalescence when compared to open surgery (28).

The quintessential objective during laparoscopic adrenalectomy is early control of the adrenal vein, and in this regard, pheochromocytomas are best suited to the transperitoneal approach (31).

Unilateral laparoscopic adrenalectomy is the treatment of choice for patients with Cushing's syndrome due to unilateral adrenal adenomas.

After an initial controversy, laparoscopic adrenalectomy for pheochromocytoma is now well accepted as a standard indication for unilateral or bilateral disease.

The quintessential objective during laparoscopic adrenalectomy is early control of the adrenal vein, and in this regard, pheochromocytomas are best suited to the transperitoneal approach.

The posterior retroperitoneal approach has also been utilized because it also allows early access to the adrenal vein, particularly for right-sided pathology (28).

Possible Malignancy

Laparoscopic management of possible adrenal malignancy has been an area of controversy. Firstly, size criteria for the removal of nonfunctioning incidental adrenal masses continue to evolve, and secondly, debate exists as to whether it is appropriate to manage potentially malignant adrenal lesions laparoscopically.

Nonfunctioning Incidentalomas

Adrenal carcinomas are larger than 6 cm in size in 92% of cases; however, because computed tomography scanning can underestimate the true size of a lesion, a limit of 5 cm has been used empirically (32–34).

Other factors that require consideration include the patient's age and comorbidities, and the burden associated with ongoing monitoring of the lesion. Older patients are more likely to have nonfunctioning adenomas, whereas younger patients may require serial imaging for many years (24). The management of 3 to 6 cm nonfunctioning adrenal masses is controversial, but laparoscopic adrenalectomy is recommended if the lesion has suspicious features on imaging, demonstrates growth on serial imaging, or if the patient is young and fit (24).

Adrenal Malignancy

Another matter of debate is the oncological safety of laparoscopic adrenalectomy for primary adrenocortical carcinoma and metastatic disease. Opinion varies from absolute contraindication (35–37) to acceptance as a form of treatment for large, potentially malignant lesions up to 15 cm in diameter, provided that the lesion is not locally invasive (38,39). Sung and Gill recommend open adrenalectomy if the mass is larger than 10 cm in size, is locally invasive, or has tumor thrombus (6). Smaller, discrete, solitary metastases or primary carcinomas may, however, be suitable for laparoscopic resection (6). Although successful laparoscopic management of primary and metastatic adrenal masses has been reported (38–40), case reports of local recurrence following laparoscopic adrenalectomy for carcinoma have been described (41–44).

It is now generally considered reasonable to perform laparoscopic adrenalectomy for organ-confined disease if the tumor is not locally invasive and if the surgeon is experienced (5,39,40).

Masses demonstrating local organ invasion or venous tumor thrombus are not suitable for laparoscopic resection, because the ability to achieve an adequate en-bloc resection is extremely difficult in this setting (7,8,34,45). Hand-assisted techniques, however, may overcome this (7,45,46).

In contrast to primary adrenocortical carcinomas, metastatic lesions are generally small and confined to the adrenal gland, and thus amenable to laparoscopic resection (8). Laparoscopic adrenalectomy for metastatic disease may be indicated provided that the primary cancer is controlled or controllable, other metastatic diseases, if present, are resectable, and the patient is fit enough to tolerate general anesthesia (8,40).

Symptomatic Lesions

Benign but nonfunctioning lesions may also require laparoscopic adrenalectomy for control of local symptoms. Myelolipomas larger than 4 cm in size should be considered for resection because of the potential for life-threatening hemorrhage (47).

TABLE 2 ■ Contraindications for laparoscopic adrenalectomy

	Absolute contraindications	Relative contraindications
General	Severe cardiopulmonary disease	Pregnancy[a]
	Uncorrected coagulopathy	Prior intra-abdominal or retroperitoneal surgery[b]
Specific	Uncontrolled pheochromocytoma	Primary carcinoma[c]
	Invasive carcinoma or	Malignant pheochromocytoma[c]
	tumor thrombus	Mass >6 cm[c]

[a]Perform in second trimester if clinically required.
[b]May be performed via an alternative approach.
[c]Controversial.

Margin notes:

Adrenal carcinomas are larger than 6 cm in size in 92% of cases; however, because computed tomography scanning can underestimate the true size of a lesion, a limit of 5 cm has been used empirically.

Masses demonstrating local organ invasion or venous tumor thrombus are not suitable for laparoscopic resection, because the ability to achieve an adequate en-bloc resection is extremely difficult in this setting. Hand-assisted techniques, however, may overcome this.

Contraindications

The contraindications for laparoscopic adrenalectomy are summarized in Table 2.

Absolute

There are few absolute contraindications for laparoscopic adrenalectomy. General contraindications for surgery such as severe cardiopulmonary disease and uncontrolled coagulopathy also apply to laparoscopic adrenalectomy.

Specifically, pheochromocytomas should be medically controlled with alpha- and beta-adrenergic blockade prior to surgery to avoid intraoperative hypertensive crises. As discussed above, invasive carcinoma and carcinoma with tumor thrombus are considered to be contraindications at present.

Relative

Pregnancy is a relative contraindication for laparoscopic adrenalectomy, and the procedure is best deferred until after delivery when possible, especially if the adrenal lesion is diagnosed in the third trimester. However, clinical circumstances may mandate surgery during pregnancy. Shalhav et al. (48) summarized the important points of performing laparoscopic adrenalectomy during pregnancy as follows:

- Perform surgery during the second trimester, because surgery in the first trimester carries a risk of spontaneous abortion and congenital abnormalities, while surgery in the third trimester carries a higher risk of premature labor.
- Open access is preferred to avoid insufflation of the uterus with resultant CO_2 embolism. As an alternative, closed pneumoperitoneum can be created with the subcostal passage of a Veress needle.
- The pneumoperitoneum should be ≤ 12 mmHg.
- Fetal monitoring should be performed throughout the procedure.

Obesity may make laparoscopic surgery more challenging; however, the obese patient has much to gain from a laparoscopic approach. In obese patients, laparoscopic adrenalectomy has been shown to be more effective than open surgery because it offers significant benefits in terms of postoperative recovery and convalescence (49).

Extensive previous intra-abdominal surgery may preclude a transperitoneal laparoscopic approach; however, the retroperitoneal route may be used (8). Conversely, a transperitoneal approach may be preferable in cases of previous retroperitoneal surgery. In rare cases of extensive previous surgery in both the peritoneal cavity and the retroperitoneum, a transthoracic approach has been described as an option (8). The issue of primary and metastatic adrenal disease is controversial as discussed in the preceding section. Similarly, the upper limit for safe resection with respect to size is also debatable. A maximum of 6 cm was previously recommended (35,50). However, lesions of up to 15 cm have been resected (22,38).

> The upper size limit that may be safely resected is not an absolute, arbitrarily defined number, but rather relates to the surgeon's experience, size of the lesion, patient body habitus, surrounding anatomy, and, because right-sided tumors may be intimately associated with the inferior vena cava, the side of the lesion.

The upper size limit that may be safely resected is not an absolute, arbitrarily defined number, but rather relates to the surgeon's experience, size of the lesion, patient body habitus, surrounding anatomy, and, because right-sided tumors may be intimately associated with the inferior vena cava, the side of the lesion (45).

Gill recommends that laparoscopic adrenalectomy may not be advisable for lesions greater than 10 to 12 cm in diameter (8). At least initially, it would not be unreasonable to use 6 cm as an upper limit for resectability because larger lesions are technically more demanding (34). Age per se is not a contraindication. Laparoscopic adrenalectomy has been well described in pediatric patients via both transperitoneal and retroperitoneal approaches, although the transperitoneal approach may be preferable because of the smaller working space in children (24,51).

PREOPERATIVE PREPARATION

The preoperative preparation encompasses the general preparation of a patient for any major abdominal surgery, and, additionally, the optimization of specific metabolic and endocrine abnormalities imposed by the pathology.

Informed consent should warn the patient of the risks of conversion to open surgery, adjacent organ injury, hemorrhage, and blood transfusion. Blood should be cross-matched, and the patient fasted for six hours prior to surgery. The operative side should be confirmed with the patient prior to admission to the operating theatre and marked on the patient's abdomen away from the operative site to avoid tattooing the skin. All imaging should be placed on the viewing screens in the operating theatre and reviewed prior

to the commencement of surgery. Antithromboembolism stockings and pneumatic compression devices should be applied and subcutaneous heparin administered on induction as part of deep venous thrombosis prophylaxis. Antibiotic prophylaxis with an intravenous cephalosporin should be administered on induction. Bowel preparation is not routinely administered, because the incidence of bowel injury is extremely low.

Specific electrolyte and metabolic abnormalities are corrected in close liaison with an endocrinologist. Patients with aldosteronomas may have hypokalemia requiring correction with potassium supplements or potassium-sparing diuretics. Pheochromocytomas require preoperative blood pressure control, initially with alpha-adrenergic blockade, followed by beta-adrenergic blockade if reflex tachycardia occurs. An arterial line and central venous cannula are placed for intraoperative monitoring.

TECHNIQUE
Options
The primary approaches to the adrenal gland are via either the transperitoneal or retroperitoneal route (Table 3). The transperitoneal route may be anterior, with the patient in a supine or semilateral position, or lateral, with the patient in the lateral decubitus position. The retroperitoneal approach may also utilize the lateral decubitus position or alternatively, the patient may be placed in the prone jack-knife position and the adrenal gland approached from the posterior aspect. More recently, a transthoracic approach has also been described (12). The advantages and disadvantages of each of the transperitoneal and retroperitoneal routes have been extensively addressed in the literature and are summarized below in Table 3.

Lateral Transperitoneal Approach
In this approach, the lateral decubitus position allows the viscera to fall medially with gravity, facilitating access to the adrenal gland (45). This contrasts the anterior approach in which the adrenal lies in the most dependent part of the operative field (45).

> Early access to the adrenal vein prior to manipulation of the adrenal gland or periadrenal tissue is the main advantage of the lateral transperitoneal route.

Early access to the adrenal vein prior to manipulation of the adrenal gland or periadrenal tissue is the main advantage of the lateral transperitoneal route (31).

This is not only of particular importance in cases of pheochromocytoma (31), but, in accordance with basic oncological principles, is also important to achieve early vascular control to minimize the risk of tumor cell embolism in cases of suspected malignancy (61).

> Mobilization of the colon is rarely required on the right side; however, mobilization of the splenic flexure and descending colon are required to gain access to the left adrenal vein.

Mobilization of the colon is rarely required on the right side; however, mobilization of the splenic flexure and descending colon are required to gain access to the left adrenal vein.

Other advantages of this approach include the familiarity of intraperitoneal landmarks and a large working space (5,46). It is therefore a useful approach for less-experienced surgeons and for larger lesions.

TABLE 3 ■ Advantages and Disadvantages of Transperitoneal and Retroperitoneal Routes

Approach	Advantages	Disadvantages
Transperitoneal lateral	Early venous control Large working space Familiar landmarks Adrenal exposure facilitated by gravity	Mobilization of viscera (liver, spleen and descending colon) Repositioning if bilateral
Transperitoneal anterior	Early venous control Large working space Familiar landmarks No repositioning if bilateral	Mobilization of viscera (liver, spleen and descending colon) Difficult exposure
Retroperitoneal lateral	Peritoneal cavity avoided	Difficult access to vein Small working space Unfamiliar landmarks Repositioning if bilateral
Retroperitoneal posterior	Peritoneal cavity avoided Early venous control No repositioning if bilateral	Small working space Unfamiliar landmarks Jack-knife position

Source: From Refs. 5,7,21,23,24,28,30,31,45, 46,51–60.

The potential disadvantages are an increased risk of adjacent organ injury and slower convalescence (5,23,52). However, as discussed below, the literature comparing transperitoneal and retroperitoneal approaches does not consistently demonstrate significant differences between the two.

Anterior Transperitoneal Approach

The anterior transperitoneal approach, utilizing either the supine or semilateral position, was used initially but has now largely fallen out of favor because of the difficulty associated with accessing the adrenal (5,7,62). The visceral contents do not fall away with the effects of gravity, and the adrenal lies in a dependent position in the operative field (46). Blood therefore tends to pool around the adrenal, and multiple ports and retractors are required to facilitate exposure of and access to the adrenal gland (46,63).

This approach may be useful in cases requiring bilateral resection because it avoids intraoperative repositioning of the patient (51), but given the advantages in exposure with the lateral approach, our preference is to reposition the patient after the first side has been completed.

Lateral Retroperitoneal Approach

The lateral retroperitoneal approach allows more direct access to the adrenal gland and therefore may potentially facilitate convalescence and decrease morbidity. In particular, select patients with morbid obesity or a history of extensive intra-abdominal surgery may benefit from the lateral retroperitoneal approach (53).

Disadvantages include a smaller working space, lack of familiar anatomical landmarks, difficulty in identifying the adrenal gland in the retroperitoneal fat, and the need for intraoperative repositioning in cases of bilateral resection (5,24,46). For these reasons, this approach is not recommended for lesions more than 5 to 6 cm or inexperienced laparoscopists (23,29,51). Laparoscopic ultrasound has been advocated as a useful adjunct to dissection in order to help overcome these difficulties (6,64–66). Although early control of the adrenal vein has been reported with this technique (53), extensive dissection is usually required in order to achieve vascular control (31) and it is therefore not recommended for pheochromocytoma (30).

Posterior Retroperitoneal Approach

The posterior retroperitoneal approach utilizes the prone jack-knife position. In addition to the above advantages and disadvantages of the retroperitoneal approach, it also allows access to both glands for bilateral procedures (51,54).

Early venous control can also be achieved by this approach, particularly on the right where the adrenal vein tends to run in a slightly retrocaval course (21,55). The main disadvantages of this route are problems caused by the prolonged jack-knife position along with the small working space (21,55). Therefore, this approach is not recommended for lesions greater than 5 to 6 cm in diameter (54,55).

Transperitoneal vs. Retroperitoneal Approaches

One of the primary controversies currently surrounding laparoscopic adrenalectomy relates to transperitoneal versus retroperitoneal approaches (Table 4). Comparative studies to date have not found significant differences between the two approaches in terms of surgical efficacy and convalescence.

Initial series suggested that the transperitoneal route was associated with longer operative times (56,63,75); however, these studies compared retroperitoneal access with the anterior transperitoneal approach, which is known to involve more difficult adrenal exposure than the lateral transperitoneal approach. Latter studies comparing transperitoneal and retroperitoneal routes have shown either no difference in operative times (57,68,70,72–74,76) or shorter operative times for the lateral transperitoneal approach (52,67,69,71). Lezoche et al. found that for left-sided adrenalectomies, operative times were longer for the transperitoneal approach than the retroperitoneal approach, but for right-sided lesions, there was no difference between the two (61).

Similarly, earlier studies demonstrated greater blood loss with the anterior transperitoneal route (56,63,75); however, later studies examining the lateral transperitoneal approach have not reproduced this finding (52,67–71,73).

Select patients with morbid obesity or a history of extensive intra-abdominal surgery may benefit from the lateral retroperitoneal approach.

The posterior retroperitoneal approach utilizes the prone jack-knife position. Besides the advantages and disadvantages of the retroperitoneal approach, it also allows access to both glands for bilateral procedures.

Comparative studies to date have not found significant differences between the transperitoneal and retroperitoneal approaches in terms of surgical efficacy and convalescence.

[a]Significantly larger in the transperitoneal groups compared to PRA.
[b]LRA significantly longer than LTA.
[c]Open approach significantly different from laparoscopic approaches.
[d]LTA significantly faster than ATA and LRA.
[e]Oral intake and ambulation faster for LRA than ATA but not different from that of LTA.
[f]Significant differences compared to both laparoscopic groups.
[g]LTA involves significantly shorter operative time than PRA.
[h]Left-sided ATA significantly longer than right-sided ATA and left-sided LRA, but right-sided ATA not significantly different from right-sided LRA.
[i]ATA involves significantly more blood loss than LRA.
[j]ATA involves significantly longer and more blood loss than LRA and PRA.
[k]ATA involves significantly longer operative time compared to LRA and open approach.
[l]LRA involves significantly lesser blood loss compared to ATA and open approach.
[m]LRA involves significantly lesser analgesic use compared to ATA and open approach and shortest hospital stay.
[n]Significantly greater gland weight in the LRA group.
[o]Three converted to transperitoneal approach because of intraoperative difficulties.
Abbreviations: ATA, anterior transperitoneal laparoscopic adrenalectomy; LRA, lateral transperitoneal laparoscopic adrenalectomy; LTA, lateral transperitoneal laparoscopic adrenalectomy; PRA, posterior retroperitoneal adrenalectomy; RPA, Retroperitoneal adrenalectomy; NS, Not significant

Reported series have not consistently demonstrated significant differences in analgesic requirement, time to oral intake, ambulation, length of stay, convalescence, conversion rates, and complication rates between the transperitoneal and retroperitoneal approaches.

Tumor size, obesity, and the learning curve are the most important factors influencing operative outcome .

Overall, reported series have not consistently demonstrated significant differences in analgesic requirement, time to oral intake, ambulation, length of stay, convalescence, conversion rates, and complication rates between the two approaches.

Surgical experience and body mass index independently predict operative times (52,61,68), whereas blood loss has also correlated with operative experience and tumor size (52). Tumor size, obesity, and the learning curve are the most important factors influencing operative outcome (52).

Overall, these studies have not consistently shown significant beneficial differences between the retroperitoneal and transperitoneal approaches. Rather than the approach used, surgeon experience, patient habitus, and size of the lesion affect operative outcome measures. Given the lack of evidence demonstrating any advantage of the retroperitoneal technique, in conjunction with the advantages of the lateral transperitoneal approach, particularly with regard to early venous control, we routinely use the latter approach as our preferred method of laparoscopic adrenalectomy. However we concur with the statements of Sung et al., who indicate that surgeons should be familiar with both transperitoneal and retroperitoneal approaches because individual case characteristics may dictate the use of one approach in preference to the other (73).

LATERAL TRANSPERITONEAL TECHNIQUE

Equipment and Theatre Set-Up

Tables 5 and 6 list the equipment used. The operating table is placed obliquely in the operating theatre with the anesthetic equipment at the head of the table and the camera stack system, containing the insufflator, monitor, light source, and camera system, at the foot (Fig. 1). In this position, the scrub nurse can easily view the monitor. The diathermy machine is placed next to the stack system. Because we prefer to operate with a larger image, we use a 5-foot projector screen placed in the far corner of the operating theatre, with a projector placed on the opposite side to the surgeon close to the head of the table. If available, a plasma screen is also suitable. The patient is placed in the lateral decubitus position. The surgeon stands in front of the patient with the assistant on the surgeon's left and the Mayo table on his/her right. The Mayo table is useful to place frequently used instruments such as the clip applier, hook diathermy, and diathermy scissors in easy reach of the surgeon. The scrub nurse's tables are on the opposite side to the surgeon adjacent to the diathermy machine. It is useful for the nurse to be seated so as not to block the surgeon's view of the screen. Similarly, it is useful for either the assistant to be seated or to stand on a platform, or the surgeon to stand on a platform; this places the surgeon's arms and assistant's arms at different levels to avoid clashing.

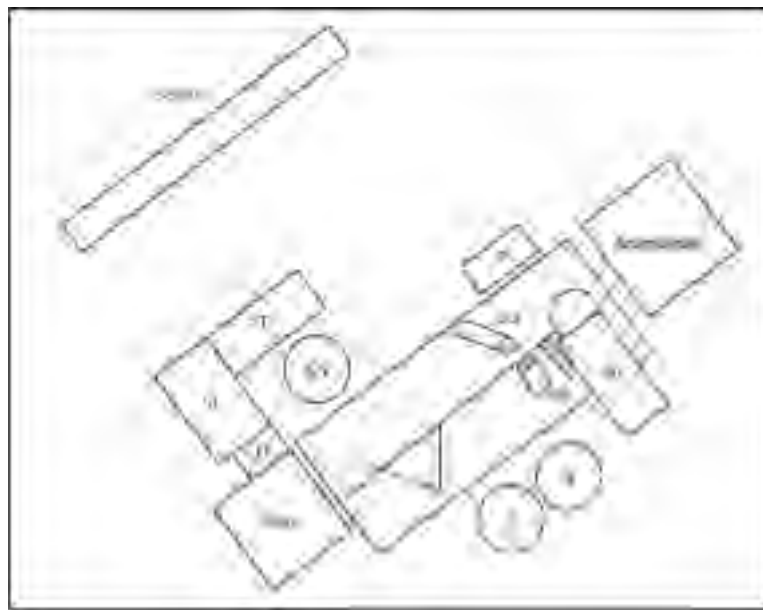
TABLE 6 ■ Specific Laparoscopic Adrenalectomy Equipment

No. 11 scalpel blade
2 Langenbeck retractors
0° Laparoscope
4 × 5-11 Autosuture Versaseal ports with spring grip (Tyco Healthcare, Mansfield, U.S.A.)
5 mm Electrosurgical scissors
5 mm Electrosurgical hook
10 mm Autosuture Endoretract[a]
10 mm ML Endoclip[a]
10 mm Endocatch[a] bag
Tonsil swabs
5 mm laparoscopic suction probe
Camera sleeve
Sterile flask filled with hot water to warm laparoscope
Endo-GIA 30 with reloads
Projection screen and projector
Mayo table
5 mm Maryland dissecting forceps
2 × Laparoscopic needle holders
3/0 Prolene vascular suture on a round-bodied needle
Have available—laparotomy set with vascular clamps and 4 × small bulldog clips

[a]U.S. Surgical Corp., Norwalk, CT.


Steps

The steps involved in transperitoneal laparoscopic adrenalectomy include:

1. Patient positioning
2. Access and port placement
3. Exposure
4. Control of the adrenal vein
5. Mobilization of the adrenal gland
6. Removal and closure

Patient Positioning

Following induction, the patient is catheterized with a 16 French urethral catheter. A nonsteroidal analgesic suppository is then placed if there is no contraindication. A nasogastric tube is placed to deflate the stomach. The patient is placed in a standard lateral decubitus position with the table broken, a padded lumbar support behind the patient's upper back, both elbows flexed with the upper forearm supported on a padded arm rest, and the upper leg straight and the lower leg flexed at the knee and thigh. The patient lies on a gel mattress with a pillow placed between the legs and padding applied to lower knee and ankle. Broad adhesive tape is applied across the hips and the diathermy pad is placed on the thigh or buttock of the upper leg.

The operative field is prepared with aqueous povidone-iodine and draped with possible open conversion in mind. The diathermy leads, light leads, inflow tubing, and suction tubing run to the video stack and diathermy machines at the foot of the table, and are covered with another drape. A large clear adhesive film is used to secure the drapes and isolate the operative field. A long scabbard for the sucker is placed on the opposite side to the surgeon toward the head, and a short scabbard for the hand-held diathermy is placed on the same side.

Right Side

The aim of a right-sided laparoscopic adrenalectomy is to remove the adrenal gland with early ligation of the adrenal vein. It is essentially a dissection of the inferior vena cava.

> The aim of a right-sided laparoscopic adrenalectomy is to remove the adrenal gland with early ligation of the adrenal vein. It is essentially a dissection of the inferior vena cava.

Access and Port Placement. Four 5-11 Versaport™[a] disposable ports are used (Fig. 2). The first port is placed between the umbilicus and the tip of the ninth rib using an open access technique, close to the inferior epigastric artery. The two working ports are placed under direct vision on either side of the first port parallel to the costal margin approximately in the midline and the anterior axillary line. The fourth port is placed superior to the iliac crest in the midaxillary line and is used for the fan retractor. We prefer to

---

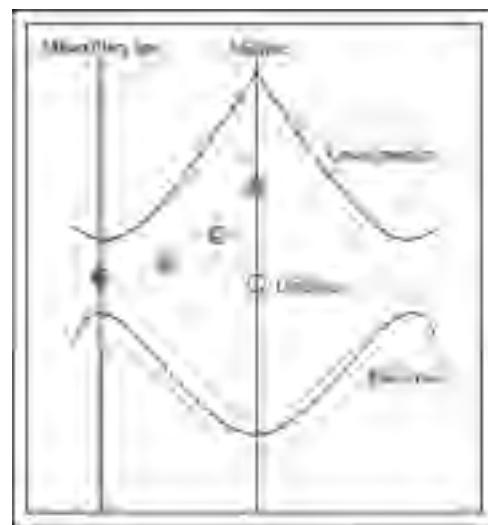
FIGURE 2 ■ Port positions for right-sided transperitoneal laparoscopic adrenalectomy.


use a 0° laparoscope because it is easier for the assistant to orient the image correctly. The gas flow is commenced on high flow with a pressure limit of 15 mmHg.

Exposure.   Following port placement, the operative field is inspected, noting particularly whether the adrenal lesion is visible and also the relationship of the adrenal to the surrounding structures: the hepatic flexure, the right lobe of the liver, the inferior vena cava, and also the duodenum. The inferior vena cava lies just behind the peritoneum, and thus the hepatic flexure and duodenum do not usually require mobilization. However, in some cases, these maneuvers may be necessary.

A fan retractor is passed through the most lateral port to elevate the right lobe of the liver, and the assistant holds this gently in position. Alternatively, an adjustable fixed table retractor may be used (77). We find a combination of sharp and blunt dissection with scissors and hook to be the most expedient mode of dissection. Others have found the harmonic scalpel to be of particular value in reducing operative time (78). We prefer diathermy because we find it more expedient, but this is largely a matter of individual preference.

The inferior leaf of the right coronary ligament is incised to allow superior retraction of the liver with the fan retractor. For large lesions, it may be necessary to incise the right triangular ligament. The peritoneum over the inferior vena cava is incised and the inferior vena cava traced superiorly and inferiorly using a combination of sharp and blunt dissection.

In accordance with general vascular principles, it is safer to dissect close to the vena cava to avoid troublesome small-vessel bleeding from the adjacent tissue and also to minimize the risk of injury to the cava.

Vascular Control.   Once the adrenal vein is identified, it is clipped twice on the inferior vena cava side and once on the specimen side, and then divided. Extreme caution must be exercised when dissecting the adrenal vein because bleeding from this may be extremely difficult to control due to its position in the hepatorenal pouch and its drainage into the vena cava.

It is not necessary to dissect fully around behind the vein, and such dissection behind the vein may result in bleeding that is difficult to access and control. It is therefore safer to clip the vein once it has been exposed to a reasonable degree. Because this vein is short, it is important to place the two cava-side clips as close as possible to each other, thereby exposing a reasonable segment of the vein between the two sets of clips to divide with scissors. Occasionally, the adrenal vein may be wide and require division using an Endo-GIA™[b]. In such instances, the right hand working port will need to be exchanged for a 5-12 port to accommodate the instruments.

Mobilization of the Gland.   Once the adrenal vein has been divided, the vein is grasped with dissecting forceps and elevated. The hook diathermy is used to mobilize the medial aspect of the gland off the posterior abdominal wall.

[b]U.S. Surgical Corp., Norwalk, CT.

Sidebar notes:

In accordance with general vascular principles, it is safer to dissect close to the vena cava to avoid troublesome small-vessel bleeding from the adjacent tissue and also to minimize the risk of injury to the cava.

Extreme caution must be exercised when dissecting the adrenal vein because bleeding may be extremely difficult to control due to its position in the hepatorenal pouch and its drainage into the vena cava.

> The inferior aspect of the gland is mobilized from the upper pole of the kidney; dissecting a few millimeters away from the surface of the adrenal, taking care not to cut or tear the gland, will minimize small-vessel bleeding.

The superior, inferior, and lateral aspects of the gland are sequentially mobilized, and the superior, middle, and inferior adrenal arteries are controlled with clips as they are encountered. The exact order of dissection is not important and may vary between cases; however, we generally mobilize the lateral aspect of the gland last because the lateral attachments aid stability of the gland.

The inferior aspect of the gland is mobilized from the upper pole of the kidney; dissecting a few millimeters away from the surface of the adrenal, taking care not to cut or tear the gland, will minimize small-vessel bleeding.

Removal and Closure.   Once the gland has been fully mobilized, it is placed in an Endocatch I® c bag and left in the abdomen while hemostasis is checked. Surgicel® d is placed to control any minor venous ooze, and the specimen is removed through the primary port site. A drain is not routinely placed. The wounds are closed with one PDS for the muscle, 2/0 Monocryl for the superficial fascia, and 4/0 Monocryl for the skin. The wounds are infiltrated with 0.25% plain marcain. The nasogastric tube is removed.

Left Side

> The aim of a left-sided laparoscopic adrenalectomy is to remove the adrenal gland and periadrenal fat with early ligation of the adrenal vein. It is essentially a dissection of the left renal vein.

The aim of a left-sided laparoscopic adrenalectomy is to remove the adrenal gland and periadrenal fat with early ligation of the adrenal vein. It is essentially a dissection of the left renal vein.

In contrast to right-sided laparoscopic adrenalectomy, the descending colon and splenic flexure require medial mobilization to identify the left adrenal vein.

Access, Port Placement, and Exposure.   Port placement is the mirror image of the right-sided approach. Using a combination of sharp and blunt dissection with the dissecting forceps and the diathermy scissors, the line of Toldt is incised, and the plane between the posterior peritoneum and the anterior aspect of Gerota's fascia is developed to reflect the colon medially. Careful sharp dissection of any adhesions to the spleen is required to prevent avulsing segments of the splenic capsule.

Control of the Adrenal Vein.   Once the colon has been reflected medially, attention is focused on the renal hilum. The fan retractor is passed through the most lateral port and is used to displace the kidney upward. The aim is to identify the renal vein and dissect along its superior aspect to locate the adrenal vein draining into it.

> The aim is to identify the renal vein and dissect along its superior aspect to locate the adrenal vein draining into it.

The inferior phrenic vein courses along the medial border of the adrenal and may be used as a landmark to the left adrenal vein (13,79). However, we find the renal vein to be more readily identifiable and reliable than the inferior phrenic vein. Once the adrenal vein has been identified, it is clipped and divided in a similar fashion as the right side.

Mobilization, Removal, and Closure.   The adrenal vein is used to lift the gland up and develop the plane along the posterior abdominal wall. The gland is mobilized superiorly, inferiorly, and laterally using a combination of sharp and blunt dissection with the hook diathermy.

> Because the medial aspect of the gland is mobilized, it is important to be aware of the tail of the pancreas and the splenic vein, which are in close proximity. The pancreatic tail may be confused with the adrenal gland; however, the characteristic golden appearance of the adrenal is a useful guide.

Because the medial aspect of the gland is mobilized, it is important to be aware of the tail of the pancreas and the splenic vein, which are in close proximity. The pancreatic tail may be confused with the adrenal gland; however, the characteristic golden appearance of the adrenal is a useful guide.

The superior, middle, and inferior adrenal arteries are controlled with clips as they are encountered. The plane between the upper pole of the kidney and adrenal is developed to mobilize the inferior aspect of the adrenal, and the leinorenal ligament is divided to free the superior aspect from beneath the spleen. The fan retractor is used to retract the spleen superiorly to facilitate dissection. The lateral attachments of the spleen to the diaphragm may require division in order to expose the superior aspect of the adrenal. Once fully mobilized, the specimen is removed and the wounds closed in the usual manner.

Postoperative Care and Follow-Up

Cases of pheochromocytoma are monitored in the high dependency unit on the first night. Patients are allowed to sip 30 mL water per hour. Thromboembolism prophylaxis with subcutaneous heparin or Clexane in conjunction with pressure stockings is continued. A regular nonsteroidal anti-inflammatory and paracetamol are prescribed, and intravenous narcotic via a patient-controlled analgesia pump is used overnight.

---

c U.S. Surgical Corp., Norwalk, CT.
d Johnson & Johnson, Somerville, NJ.

Antibiotics are not routinely continued. On the first day, the patient-controlled analgesia and urethral catheter are removed, and the patient is upgraded to a fluid and then full diet as tolerated. The patient is usually discharged on the second or third postoperative day. The postoperative stay may be longer in cases of functioning lesions, where hormonal and metabolic factors need to be corrected in coordination with the endocrinologist. Steroid replacement if required is continued. Potassium and other electrolytes are monitored daily, and potassium supplements withdrawn as required. Following discharge, the patient is reviewed at four to six weeks to check the surgical sites and general convalescence.

TECHNICAL CAVEATS

Hemostasis

Absolute hemostasis is essential for a successful procedure. The physiological impact of minor blood loss is minimal; however, by staining tissues, masking tissue planes, and darkening the image through light absorption, it can make the procedure technically more demanding. It is best to operate slowly and achieve good hemostasis rather than accept minor bleeding and "push on." Invariably, the more slowly but deliberately one operates the faster the operation progresses overall.

Typically, troublesome bleeding may occur from:

■ The adrenal vein as it enters the inferior vena cava or renal vein on the right and left sides, respectively;
■ Small vessels in the periadrenal fat, particularly when developing the plane between the upper pole of the kidney and the adrenal;
■ The inferior phrenic vein tributary to the left adrenal vein as it courses along the medial aspect of the gland;
■ Tributaries of the main renal veins that may be at risk from traction injury;
■ An inadvertent breach of the adrenal gland itself;
■ The left lumbar and gonadal veins that may be at risk of avulsion from traction as they enter into the left renal vein complex;
■ The superior, middle, and inferior adrenal arteries; and
■ Lumbar veins entering the inferior vena cava that, particularly with large lesions, may be at risk during medial mobilization. However, in most cases, these vessels are well medial to the line of dissection.

There are several methods available to control bleeding, ranging from diathermy to conversion. If the bleeding point is small and easily seen, then simple diathermy with the diathermy scissors may suffice. A useful maneuver is to attach the diathermy lead to the dissecting forceps in the left hand and the sucker in the right hand. The sucker is used to clear the field of blood, and the bleeding vessel is then grasped and diathermied with the dissecting forceps. An endoclip may alternatively be applied. A left-handed surgeon may find the opposite easier.

If the bleeding source is difficult to identify, a tonsil swab may be pressed down onto the bleeding area before definitive hemostasis is undertaken.

Depending on the experience of the surgeon, the application of bulldog clips to gain proximal and distal control of a larger bleeding vessel such as a renal vein branch may be useful. These clips can be passed down a 10 mm port with a large toothed grasper. Similarly, direct intracorporeal suturing may be required; however, this may be difficult because the working space at the site of bleeding may be quite cramped. These latter methods require considerable laparoscopic experience and inexperienced practitioners would be best served converting to open surgery to control significant hemorrhage.

At all times, patient safety is paramount, and it is essential that the practitioner has a low threshold for open conversion to control significant hemorrhage.

> At all times, patient safety is paramount, and it is essential that the practitioner has a low threshold for open conversion to control significant hemorrhage.

Open Conversion

In some cases, intraoperative conversion may be required. Our indications for intraoperative conversion are:

■ Uncontrollable hemorrhage,
■ Obvious contiguous organ invasion that necessitates en-bloc resection, and
■ Failure to progress

Regarding failure to progress, we do not set an absolute time limit. As long as the procedure is proceeding safely, it is often better to finish the operation laparoscopically

We generally set a time limit of five hours for all laparoscopic procedures before conversion because in our experience, the risks of nerve compression increase significantly after this time.

On the left side, the tail of the pancreas may be confused with the adrenal, but it lacks the characteristic color of the adrenal. If it does not look like the adrenal, it is probably not the adrenal!

By applying the general principles of careful hemostasis, and careful, deliberate dissection to positively identify the relevant anatomy, the risk to adjacent organs is minimized.

rather than have the patient incur the morbidity of an open operation superimposed on a long laparoscopic procedure.

We generally set a time limit of five hours for all laparoscopic procedures before conversion because in our experience, the risks of nerve compression increase significantly after this time.

Organ Injury

Direct injury to the adrenal gland may cause troublesome bleeding and may also compromise the oncological safety of the procedure. This is best avoided by dissecting the periadrenal fat and the adrenal gland within the superior packet of Gerota's fascia as a whole rather than dissecting the gland itself.

On the left side, the tail of the pancreas may also be confused with the adrenal, but it lacks the characteristic color of the adrenal. If it does not look like the adrenal, it is probably not the adrenal!

Similarly, the spleen is at risk during left-sided procedures. Attachments to the spleen should be divided sharply to avoid avulsion of part of the splenic capsule. Incising the leinorenal ligament allows the spleen to be retracted superiorly and medially away from the operative site.

The diaphragm and colon are at risk on both sides, whereas the duodenum and liver are at risk on the right. Dividing the inferior coronary ligament to allow gentle superior retraction of the liver away from the adrenal minimizes hepatic injury.

By applying the general principles of careful hemostasis, and careful, deliberate dissection to positively identify the relevant anatomy, the risk to adjacent organs is minimized.

At times, the operative view may be compromised by camera fogging, poor lighting, or poor image quality. A detailed discussion of these issues is beyond the scope of this chapter; however, in such instances, it is imperative to stop and correct the problem rather than continue in suboptimal circumstances.

GENERAL TECHNICAL MODIFICATIONS

Procedural Modifications

The technique of lateral transperitoneal laparoscopic adrenalectomy is quite consistent in most accounts. Port positions differ slightly according to the surgeon's preference. Generally, four ports are required, with one camera port, two working ports, and one additional port for retractor placement. Most reports describe a subcostal arrangement along the line of the costal margin (24,35,37,45,50,80); however, they may also be placed in a quadrangular arrangement beneath the costal margin (81).

The primary camera port may be placed in the midline at a supraumbilical site (45) and may also be moved among the ports to aid vision (50,81). Some authors describe mobilizing or defining the adrenal prior to securing the adrenal vein (7,50,82). For the reasons stated, we do not believe that this is consistent with achieving an optimal surgical outcome.

Instrument Modifications

A variety of instrument modifications that aid in dissection of the adrenal gland have been described. The harmonic scalpel may be of particular use in reducing operative time (58,78).

Laparoscopic ultrasound probes with frequencies in the order of 5 to 7.5 MHz may be useful in identifying the adrenal gland and vein, confirming the presence or absence of an abnormality on the affected and contralateral sides, determining the resectability of large masses, facilitating partial resection, and identifying pathology in adjacent organs (6,64–66). However, data pertaining to the usefulness of this modality has been conflicting. Lucas et al. found laparoscopic ultrasound particularly useful in identifying the adrenal vein on the left when it is obscured by large amounts of retroperitoneal fat (66); in contrast, Brunt et al. found that laparoscopic ultrasound identified the vein in only 21% of cases (65). Laparoscopic ultrasound may be of particular benefit in retroperitoneal approaches where the landmarks may not be as readily apparent and the adrenal is more difficult to identify. This modality has also been used to localize extra-adrenal pheochromocytoma (83).

Ultrasonic aspirator systems have been used to aid in the dissection of the inferior vena cava and renal hilum to dissect the adrenal from the surrounding fat (84). Suzuki et al. found that the operative time was shorter and blood loss less with its use (84), whereas conversely, Takeda et al. found no differences in these parameters (85).

The argon beam coagulator has been described as useful for some right-sided lesions with attachments to the liver (85). Atraumatic suction graspers have been associated with shorter operative times and aim to facilitate gentle handling of the adrenal, allowing better exposure of the vessels by enabling retraction of the gland (86). Obermeyer et al. described administering intravenous methylene blue in five mini-Hanford pigs to aid in adrenal identification (87).

ANTERIOR TRANSPERITONEAL TECHNIQUE

As discussed previously, this approach has been largely superseded by the lateral transperitoneal approach. Typically, the patient is placed in either the supine or the semilateral position (9,58,88). Ports are generally placed in a subcostal arrangement (9,58,88). On the right side, the liver is retracted superiorly, and the paracaval posterior peritoneum is incised to achieve direct access to the inferior vena cava and therefore the adrenal vein (9,58,88). Once the vein has been divided, the adrenal is then mobilized (9,58,88). On the left side, the splenic flexure is mobilized medially and access to the adrenal achieved by reflecting the stomach and pancreatic tail medially (9,88). The adrenal vein is identified and divided, and the adrenal gland is then mobilized and removed (9,58,88).

LATERAL RETROPERITONEAL TECHNIQUE

Lateral retroperitoneal laparoscopic adrenalectomy is the main alternative to the lateral transperitoneal approach. This procedure is well described by Sung et al. and a summary is provided here (73).

Patient Positioning and Retroperitoneal Access

The lateral decubitus position is utilized. The first port is placed via an open access technique just below the tip of the 12th rib. The flank muscle fibers are separated bluntly, and the thoracolumbar fascia pierced with a hemostat or fingertip. The posterior pararenal space is developed initially with the index finger and further developed with a balloon dilator.

In our experience of retroperitoneoscopy for pyeloplasty and nephrectomy, we have found that when this space is first developed with the index finger, it is important not to sweep the finger anteriorly because this can tear the peritoneum.

Sung et al. (53) also state that it is important to finger dissect along the psoas and therefore stay outside of Gerota's fascia. The authors describe balloon dilation using a commercially available trocar-mounted balloon dilator. We use a similar system for extraperitoneal laparoscopic radical prostatectomy; however, for retroperitoneoscopy, to provide maximal protection to the peritoneum, we utilize the middle finger of a number 8 glove secured with a silk tie to the tip of an 18 French urethral catheter and instill, depending on the patient's body habitus, 500 to 700 mL of saline into the catheter.

Port Placement

A 10 mm trocar is placed as the primary port, and CO_2 pneumoretroperitoneum is created to 15 mmHg. A 30° laparoscope is inserted, and the psoas identified as the primary landmark. An anterior 5 mm port is placed in the anterior axillary line 3 cm cephalad to the iliac crest. A posterior 5 mm port is positioned at the junction of the lateral surface of the erector spinae with the inferior surface of the 12th rib. A fourth 2 mm port may also be required at the level of the primary port in the anterior axillary line for retraction of the kidney and the adrenal gland.

Control of the Main Adrenal Vein

Gerota's fascia is incised transversely at the level of the upper pole of the kidney. The upper renal pole is mobilized and allowed to fall posteriorly away from the adrenal.

On the left side, dissection continues between the upper pole of the kidney and the adrenal to the renal hilar vessels. The dissection continues medially along the renal artery or vein until the adrenal vein is identified and then clipped and divided. If the adrenal vein cannot be identified, the dissection is recommenced laterally and superiorly to free the adrenal from the diaphragm. The dissection then continues around the inferomedial aspect of the gland where adrenal vein will be identified.

On the right side, the dissection is carried superiorly along the lateral aspect of the vena cava until the adrenal vein is seen. The vein is divided, and the gland mobilized.

In our experience of retroperitoneoscopy for pyeloplasty and nephrectomy, we have found that when this space is first developed with the index finger, it is important not to sweep the finger anteriorly because this can tear the peritoneum.

Instead of incising Gerota's fascia to enter the plane between the upper pole of the kidney and the adrenal, an alternative strategy is to lift the kidney medially and anteriorly and incise Gerota's fascia just anterior to the psoas muscle and then identify the renal hilum. The dissection then continues along the lateral aspect of the vena cava on the right or aorta on the left superior to the renal hilum. On the right, the adrenal vein is encountered during this medial dissection but on the left, it may not be seen and may require circumferential mobilization of the gland before it is identified.

Specimen Mobilization, Extraction, and Closure

Following control of the adrenal vein, the gland is mobilized in a circumferential manner with meticulous hemostasis. Once mobilized, a 5 mm laparoscope is inserted through the anterior 5 mm port, a 10 mm retrieval bag is inserted through the primary port, and the specimen is retrieved. The wounds are closed after hemostasis has been checked and secured.

POSTERIOR RETROPERITONEAL TECHNIQUE

This technique is well described by Baba et al. (10,21,55,75). The patient is placed prone with the lumbar area flexed on a jack-knife table. Open Hasson cannulation is employed at the primary port site 2 cm below the tip of the 12th rib. Once the posterior pararenal space is entered, it is further developed with balloon dissection. Three ports are generally used: a 12 mm trocar 3 cm below the 12th rib on the lateral edge of sacrospinalis, a 5 mm trocar on the posterior axillary line in the 11th intercostal space, and a 12 mm trocar placed through the primary port site. If retraction of the kidney is necessary, then a further 5 mm port may be placed in the posterior axillary line above the iliac crest.

Gerota's fascia is incised along its medial aspect along quadratus lumborum and the crus of the diaphragm. The incision is continued transversely over the adrenal gland. The middle adrenal arteries are controlled as they emerge from the crus. The renal pedicle is then identified. On the right side, the inferior vena cava is observed below the level of the adrenal arteries along the crus of the diaphragm. The right adrenal vein runs in a retrocaval direction and therefore is easily dissected from the dorsal side. The vein is clipped and transected, Gerota's fascia is incised transversely, and the inferior aspect of the adrenal is mobilized from the upper pole of the kidney and the inferior adrenal vessels are controlled. The dissection then continues laterally and superiorly, and the superior vessels are controlled.

Siperstein et al. describe a similar approach but state that the position of the adrenal gland and kidney relative to the 12th rib is variable and therefore utilize transcutaneous ultrasound prior to skin preparation to mark out the position of the kidney and the adrenal gland (54). All three ports are placed below the 12th rib posteriorly. The balloon dissection is performed within Gerota's fascia. A 12 mm Optivue® [e] trocar with a 0° laparoscope is used to create the primary port site inferior to the 12th rib and enter into Gerota's fascia at the upper pole of the kidney. Balloon dissection is performed, and two additional 12 mm ports are inserted on either side of the primary port. Laparoscopic ultrasound is used to confirm the position of the adrenal and the lesion. The harmonic scalpel is used for dissection, and the atraumatic suction grasper to manipulate the gland. The adrenal is mobilized initially superiorly and then laterally and inferiorly. The medial dissection is performed last, and the vein transected. The specimen is then placed in a retrieval bag and removed.

OTHER TECHNIQUES AND MODIFICATIONS

Direct Supragastric Left-Sided Adrenalectomy

Basso et al. initially described direct left-sided supragastric laparoscopic adrenalectomy (13). With the patient in the lithotomy position, the gastrophrenic ligament and one or two short gastric vessels are divided, thereby allowing displacement of the gastric fundus inferiorly and exposure of the diaphragmatic crus. The constant tributary from the inferior phrenic vein, the so-called "diaphragmatic-adrenal-renal channel," is identified and divided and traced to the adrenal vein, which is then transected. All six procedures in this series were successfully completed.

Vereczkei et al. described a similar approach wherein initial access to the adrenal gland is afforded by incising the leinodiaphragmatic ligament laterally from the left diaphragmatic crus, allowing the spleen to be retracted inferiorly and laterally.

[e]Ethicon, Cincinnati, OH.

The gland is dissected along its medial and then inferior aspects, and the main adrenal vein then identified and divided (14). In this series of 23 cases, however, three required conversion owing to intraoperative hemorrhage, and one case of pheochromocytoma was complicated by intraoperative hypertension secondary to gland manipulation prior to venous control.

Both of these approaches aim to minimize visceral mobilization and allow direct access to the adrenal gland; however, because the adrenal vein is accessed only after dissection of a large part of the tumor, these approaches are not suitable for removal of pheochromocytomas (5).

Hand-Assisted Laparoscopic Adrenalectomy

This technique, described by Bennett and Ray, is reported to be associated with short operative times and has the advantage of introducing tactile feedback in locating the adrenal gland. This technique utilizes the Handport® [f], which is placed in the upper midline for left-sided lesions and via an oblique right lower subcostal incision for right-sided procedures. The procedure then follows the same dissection as for open surgery with Kocherization of the duodenum on the right prior to control of the adrenal vein, whereas on the left, the greater omentum is divided, and the adrenal gland and vein accessed through the lesser sac (15).

In this series, three procedures were performed successfully with operative times of 55 to 90 minutes. Hand-assisted laparoscopic adrenalectomy may offer an alternative to cases where an open procedure is being considered, such as with large or potentially malignant lesions, or where conversion from a laparoscopic adrenalectomy may be required (15).

Needlescopic Laparoscopic Adrenalectomy

Gill et al. described the initial series of needlescopic transperitoneal laparoscopic adrenalectomy (16). In this series, 15 patients underwent needlescopic laparoscopic adrenalectomy using three subcostal ports (two 2 mm ports and one 5 mm port) and one 10 to 12 mm umbilical port through which the specimen was ultimately removed. The needlescopic group had less blood loss, a shorter operative time, shorter hospital stay, and more rapid convalescence compared to standard laparoscopy. Needlescopic instruments are however more flimsy and less reliable than standard laparoscopic instruments, and therefore, considerable laparoscopic experience is required for their use (17). Chueh et al. described transperitoneal laparoscopic adrenalectomy using needlescopic instruments and a clipless technique in which the adrenal vein was controlled with bipolar diathermy using mini bipolar forceps to diathermy the vein over a distance of 6 mm in two to three sequential applications (17). The authors found that convalescence and pain scores were improved but operative time was longer compared to standard laparoscopy (17). Concern has been expressed regarding the sole use of diathermy to control the adrenal vein, particularly on the right side (17).

Thoracoscopic Transdiaphragmatic Adrenalectomy

Thoracoscopic transdiaphragmatic adrenalectomy is a procedure that may be of particular use in patients who have had extensive surgery both in the peritoneal cavity and the retroperitoneum.

Initially described by Pompeo et al. in a porcine model (89), this approach was further developed and the initial clinical series described by Gill et al. (12). In this series, the procedure was performed initially on four cadavers to develop the technique and then on three patients, all of who had significant abdominal scarring and prior ipsilateral renal surgery. After the placement of a double-lumen endotracheal tube, the patient is placed prone and a four-port transthoracic approach without pneumoinsufflation is used. Real-time laparoscopic ultrasound is used to identify the adrenal gland transdiaphragmatically. The diaphragm is incised, and the adrenal gland dissected. There were no intraoperative or postoperative complications, operative times ranged from 2.5 to 6.5 hours, and blood loss ranged from 50 to 500 mL (12).

Robotic Surgery

Because technology has improved, robotic applications to laparoscopic adrenalectomy have been reported. Use of the automated endoscopic system for optimal patient

> Thoracoscopic transdiaphragmatic adrenalectomy is a procedure that may be of particular use in patients who have had extensive surgery both in the peritoneal cavity and the retroperitoneum.

[f]Smith and Nephew, Sydney, Australia.

An experienced human assistant familiar with the modus operandi of the primary surgeon will provide a dynamic view of the object of interest in a much more expedient fashion than a voice-activated robot, particularly during complex maneuvers such as intracorporeal suturing.

positioning voice-controlled robot has been well described, and is reported to provide a steadier, more reliable picture with fewer camera smears when compared to human assistance, while allowing the assistant more freedom to assist the primary surgeon actively (10,90).

An experienced human assistant familiar with the modus operandi of the primary surgeon is able to provide a dynamic view of the object of interest in a much more expedient fashion than a voice-activated robot, particularly during complex maneuvers such as intracorporeal suturing.

More recently, the *daVinci* and Zeus master–slave robot systems have been developed and used in clinical practice (18–20). Proposed advantages include absence of tremor, up to seven degrees of freedom, a relaxed working position at the console, and a minimal learning curve (18). Overall, the major advantage with these systems is that they enable surgeons with little prior laparoscopic experience to perform minimally invasive procedures. The major disadvantage at this stage, however, is cost. Sung and Gill compared the *daVinci* and the Zeus systems for laparoscopic adrenalectomy and laparoscopic nephrectomy and felt that the intraoperative technical movements were more intuitive with the *daVinci* system but that the procedures were feasible with both units (91).

CONCLUSION

Since its inception in 1992, laparoscopic adrenalectomy has evolved as the procedure of choice for the vast majority of surgical pathologies of the adrenal gland and has clear benefits when compared to open surgery. Procedural advancements have resulted in the development of new approaches to the adrenal, from the initial anterior transperitoneal approach, to the lateral transperitoneal approach, posterior and lateral retroperitoneal approaches, and more recently the thoracoscopic approach. Comparative studies to date have not demonstrated significant differences in outcome measures between transperitoneal and retroperitoneal routes. We prefer the lateral transperitoneal approach because of its particular advantage in allowing early control of the adrenal vein.

SUMMARY

- Laparoscopic adrenalectomy has become the standard surgical approach for most surgically correctable disorders of the adrenal gland.
- Aldosteronomas may be considered as lesions of choice for surgeons early in the operative learning curve.
- Unilateral laparoscopic adrenalectomy is the treatment of choice for patients with Cushing's syndrome due to unilateral adrenal adenomas.
- After initial controversy, laparoscopic adrenalectomy for pheochromocytoma is now well accepted as a standard indication for unilateral or bilateral disease.
- The quintessential objective during laparoscopic adrenalectomy is early control of the adrenal vein and in this regard, pheochromocytomas are best suited to the transperitoneal approach.
- Masses demonstrating local organ invasion or venous tumor thrombus are not suitable for laparoscopic resection because the ability to achieve an adequate en-bloc resection is extremely difficult in this setting.
- Early access to the adrenal vein prior to manipulation of the adrenal gland or periadrenal tissue is the main advantage of the lateral transperitoneal route.
- The posterior retroperitoneal approach utilizes the prone jack-knife position. In addition to the advantages and disadvantages of the retroperitoneal approach, it also allows access to both glands for bilateral procedures.
- Tumor size, obesity, and the learning curve are the most important factors influencing operative outcome.
- The aim of a right-sided laparoscopic adrenalectomy is to remove the adrenal gland with early ligation of the adrenal vein. It is essentially a dissection of the inferior vena cava.
- The aim of a left-sided laparoscopic adrenalectomy is to remove the adrenal gland and periadrenal fat with early ligation of the adrenal vein. It is essentially a dissection of the left renal vein.
- At all times, patient safety is paramount, and it is essential that the practitioner has a low threshold for open conversion to control significant hemorrhage.

LAPAROSCOPIC PARTIAL ADRENALECTOMY

Günter Janetschek

*Department of Urology, KH der Elisabethinen, Teaching Hospital of
University of Innsbruck, Linz, Austria*

INTRODUCTION

The applications of laparoscopy in urology have expanded immensely in the last decade. Procedures that initially appeared to be immensely challenging are increasingly becoming routine. Undoubtedly, the era of minimally invasive surgery is now upon us. Laparoscopy has become the standard of care for benign surgical adrenal disease, due to its minimal invasiveness, equivalent operative time, shorter hospital stay, and faster convalescence. This is borne out of a number of retrospective and case control studies even though prospective, randomized trials are lacking (1–5). The surgical community has evolved from performing radical extirpative surgery to organ- and function-preserving surgery, without compromising the primary therapeutic goal. Such advances have occurred in many abdominal and thoracic solid organ systems, and recently in adrenal surgery. The concept of laparoscopic partial adrenalectomy or adrenal-sparing surgery includes the preservation of the functioning adrenal cortex to obviate the need for hormonal replacement therapy and its attendant, undesired consequences. The initial laparoscopic patial adrenalectomies were performed by Janetschek et al. for aldosterone-producing adenoma (6) and pheochromocytoma (7) and by Walz et al. for Cushing's adenoma (8). However, at the onset, it is clearly stated that partial adrenalectomy has limited application in highly selected patients, and, at this writing, is not an accepted treatment for the majority of surgical adrenal diseases.

RELEVANT ANATOMIC DETAILS

The arterial supply of adrenal gland is derived from three sources, namely the inferior phrenic artery, the aorta, and the renal artery. Adrenal vessels subdivide into minute branches prior to entering the adrenal cortex, where they further branch into capillaries ending in venous plexii within the adrenal medulla (9). On the right side, a single right adrenal vein emerges from the right adrenal apex and drains into the inferior vena cava. On the left side, a single left adrenal vein emerges from the middle portion of the gland and drains into the left renal vein. The left inferior phrenic vein, usually not easy to identify and typically communicating, can be injured during the dissection along the medial edge of the left gland due to its medial course. Hence, delicate dissection is essential to preserve the periadrenal vascular plexus, and the fibro-areolar tissue attachment of the remaining portion of adrenal gland.

Its rich vascular supply makes the adrenal a highly vascularized organ. Its segmental arterial supply enables partial adrenalectomy. If the main adrenal vein needs to be sacrificed during the surgical procedure, the adrenal venous drainage gets diverted

The rich vascular supply of the adrenal makes it a highly vascularized organ. Its segmental arterial supply enables partial adrenalectomy. If the main adrenal vein needs to be sacrificed during the surgical procedure, the adrenal venous drainage gets diverted through the venae comitantes, ensuring viability of the remnant gland.

through the venae comitantes, which accompany the artery, ensuring viability of the remnant gland.

INDICATIONS AND CONTRAINDICATIONS

Indications of Laparoscopic Partial Adrenalectomy

- Phaeochromocytoma—hereditary von Hippel–Lindau, multiple endocrine neoplasia
- Adrenal adenoma
- Aldosterone-producing adenoma—bilateral or unilateral
- Cushing's adenoma

Contraindications of Laparoscopic Partial Adrenalectomy

- Aldosteroma—concentric lesions, multiple ipsilateral tumors
- Adrenal carcinoma (or clinical suspicion, i.e., incidentaloma)
- Malignant pheochromocytoma
- Uncorrected coagulopathy

Technically, a solitary, peripheral adrenal lesion located at some distance from the main adrenal vein is preferable for partial adrenalectomy. laparoscopic partial adrenalectomy must be avoided in multiple aldosterone-producing adenomas, although laparoscopic partial adrenalectomy in the presence of two pheochromocytomas in the same adrenal gland has been reported (10).

The main adrenal vein may be sacrificed if needed, although every effort to preserve it should be made.

> The main adrenal vein may be sacrificed if needed, although every effort to preserve it should be made.

Main adrenal vein ligation does not compromise the postoperative function. However, adrenal functional recovery could be delayed in patients with pheochromocytoma, and temporary adrenal replacement may be needed. Previous abdominal surgery and morbid obesity are not absolute contraindications but may necessitate consideration of the retroperitoneal laparoscopic approach.

THERAPEUTIC CONCEPTS

Complete removal of the tumor is the primary goal of adrenal surgery. In the past, this almost routinely meant complete adrenalectomy. In case of bilateral tumors, bilateral adrenalectomy resulted in adrenal insufficiency necessitating for life-long hormonal replacement therapy. The hormonal replacement often consists of fixed dosage schedule, without respect for the physiological diurnal circadian rhythm. This may lead to overtreatment with increased incidence of osteoporosis, hypertension, diabetes, and other adverse effects of steroid replacement therapy. These patients are also at risk for undertreatment during periods of stress. Hypoandrogenism in females and addisonian crisis have been reported in 25% to 33% of cases (11,12). The quality of life is also significantly affected because 30% of patients experience significant fatigue and 48% consider themselves disabled (13). Hence, the concept of organ- and function-preserving surgery—partial adrenalectomy—was developed to address these concerns.

Aldosteronoma

The most common cause of hyperaldosteronism is an aldosterone-producing adenoma. Aldosteromas are rarely bilateral. Other causes of hyperaldosteronism include hyperplasia and, very rarely, carcinoma. Total adrenalectomy is the standard of care for unilateral adenomas, because the function is preserved by contralateral adrenal hypertrophy. Partial adrenalectomy was initially proposed for bilateral aldosteroma. Nakada et al. (14) compared the functional outcome of open unilateral partial versus total adrenalectomy in 48 patients. Despite adequate hormone levels and the lack of replacement therapy, patients who underwent unilateral total adrenalectomy demonstrated suboptimal response to stress. Conversely, patients undergoing tumor enucleation (partial adrenalectomy) had better functional reserve. Further, there were no tumor recurrences in either group over a mean follow-up of five years. As a result, indications for adrenal-sparing surgery have been expanded by select groups to include unilateral aldosteromas. Estimated incidence of malignancy in adrenal lesions smaller

than 6 cm in diameter is low—1 in 10,000 (15–17). However, micro- or macronodularity in an adjacent area of the gland is present in 7% to 38% of aldosteromas, a circumstance that is a clear contraindication for partial adrenalectomy (18).

Cushing's Syndrome

The major cause of Cushing's syndrome is adrenal hyperplasia. A small percentage of patients with Cushing's syndrome have a radiologically well-defined adenoma amenable to partial adrenalectomy. Cushing's adenomas are usually larger in size (several centimeters) than aldosteromas, and the adjacent adrenal parenchyma and the contralateral adrenal gland are often atrophic. laparoscopic partial adrenalectomy is technically more challenging in such cases. Because of this, the remnant adrenal recovers slowly, with the need for temporary steroid substitution.

Pheochromocytoma

The least controversial indication for partial adrenalectomy is hereditary pheochromocytoma.

> The least controversial indication for partial adrenalectomy is hereditary pheochromocytoma.

Pheochromocytoma is inherited in an autosomal dominant pattern and can be occasionally associated with different syndromes, including von Hippel-Lindau disease, multiple endocrine neoplasia type 2 (multiple endocrine neoplasia 2A/B), and neurofibromatosis type 1. In this specific subset of patients, an increased incidence of multifocal tumors, risk of delayed relapse over the long term, and detection of asymptomatic tumors on screening patients with known syndrome or relatives of a proband patient are not infrequent. Bilateral total adrenalectomy followed by hormonal replacement has been the standard treatment so far. Patients with hereditary unilateral or bilateral pheochromocytomas are candidates for partial adrenalectomy because of a definite risk of contralateral metachronous tumors formation. In this specific setting, open partial adrenalectomy has achieved encouraging results (19–23). The major drawback of partial adrenalectomy is the risk of recurrent tumors in the adrenal remnant due to medullary cells inevitably remaining within the spared cortex. Such tumor recurrence is, in fact, due to genetic predisposition rather than residual tumor from incomplete resection (Fig. 1). Hence, it is essential to weigh the benefits of adrenal function preservation against the risk tumor reoccurrence. The risk of reoccurrence after open partial resection for pheochromocytoma in patients with von Hippel-Lindau has been assessed in two large series. Walther et al. reported recurrent tumor in 1 of 13 patients after a median follow-up of 18 months (20). Neumann et al. noted one ipsilateral recurrence out of 29 patients undergoing partial adrenalectomy at a mean follow-up of six years (19). Patients with multiple endocrine neoplasia 2 have a 0% to 33% risk of developing

FIGURE 1 ■ Recurrent right pheochromocytoma after dissection. Note the clear distinction between tumor-containing adrenal gland and normal adrenal gland, and the adrenal vein could be spared after ligating the small venous tributary draining the tumor.
Abbreviations: L, liver; TU, tumor mass; AG, normal adrenal gland; AV, adrenal vein; VC, vena cava.

recurrence over a median follow-up of 54 to 88 months (22,23). Considering the available evidence, partial adrenalectomy appears to be well justified, given the rarity of malignant tumors in inherited pheochromocytoma (10). Subtotal adrenalectomy has been advocated (23–25), but this does not necessarily remove all medullary tissue and hence the risk of recurrence remains with the additional disadvantage of removing an excessive amount of cortical tissue, thus compromising the adrenal function.

Incidentaloma

Partial adrenalectomy for nonfunctioning incidentaloma has been performed by some authors (26). The main indication for surgical treatment of incidentaloma is the suspicion of malignancy. This is assessed based on tumor size greater than 5 cm, functional status (nonfunctioning), and high signal intensity on T2-weighted magnetic resonance imaging images. Watchful waiting is well accepted for lesions smaller than 3 cm. Lesions between 3 and 5 cm represent the main area of controversy. However, despite the majority of these lesions ultimately proving to be benign on final pathology, malignancy can occur occasionally (27). Hence, unilateral total adrenalectomy still remains the gold standard treatment for patients with a normal contralateral adrenal gland, with no predisposition for multiple tumors, and with suspected malignant lesions.

PREOPERATIVE INVESTIGATION

Preoperative investigations include radiological imaging to study the anatomical details and endocrinological investigation to determine the functional status. Elevated plasma or urinary aldosterone level indexed against urinary sodium excretion, and measured after sodium loading in combination with previously demonstrated low peripheral renin activity during sodium depletion, is the biochemical hallmark of hyperaldosteronism. Pre- and post-contrast computed tomography scan is the most accurate imaging modality. Conversely, small adrenal lesions are often not well visualized with adrenal magnetic resonance imaging (28). Twenty-four hour urine cortisol and plasma cortisol levels and adrenocorticotrophic hormone after dexamethasone suppression test are the cornerstone of biochemical diagnosis of cortisol-hypersecreting Cushing's adenoma. A 24-hour urine analysis for norepinephrine, epinephrine, and vanillylmandelic acid is mandatory whereas serum norepinephrine and epinephrine levels are less sensitive in diagnosing pheochromocytoma (29).

Combination of computed tomography, magnetic resonance imaging, and ^{131}I metaiodo-benzylguanidine scintigraphy allows accurate localization of virtually all pheochromocytomas (30). The authors use surface- and volume-rendered three-dimensional spiral computed tomography datasets for preoperative planning of laparoscopic partial adrenalectomy. Interactive visualization of volume-rendered computed tomography images are helpful for preoperative planning and successful performance of the procedure, whereas color-coded surface-rendered computed tomography datasets are more accurate and convenient for intraoperative reference.

PREOPERATIVE OPTIMIZATION

Patients with hyperaldosteronism should have adequate control of blood pressure and correction of hypokalemia and other electrolyte abnormalities. Alpha-blockers, namely phenoxybenzamine, and beta-blockers are administered in patients with pheochromocytomas to control reflex tachycardia when needed. The authors initiate administering these drugs three to four weeks prior to surgery and assess their efficiency by monitoring the improvement of symptoms, stabilization of blood pressure, and the presence of mild orthostatic hypotension. Following this concept, the mortality of patients with pheochromocytoma has declined to 1% (31). A different approach to manage hypertension using calcium channel blockers started as late as 24 hours prior to surgery has shown good results (32).

PHEOCHROMOCYTOMA: POTENTIAL SURGICAL RISKS

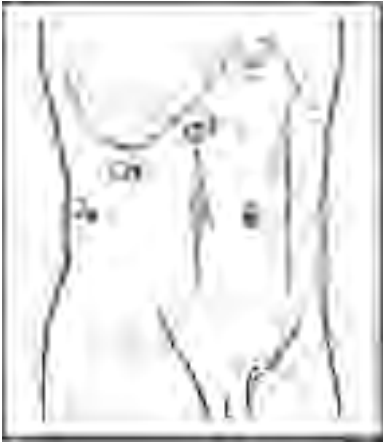
Long-standing hypertension can produce end-organ damage resulting in heart failure, catecholamine-induced cardiomyopathy, stroke, and retinal damage. Such patients with pheochromocytoma constitute a high-risk group. Intraoperative manipulation of the tumor may induce excess catecholamine release resulting in life-threatening hypertensive crisis. Although it has been speculated that pneumoperitoneum may induce a hypertensive crisis owing to hypercapnia or positive pressure, available evidence


FIGURE 2 ■ Typical trocar positions for right-side transperitoneal approach.

suggests to the contrary (33,34). In the author's experience, severe hypertension was triggered only by direct manipulation of the adrenal gland and not by pneumoperitoneum. Hence, laparoscopic tissue dissection is kept to a minimum, and a direct transperitoneal approach to the adrenal vein is preferred (Fig. 2) (7). Interestingly, when performing partial adrenalectomy without clamping or dividing the adrenal vein, no major problem was encountered in authors' series (7) owing to effective alpha blockade.

Because patients are often volume depleted, there is a potential danger of hypotension after removal of the tumor. This risk is best avoided by adequate preemptive fluid replacement with crystalloids preoperatively.

ANESTHETIC MANAGEMENT

Patients with pheochromocytoma need expert intraoperative care by experienced anesthesiologists. Invasive, continuous monitoring of arterial blood pressure and close monitoring of partial pressure of arterial carbon dioxide are essential. Hypertensive crises are treated with sodium nitroprusside, nitroglycerin, labetolol, esmolol, urapidil, or magnesium sulphate depending upon the specific patient condition.

SURGICAL TECHNIQUE

Laparoscopic approaches to the adrenal gland can be transperitoneal, retroperitoneal lateral, or retroperitoneal posterior. Although each of these approaches have their own advantages and disadvantages, the choice of approach depends on surgeon's experience and preference. The transperitoneal approach is the most popular, because of easier orientation. However, delayed bowel function and adhesion formation can possibly occur. The retroperitoneal approach is gaining popularity because it allows direct access to the adrenal gland without interfering with intra-abdominal organs. However, with this approach, the working space is limited and anatomical landmarks may be difficult to recognize especially for the beginner laparoscopist. The only randomized, prospective study on this topic documented equivalent patient outcomes between transperitoneal and retroperitoneal adrenalectomy (35). The authors prefer the transperitoneal approach because it allows direct approach to the adrenal vein especially on the right side where the adrenal gland is just posterior to the peritoneal sac. This is particularly important in pheochromocytoma. Walz et al. and Baba et al. popularized the retroperitoneal posterior approach for adrenalectomy (36,37). Sasagawa et al. have successfully performed laparoscopic partial adrenalectomy through this approach (26).

Transperitoneal Approach

Following general anesthesia, a nasogastric tube and a urinary catheter are placed. The patient is positioned in the modified 45° flank position with minimal flexion of the table. All the pressure points are well padded. Once strapped to the table by a wide tape across the hips, the patient is rotated toward the surgeon for another 30° to 40° to facilitate spontaneous, gravity-induced displacement of the bowel off the kidney. A 12-mmHg pneumoperitoneum is created, and the CO_2 is prewarmed with a heat exchanger integrated in the insufflation tubing to prevent catecholamine release due to cold stress. The primary port (10 mm) is placed pararectally 5 cm above the umbilicus on the affected side. Two secondary ports (5 or 10 mm) are placed in the ipsilateral subcostal area to form an equilateral triangle. Three trocars are usually sufficient on the left side. An optional fourth trocar can be placed if necessary, especially on the right side. The authors routinely use a robotic arm (AESOP 3000[®a]) to hold the camera and to provide a steady good quality picture. On the right side, after retracting the liver anteriorly, a vertical incision is performed on the posterior peritoneum along the inferior vena cava and continued laterally at a right angle, parallel to the lower margin of liver (Fig. 3). Because the adrenal gland lies directly under the peritoneum, this maneuver usually exposes the gland without the need to mobilize the colon or the duodenum. The right main adrenal vein has a consistent location lateral to the inferior vena cava. The left adrenal gland requires wider mobilization of the descending colon and the spleen. As such, the peritoneum is incised along the line of Toldt and the incision is continued upward along the spleen to allow medial descent of the spleen away from the adrenal gland. The splenocolic ligament may be incised as needed. After adequate exposure the adrenal gland, intraoperative laparoscopic color Doppler ultrasound

FIGURE 3 ■ Line of incision of the peritoneum on the right and left side to achieve optimum exposure.

[a]Computer Motion, Goleta, CA.

FIGURE 4 ■ Intraoperative ultrasound showing the liver and solitary tumor mass and adrenal vein. *Abbreviations*: L, liver; AG, adrenal gland.

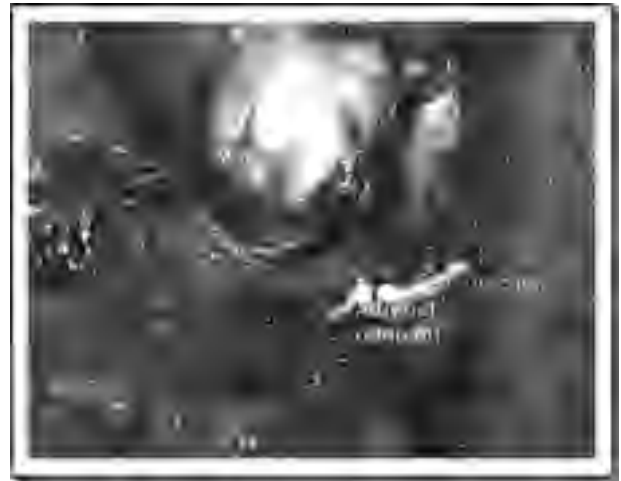
with 7.5-MHz transducer is a valuable adjunct to image the gland, the tumor, and the adrenal vein (Fig. 4) (38). The dissection of the tumor depends on its location and relationship to the vein. The tumor margin has to be identified and partial removal of the adipose tissue surrounding the tumor may be necessary to clearly delineate the tumor. The tumor is dissected with a small rim of normal adrenal gland to achieve an oncologically safe removal. The adrenal gland parenchyma should not be directly grasped, because of easy friability leading to bleeding. Various techniques of dissection have been proposed. However, the authors prefer preliminary bipolar coagulation along the intended line of dissection and cutting with endoscissors, which allows precise dissection. Harmonic scalpel is also an effective tool to divide the adrenal gland while securing hemostasis (39). The use of a vascular stapler, although feasible (40), does not allow precise dissection. Suture ligature has been used by Walther et al. (41). Every possible effort to spare the adrenal vein should be made, although it can be sacrificed if it is deemed necessary for definitive tumor clearance.

The cortex attached to the surrounding connective tissue via a wide strip of undisturbed tissue containing small arteries and veins is spared. The cut surface is covered with fibrin glue or similar hemostatic agents as a precautionary measure to avoid secondary bleeding. The postoperative viability of adrenal remnants after main adrenal vein division has been elegantly shown with ^{131}I adosterol scintigraphy by Ikeda et al. (42). The tumor is entrapped in an impermeable retrieval bag system and extracted through the primary port. All port sites are closed with fascial and subcuticular sutures after leaving an optional drain at the discretion of the surgeon.

> The cortex attached to the surrounding connective tissue via a wide strip of undisturbed tissue containing small arteries and veins is spared.

Retroperitoneal Approach

Comparing the lateral and posterior retroperitoneal approaches for total adrenalectomy, Baba et al. (37) found that the retroperitoneal posterior approach allowed direct access to the main vascular supply prior to gland manipulation. Sasagawa et al. (26) reported their experience of partial adrenalectomy using a posterior retroperitoneoscopic approach. The patient is positioned in low jackknife position with the trunk–thigh hinge of the table used as a flexion point to open the relevant posterior lumbar area between the 12th rib and iliac crest. A 20-mm transverse muscle splitting incision is made below the tip of 12th rib for the primary port. The retroperitoneal space is accessed by digital dissection. The use of a commercially available balloon dilator is optional. After creating the space, two 10-mm trocars are placed 2 to 3 cm medial and lateral to the first port by finger guidance. A blunt-tip trocar is inserted as the primary port and fixed with sutures to avoid gas leak. CO_2 is insufflated into the retroperitoneum. Dissection begins by incising the Gerota's fascia from just below the diaphragm to the level of renal pedicle along the medial crus of the diaphragm. On the left side, adrenal arteries including middle adrenal artery need to be clipped before isolating the main adrenal vein and inferior phrenic vein cranial to

FIGURE 5 ■ Removed tumor mass.


the renal pedicle. On the right side, multiple adrenal arteries are encountered before reaching the inferior vena cava and main adrenal vein. Further steps of dissection depend on the location of the tumor and are akin to the transperitoneal approach (Fig. 5).

RESULTS

Following the demonstration of the feasibility of laparoscopic partial adrenalectomy (6), several authors have reported on short-to-medium term follow-up results of small series of patients with aldosterone adenoma. Al-Sobhi et al. deemed transperitoneal laparoscopic partial adrenalectomy in seven patients with aldosterone-producing adenomas as effective and safe—six patients had normalization of blood pressure and no recurrence at a median follow-up of 12 months (43). Jeschke et al., who employed a transperitoneal approach in 13 patients with aldosterone-producing adenoma, were able to remove the tumor (mean tumor size, 2.1 cm) with negative margins. The mean operative time was 99 minutes, and blood loss was 78 mL. Mean hospital stay was 4.3 days (range, 2–6 days). Normal blood pressure, serum electrolytes, and aldosterone and no local recurrence were observed at a median follow-up of 39 months (44). The same transperitoneal approach was used by Ishikawa et al. in 11 patients with benign adrenal tumors. Operative time for laparoscopic partial adrenalectomy was shorter compared to total adrenalectomy (92 vs. 154 minutes, respectively) (45). Kok and Yapp prospectively reviewed eight patients who underwent laparoscopic partial adrenalectomy for aldosterone-producing adenomaaldosterone-producing adenoma (seven by enucleation and one by vascular stapler). At a mean follow-up of 25 months, hypertension was cured in seven patients and medication requirement significantly reduced in one patient (46). Ikeda's experience in seven patients with aldosterone-producing adenomas and three patients with pheochromocytoma showed no correlation between adrenal vein preservation and the functional status of the adrenal gland, as assessed by postoperative ^{131}I adosterol scintigram (42). At a mean follow-up of 24 months for aldosterone-producing adenoma patients and 33 months for pheochromocytoma patients, the hormone levels returned to normal. Munver et al. employed this technique successfully in two patients and reviewed worldwide experience (47). Imai et al. effectively used vascular staplers during laparoscopic partial adrenalectomy in five patients with lesions located at the adrenal poles (48). Meria et al. reported a large series of laparoscopic management of primary hyperaldosteronism in 212 consecutive patients, including 20 cases of transperitoneal laparoscopic partial adrenalectomy (49). At a mean follow-up of 44 months, the longest reported to date, hypokalemia was cured in all patients and hypertension was cured or significantly improved with reduction of medication requirements.

The safety and efficacy of laparoscopic partial adrenalectomy for hereditary pheochromocytoma was shown by Janetschek et al. (7). Six patients, two with bilateral disease, successfully underwent laparoscopic partial adrenalectomy. The feasibility of laparoscopic partial adrenalectomy in the presence of more than one tumor in the gland, tackling both adrenal glands, and managing the extra-adrenal pheochromocytoma at the same time was assessed. Blood pressure and urine catecholamines returned to normal and none of the patients required steroid supplementation. After a mean follow-up of

13.5 months (range, 3–18 months), no recurrence was noted. Walther et al. used silk suture ligation and harmonic scalpel in three patients, among whom one had bilateral disease, and removed seven tumors by laparoscopic partial adrenalectomy. During short follow-up, there was no need for steroid supplementation and no tumor recurrence.

Sasagawa et al. (26) performed partial adrenalectomy by the posterior retroperitoneoscopic approach in 13 patients with aldosterone-producing adenoma, 10 with Cushing's adenoma, three with pheochromocytoma, two with myelolipoma, one with ganglioneuroma, and 18 with a nonfunctioning tumor larger 3 cm (total, $n = 47$). Mean operative time was 198 minutes, blood loss 40.8 mL, and open conversion rate 2.1%. Due to the impact of the learning curve, significant operative time reduction was noted in the 26 most recent cases compared to initial cases. Walz et al. reported their experience with laparoscopic management of pheochromocytomas and paraganglionoma, including partial adrenalectomy in 19 patients (50). A retroperitoneal approach was predominantly used and a combination of electrocoagualtion, harmonic scalpel, and clips was employed as needed. In seven patients with bilateral disease, partial adrenalectomy was performed, at least unilaterally. All patients had normalization of their biochemical profiles and had no recurrence after a mean follow-up of 34 months. Only one patient in the bilateral group needed cortisol replacement (10 mg hydrocortisone). Interestingly, the main adrenal vein could not be spared in any of these seven patients because of tumor location. Neumann et al. meticulously evaluated the functional result of laparoscopic partial adrenalectomy in four patients with pheochromocytoma (51). Two to 24 months following surgery, all patients were normotensive, had normal sodium, glucose, aldosterone, rennin, and serum cortisol concentrations, and a normal 24-hour excretion of norepinephrine, epinephrine, and vanillylmandelic acid. Imaging failed to disclose any recurrence. adreno corticotrophic hormone stimulation test showed normal cortisol responses.

LAPAROSCOPIC PARTIAL ADRENALECTOMY FOR RECURRENT PHEOCHROMOCYTOMAS

The author reported the first case of laparoscopic partial adrenalectomy for recurrent pheochromocytoma in the literature (52). Walz et al. demonstrated successful laparoscopic surgical treatment of three locally recurrent pheochromocytomas following open transperitoneal surgery, including one case of partial resection (50). They noted limited scarring around the recurrent tumors allowing clear and rapid identification of landmarks and neoplasm, and recommended endoscopic surgery for recurrent pheochromocytomas in experienced hands. In the author's personal experience, laparoscopic partial adrenalectomy was attempted on seven recurrent tumors in five patients with hereditary pheochromocytoma and was successful in five (71%). Total laparoscopic adrenalectomy was necessary in two cases (Table 1).

TABLE 1 ■ Patient Demographics and Tumor Characteristics

No.	Age	Sex	Syndrome	Pheochromocytoma	Previous surgery	Laparoscopic surgery
1	60	F	VHL	R: 2.5, L: 2.0 L retroperitoneum lateral to inferior mesenteric artery 3.5, aortic bifurcation 1.0	L: OPA, R: open exploration ileocolic Area: open exploration	L: TA, R: LPA, excision of paragangliomas
2	20	M	VHL	L: 4.0, 2.0	L: OPA	L: LPA

SUMMARY

- The concept of laparoscopic partial adrenalectomy or adrenal-sparing surgery includes the preservation of the functioning adrenal cortex to obviate the need for hormonal replacement therapy and its attendant, undesired consequences.
- Partial adrenalectomy has limited application in highly selected patients, and, at the time of writing, it was not accepted treatment for the majority of surgical adrenal diseases.
- Micro- or macronodularity in an area of the gland adjacent to an aldosteronoma is a clear contraindication for partial adrenalectomy.
- Laparoscopic partial adrenalectomy of large-sized Cushing's adenomas is technically challenging.
- The least controversial indication for partial adrenalectomy is hereditary pheochromocytoma. Patients with unilateral or bilateral pheochromocytomas are candidates for partial adrenalectomy because a definite risk of contralateral metachronous tumor formation exists.
- Partial adrenalectomy has limited application in highly selected patients, and, at the time of writing, it was not an accepted treatment for the majority of surgical adrenal diseases.

INTRODUCTION

> Pheochromocytomas are tumors of chromaffin cells located in the paraganglionic system and can occur in the adrenal glands or in the sympathetic chain.

Pheochromocytomas are tumors of chromaffin cells located in the paraganglionic system and can occur in the adrenal glands or in the sympathetic chain.

It has been estimated that one in two million people in the United States is affected each year by extra-adrenal pheochromocytoma. Sporadic pheochromocytoma has been found in 0.002% to 0.13% of the population, and is the sole cause of hypertension in less than 1% (1,2) of all newly diagnosed hypertension. In 15% to 50% of hereditary causes, of which von Hippel-Lindau disease and multiple endocrine neoplasia type 2 are the most common types, pheochromocytoma is present (3). About 10% of pheochromocytomas are extra-adrenal, although recent reports suggest that as many as 18% may occur in extra-adrenal locations (4,5).

EMBRYOLOGY

The paraganglion system comprises several groups of structures of neural crest origin, characterized by the presence of granule-storing chief cells. The classification of the extra-adrenal paraganglion system is based on the anatomic distribution, innervation, and microscopic structure into branchiomeric, intravagal, aorticosympathetic, and visceroautonomic paraganglia (6). Branchiomeric and intravagal paraganglia most commonly refer to chemoreceptors of the carotid bodies and aortic arch as well as the paraganglia of the head, neck, and superior mediastinum. Pheochromocytomas in these locations are called carotid body and glomus jugulare tumors. Tumors arising from these bodies are referred to as paragangliomas, and when functional are referred to as extra-adrenal pheochromocytomas or functional paragangliomas (7,8). Visceroautonomic paraganglia are found in the atrial septa, liver hilum, and bladder submucosa and associated with mesenteric vessels (6).

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical manifestations of paraganglioma are varied and related to tumor function. Micturitional headaches have been reported with functional bladder pheochromocytoma (9).

Functional tumors can cause classic paroxysmal hypertension, tachycardia, hypovolemia, and flushing. Nonfunctioning tumors may only be diagnosed when symptoms from local growth develop, i.e., palpable mass or abdominal pain.

> Functional tumors can cause classic paroxysmal hypertension, tachycardia, hypovolemia, and flushing. Nonfunctioning tumors may only be diagnosed when symptoms from local growth develop, i.e., palpable mass or abdominal pain.

Patients with hereditary pheochromocytoma typically present at younger ages, in the second to third decades, than sporadic tumors. Hereditary pheochromocytoma syndromes include von Hippel-Lindau disease, multiple endocrine neoplasia type 2, neurofibromatosis type 1, and familial carotid body tumors. Tumors in von Hippel-Lindau disease patients identified by screening tend to be less symptomatic, smaller, and less functional when compared to sporadic pheochromocytoma (10).

Biochemical assays testing for elevated plasma and urine catecholamines have been the mainstay in screening for pheochromocytoma. These assays have their limitations,

Measurements of plasma-free metanephrines have been shown to be a more sensitive biochemical assay for the detection of pheochromocytoma.

Localization of a suspected pheochromocytoma or paraganglioma can occasionally be challenging because these tumors can occur anywhere along the sympathetic chain from the carotid bodies to the adrenergic plexus of the bladder.

Laparoscopy is now used to remove adrenal and extra-adrenal pheochromocytoma, leaving open exploration as a less-used option for patients with bulky, invasive tumors or many sites of metastases.

Patients are evaluated two to three months after surgery with imaging and catecholamine studies to confirm removal of all tumors. Metaiodobenzylguanidine scanning along with cross-sectional imaging is used as clip artifact, and postoperative changes can decrease the sensitivity of computed tomography and magnetic resonance imaging if used as the sole postoperative-imaging modality.

Patients undergo pharmacologic blockade before surgery to avoid the complications of catecholamine excess.

A transperitoneal laparoscopic approach to the retroperitoneum similar to that employed during laparoscopic retroperitoneal lymphadenectomy for testicular germ cell tumors is suitable for most extra-adrenal pheochromocytoma.

because catecholamines are normally produced by sympathetic nerves and adrenal medulla; elevated catecholamine levels are not specific to pheochromocytoma. In addition, some pheochromocytomas secrete catecholamines at low levels or episodically leading to false-negative results.

Measurements of plasma-free metanephrines have been shown to be a more sensitive biochemical assay for the detection of pheochromocytoma. Metanephrines and normetanephrines are the *o*-methylated metabolites of catecholamines, and the measurement of plasma metanephrines has been shown to have greater than 97% sensitivity compared to 63% to 85% for other tests (11–13).

Conversion of norepinephrine to epinephrine requires the enzyme phenyl-ethanolamine-*N*-methyltransferase. This enzyme is found only in the adrenal medulla and organ of Zuckerkandl; theoretically extra-adrenal pheochromocytoma should present with symptoms of excess norepinephrine and with elevated plasma normetanephrines, although exceptions have been seen in tumors arising in the organ of Zuckerkandl (4,14).

Localization of a suspected pheochromocytoma or paraganglioma can occasionally be challenging because these tumors can occur anywhere along the sympathetic chain from the carotid bodies to the adrenergic plexus of the bladder (6,7).

Paraganglioma are most commonly found in the para-aortic region near the renal vessels; the next most common location is at the aortic bifurcation or organ of Zuckerkandl. Bladder, thoracic cavity, and neck are less common locations (4,15). While up to 18% of pheochromocytoma will have an extra-adrenal location, 15% to 24% of these patients will have multiple tumors and such incidence is even greater in patients with hereditary syndromes (4,14,16).

As a result of the multifocality of these tumors, historical surgical approaches mandated exploratory laparotomy, with careful abdominal and retroperitoneal exploration for occult disease. Modern preoperative imaging has replaced the need for full open exploration of the abdomen, allowing minimally invasive procedures to be used.

Laparoscopy is now used to remove adrenal and extra-adrenal pheochromocytoma, leaving open exploration as a less-used option for patients with bulky, invasive tumors or many sites of metastases.

A combination of functional and anatomic imaging provides the most accurate localization for suspected disease. Computed tomography and magnetic resonance imaging have sensitivities reaching 90% in detecting extra-adrenal disease; however, specificity is in the 30% to 50% range (17,18). Small lymph nodes or retroperitoneal tumors can be identified with computed tomography imaging. The most widely studied functional imaging study for pheochromocytoma is the I31-metaiodobenzylguanidine scan. Metaiodobenzylguanidine imaging complements cross-axial imaging, in that it provides specificity approaching 100% and a sensitivity of 83% to 90% (18,19). Recently, positron emission tomography scanning has been utilized as an adjunct in patients with positive biochemical markers and negative metaiodobenzylguanidine imaging (18,19). Clinically, metaiodobenzylguanidine imaging will detect pheochromocytoma, whereas cross-axial imaging will provide detailed anatomic relationships between the tumor and surrounding structures to allow for preoperative planning. Figure 1 outlines an imaging algorithm for patients who have suspected disease after positive biochemical testing.

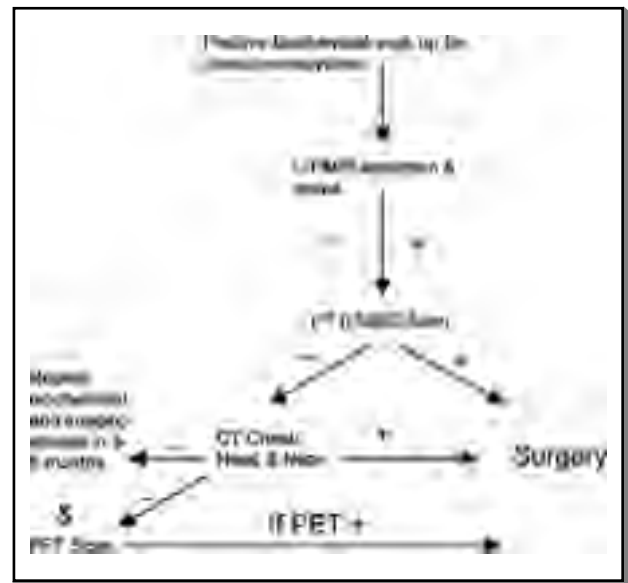
Patients are evaluated two to three months after surgery with imaging and catecholamine studies to confirm removal of all tumors. Metaiodobenzylguanidine scanning along with cross-sectional imaging is used as clip artifact, and postoperative changes can decrease the sensitivity of computed tomography and magnetic resonance imaging if used as the sole postoperative-imaging modality.

SURGICAL TECHNIQUE

Patients undergo pharmacologic blockade before surgery to avoid the complications of catecholamine excess.

Preoperative blockade consisted of metyrosine 250 mg t.i.d. and phenoxybenzamine 10 mg b.i.d. for two weeks; the dose of metyrosine is increased to 500 mg t.i.d. as tolerated. The night before surgery patients receive 50 mg phenoxybenzamine and 500 mg of metyrosine and are hydrated aggressively.

A transperitoneal laparoscopic approach to the retroperitoneum similar to that employed during laparoscopic retroperitoneal lymphadenectomy for testicular germ cell tumors is suitable for most extra-adrenal pheochromocytoma.

FIGURE 1 ■ Algorithm for localization of pheochromocytoma. *Abbreviations*: CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography; MIBG, metaiodobenzylguanidine.


Briefly, after the induction of general anesthesia, the patient is placed in the lateral decubitus position. A 10 mm Hassn port is initially placed near the level of the umbilicus along the lateral border of the rectus muscle and used to insufflate the abdomen. Lateral port placement allows good visualization behind the great vessels. Using a 30° lens laparoscope, two (5 or 10 mm) working ports are placed in the ipsilateral abdomen in a triangular shape. Patients with small tumors not requiring many 10 mm clips may be treated using 5 mm ports. In patients with right-side paragangliomas (inter-aorta-caval or right renal hilar tumor), an additional port is placed in the midline caudal to the xyphoid for liver retraction as needed.

For right-sided tumors below the renal vein, the ascending colon and duodenum are mobilized and retracted medially to expose the entire retroperitoneum. Left-sided tumors are visualized after mobilizing the colon medially to the aorta. The full flank position usually allows the overlying structures to fall medially after mobilization. An additional port for retraction can be added if visualization is not adequate. The inferior vena cava and right renal vein are identified, and borders carefully defined using sharp and blunt dissections in the area of the tumor. The right gonadal vein and ureter are isolated and retracted away from the tumor as necessary. Care is taken at the insert of the right gonadal vein to prevent avulsion requiring suturing of the vena cava.

For left-sided tumors, the descending colon, distal transverse colon, spleen, and distal pancreas are mobilized as needed and allowed to be retracted medially by gravity. The lateral margin of the aorta is identified in the location of the tumor found on preoperative imaging. The renal hilum can be defined and the right renal artery traced proximally to its aortic origin to define and preserve this structure if tumors are located in this area. At the inferior pole of the kidney, the ureter is found just lateral to the gonadal vein and isolated laterally for safety.

After the retroperitoneum is opened adequately and inspected visually, we perform ultrasonography to better examine the surgical field.

Intraoperatively, a 7.5 MHz flexible laparoscopic ultrasound probe is used to look for other retroperitoneal masses possibly not seen on preoperative imaging or visible inspection.

Once the paraganglioma is located and its margins defined, the tumor can be mobilized away from the great vessels and the renal vein.

Unlike the adrenal gland in which a well-defined anatomy is usually consistent and predictable, there is no set pattern of venous drainage or arterial supply in paraganglioma. Any tumor vessel of substantial size is isolated and doubly clipped before its division.

Once the tumor is freed from its neighboring large blood vessels, the remaining dissection is performed using harmonic scalpel or clips. Care should be taken to occlude

Intraoperatively, a 7.5 MHz flexible laparoscopic ultrasound probe is used to look for other retroperitoneal masses possibly not seen on preoperative imaging or visible inspection.

Unlike the adrenal gland in which a well-defined anatomy is usually consistent and predictable, there is no set pattern of venous drainage or arterial supply in paraganglioma. Any tumor vessel of substantial size is isolated and doubly clipped before its division.

any lymphatic tissue to prevent a postoperative leak. A formal lymph-node dissection is not routinely performed, but tried to remove all tissue in the area of the tumor, skeletonizing the great vessels and prevertebral fascia. The surgical field is also carefully examined for any enlarged lymph nodes. The finding of pheochromocytoma metastases on frozen section could lead to a wider excision, either laparoscopic or open. The tumor is placed into an Endocatch®a bag and removed through an enlargement of the camera port. After hemostasis is evaluated at low pneumoperitoneum pressure, the surgical area is reinspected visually and with ultrasound for any tumor remnant. Port sites are closed in the standard fashion.

DISCUSSION

Extra-adrenal pheochromocytoma is an uncommon manifestation of a rare disease, and historical series have reported open surgical techniques to achieve cure. As biochemical testing and radiographic imaging have improved, minimally invasive procedures have been introduced into the management of these patients.

> The advent of laparoscopy, combined with the development of sensitive biochemical assays and improved imaging, required reevaluation of all the aspects of the management of pheochromocytoma, including extra-adrenal tumors.

The advent of laparoscopy, combined with the development of sensitive biochemical assays and improved imaging, required reevaluation of all the aspects of the management of pheochromocytoma, including extra-adrenal tumors.

Review of the literature reveals a limited number of series evaluating results of laparoscopic management of extra-adrenal pheochromocytoma (20–22). Table 1 summarizes the data from those series.

Size of tumor has not been a contraindication to a minimally invasive approach, as our last patient had a 6.7 cm tumor successfully resected. Review of laparoscopic series shows that of 24 paragangliomas resected in 17 patients, 23/24 were = 4 cm in size. Sixteen of these 17 patients underwent successful laparoscopic or retroperitoneoscopic resection of tumors. One conversion in our series occurred in a patient who had significant adhesion between the paraganglioma, the aorta, and the renal hilum. Postoperative complications are infrequent and are related to pulmonary and positional issues, with one patient from the National Cancer Institute series developing a gluteal hematoma and lower-extremity lymph edema which resolved with conservative management. Noteworthily, one patient in Janetscek's series developed self-limiting lymph ascites, which resolved after four weeks (22).

> Vigilant monitoring and control of intra-operative blood pressure are critical in patients with pheochromocytoma. Intraoperative hypertensive crisis can be avoided with adequate preoperative blockade.

Vigilant monitoring and control of intra-operative blood pressure are critical in patients with pheochromocytoma. Intraoperative hypertensive crisis can be avoided with adequate preoperative blockade.

The National Cancer Institute series had only one of seven patients with a systolic blood pressure greater than 200 mmHg, whereas Walz had only 4 of 52 patients undergoing laparoscopic surgery for adrenal or extra-adrenal pheochromocytoma with a systolic blood pressure greater than 200 mmHg (20,21).

Paragangliomas have been linked to more aggressive pathologic behaviors with malignancy rates up to 50% in some series (15,23,24). Neither Walz nor Janetschek reported any evidence of local recurrence in their respective series, although noted a

short follow-up interval. In their series, with a follow range of 6 to 48 months, the authors have not detected any local or distant recurrences.

Pheochromocytomas of the bladder are rare, with mostly case reports in the literature. Management of these tumors should parallel the approach to extra-adrenal pheochromocytoma.

Once the tumor is localized, adequate preoperative blockade is performed prior to any manipulation. Cystoscopically, these tumors tend to be submucosal with occasional mucosal ulceration (10,25–27).

Kozlowski et al. reported a case of successful laparoscopic partial cystectomy for extra-adrenal pheochromocytoma using a combination of endoscopic and laparoscopic excision (25). Endoscopically, a Collin's knife was used to excise the intravesical component while a standard four-diamond laparoscopic port placement, using ultrasonic shears, was used to complete the extravesical mobilization and excision of the tumor. A laparoscopic sac was used to remove the specimen. The defect was then repaired using interrupted 2-0 polyglactin sutures placed free hand and with an EndoStitch®[b] device (25).

Transurethral resection bladder tumor has been utilized in select case reports (10,27). However, partial cystectomy should be the initial approach to treat pheochromocytoma of the bladder. Although laparoscopic cystectomy and partial cystectomy are still in their infancy, they are a viable approach to all tumors of the bladder.

CONCLUSION

Pheochromocytomas and paragangliomas present multiple challenges to urologic surgeons in terms of diagnosis, localization, and appropriate surgical management. Laparoscopy has obvious advantages for patients including shorter convalescence time, decreased pain, and improved cosmesis. From the surgeon's standpoint, laparoscopy combined with ultrasound allows for complete exploration of the abdominal cavity and increased magnification. Reported series, although small and from centers with extensive laparoscopic experience, indicate that laparoscopy is indeed a safe and technically feasible approach for the treatment of extra-adrenal pheochromocytoma.

Margin notes (left column):

Pheochromocytomas of the bladder are rare, with mostly case reports in the literature. Management of these tumors should parallel the approach to extra-adrenal pheochromocytoma.

Transurethral resection bladder tumor has been utilized in select case reports. However, partial cystectomy should be the initial approach to treat pheochromocytoma of the bladder. Although laparoscopic cystectomy and partial cystectomy are still in their infancy, they are a viable approach to all tumors of the bladder.

SUMMARY

■ Functional extra-adrenal tumors can cause classic paroxysmal hypertension, tachycardia, hypovolemia, and flushing. Non-functioning tumors may only be diagnosed when symptoms from local growth develop, i.e., palpable mass or abdominal pain.

■ Laparoscopy is now used to remove adrenal and extra-adrenal pheochromocytoma, leaving open exploration as a less used option for patients with bulky, invasive tumors or many sites of metastases.

■ Patients must undergo pharmacologic blockade before surgery to avoid the complications of catecholamine excess.

■ A transperitoneal laparoscopic approach to the retroperitoneum similar to that employed during laparoscopic retroperitoneal lymphadenectomy for testicular germ cell tumors is suitable for most extra-adrenal pheochromocytoma.

■ Intraoperatively, a 7.5 MHz flexible laparoscopic ultrasound probe is used to search for other retroperitoneal masses possibly not seen on preoperative imaging or visible inspection.

■ Pheochromocytomas of the bladder are rare, with mostly case reports in the literature. Management of these tumors should parallel the approach to extra-adrenal pheochromocytoma.

INTRODUCTION

The adrenal glands are known to harbor a variety of benign and malignant tumors. Due to the small size and location of the adrenals, lesions of the adrenal gland are rarely detected due to local symptoms. Instead, most adrenal tumors are diagnosed either incidentally or because of impaired hormonal activity.

Hormonally active adrenal lesions, tumors suspicious for carcinoma, or nonfunctioning adrenal lesions 5 cm or greater in size are suitable for surgical removal.

Traditionally, surgical procedures involving the adrenal gland were performed through an open incision with a variety of approaches. In 1992, the laparoscopic approach to adrenalectomy was introduced (1), offering a less invasive alternative to open adrenalectomy.

Parallel to the growth of experience with laparoscopic adrenalectomy, the indications for laparoscopic adrenalectomy have expanded while the absolute contraindications have diminished. Indeed, laparoscopic adrenalectomy has become a standard of care and the technique of choice for most benign surgical adrenal lesions.

The basic diagnosis and hormonal evaluation, indications, pre-operative considerations, and results of laparoscopic adrenalectomy for benign tumors of the adrenal gland are discussed in this chapter.

DIAGNOSIS

Adrenal lesions historically were diagnosed secondary to clinical manifestations of endocrinopathies. However, widespread use of abdominal ultrasound, computed tomography scanning, and magnetic resonance imaging has led to the not infrequent finding of the incidental adrenal mass. Figures 1 and 2 show typical examples of adrenal lesions diagnosed on computed tomography and magnetic resonance imaging. The differential diagnosis of an incidental adrenal mass is extensive and includes the benign nonfunctioning adenoma, hormonally active cortical tumor, myelolipoma, pheochromocytoma, adrenocortical carcinoma, and metastatic lesion.

Tumors diagnosed incidentally on computed tomography scan or magnetic resonance imaging are managed according to size and hormone functional status.

Patients with hormonally active adrenal tumors, such as aldosteronoma, Cushing's syndrome, cortisol-secreting tumors, or pheochromocytoma should generally undergo surgical removal (2,3).

Thorough hormonal evaluation of these patients is critical because pre- and post-operative considerations regarding hypertensive control, electrolyte imbalances, and fluid shifts are paramount to ensure good surgical outcomes and minimize complications.

Sidebar text

Hormonally active adrenal lesions, tumors suspicious for carcinoma, or nonfunctioning adrenal lesions 5 cm or greater in size are suitable for surgical removal.

Indications for laparoscopic adrenalectomy have expanded while absolute contraindications have diminished. laparoscopic adrenalectomy has become a standard of care and the technique of choice for most benign surgical adrenal lesions.

Tumors diagnosed incidentally on computed tomography scan or magnetic resonance imaging are managed according to size and hormone functional status.

Thorough hormonal evaluation of these patients is critical because pre- and post-operative considerations regarding hypertensive control, electrolyte imbalances, and fluid shifts are paramount to ensure good surgical outcomes and minimize complications.

FIGURE 1 ■ An adrenal lesion on computed tomography.

FIGURE 2 ■ An adrenal lesion on magnetic resonance.

A summary of standard laboratory tests in the evaluation of an adrenal lesion is listed in Table 1.

Occasionally, medical magement of aldosteronomas may be satisfactory to circumvent the need for surgical management, particularly in patients who are poor surgical candidates (4). However, side effects of pharmacotherapy may become intolerable. Hormonally inactive tumors have traditionally been managed according to size.

- Hormonally inactive tumors less than 3 cm in size are almost always benign adenomas and generally require no further treatment unless an increased in size or clinical signs of hormonal activity are detected.
- Nonfunctional lesions between 3 and 5 cm in size generally require close follow-up with serial imaging studies every six months. These lesions should be removed if tumors demonstrate interval change in appearance or develop endocrine activity.
- Hormonally inactive tumors greater than 6 cm in size are worrisome for adrenocortical carcinomas, and thus surgical excision is recommended given the aggressive nature of adrenal cancer (5).

In one meta analysis, 105 of 114 adrenocortical carcinomas measured 6 cm or greater in diameter (6).

TABLE 1 ■ Routine Laboratory Tests Useful in the Evaluation of Adrenal Lesions

Laboratory test	Frequency of usage
Cushing's syndrome	
24-hr urine cortisol	Common
Plasma ACTH and plasma cortisol	Common
Low-dose dexamethasone suppression test	Occasional
High-dose dexamethasone suppression test	Occasional
Metapyrone stimulation test	Rare
Petrosal sinus ACTH measurement	Extremely rare
Hyperaldosteronism	
Unprovoked hypokalemia	Common
Plasma aldosterone level	Common
Urinary aldosterone level	Common
Aldosterone-to-renin ratio	Common
Postural stimulation test	Rare
Adrenal vein sampling of aldosterone	Extremely rare
Pheochromocytoma	
Plasma catecholamines	Common
Urine catecholamines	Common
Clonidine suppression test	Occasional
Adrenal vein sampling of catecholamines	Extremely rare

Abbreviation: ACTH, adrenocorticotropic hormone.

■ All lesions which are 5 cm or greater in size on computed tomography scan should be removed because computed tomography scan tends to underestimate the size of lesions by as much as 1 cm (7).
■ Open radical adrenalectomy with possible en bloc resection of adjacent organs is the preferred approach whenever adrenal carcinoma with local extension into adjacent organs such as the kidney, colon, or spleen, is a concern (8,9).

More recently, improvements in radiologic imaging techniques such as unenhanced and delayed enhanced computed tomography with densitometry, chemical-shift magnetic resonance imaging, and NP-59 scintigraphy have further assisted in differentiating benign from malignant neoplasms (10).

ALDOSTERONOMAS

Primary hyperaldosteronism (Conn's syndrome) is a rare etiology of hypertension (<1%). Other clinical manifestations of Conn's syndrome arise from an increased total body sodium content and a deficit in total body potassium. Symptoms include urinary urgency or frequency, nocturia, muscle weakness, paresthesias, or visual disturbances (4,11). Computed tomography scan or magnetic resonance imaging can detect adrenal adenomas as small as 1 cm in size. Laboratory manifestations include hypokalemia, elevated plasma and urinary aldosterone level, elevated serum aldosterone-to-renin ratio, and suppressed plasma renin activity (4,11). Once an important part of the evaluation, adrenal vein sampling is currently rarely used to confirm and localize the lesion.

Once the diagnosis is confirmed, medical control of hypertension and correction of hypokalemia should be instituted at least several weeks prior to adrenalectomy. The most effective medication for management of hyperaldosteronism is spironolactone, a competitive antagonist of the aldosterone receptor (4). Side effects of spironolactone include hyperkalemia, sexual dysfunction, gynecomastia, gastrointestinal disturbances, and metabolic acidosis (12). Alternative medications include potassium sparing diuretics, calcium channel blockers, or converting enzyme inhibitors (11). Adrenalectomy improves or cures hypertension in approximately 90% of patients (13).

CUSHING'S SYNDROME

Cushing's syndrome comprises the symptom complex resulting from excess circulating glucocorticoids, regardless of etiology (3). Non-adrenal causes of hypercortisolism include pituitary adenomas, ectopic corticotrophin production, and exogenous steroid use. The urologist is most often confronted with an adrenal lesion as the etiology of Cushing's syndrome.

Cushing's syndrome manifests with a variety of well recognized clinical features, including hypertension, truncal obesity, moon facies, easy bruising, and mood disorders. Diagnosis is confirmed by laboratory testing (3). Hypercortisolism is best diagnosed by 24-hour urinary cortisol measurement. The low-dose dexamethasone suppression test can be used to further diagnose Cushing's syndrome if urinary cortisol measurement is equivocal. Abdominal computed tomography scan and magnetic resonance imaging can identify adrenal adenomas or bilateral adrenal hyperplasia.

PHEOCHROMOCYTOMA

Successful surgical management of pheochromocytoma requires close collaboration among the surgeon, endocrinologist, and anesthesiologist.

It is essential to have an anesthesiologist familiar with pheochromocytoma, able to adequately manage blood pressure intra-operatively, and knowledgable about which anesthetic agents to avoid.

Pheochromocytomas can be challenging tumors to treat because of the unique manifestations of chronic and acute catecholamine excess. In general, catecholamine excess results in hypertension, tachycardia, and a host of clinical manifestations. Laboratory diagnosis is made by elevated levels of catecholamines in the blood and urine. Radiographic diagnosis is achieved with either computed tomography scan or magnetic resonance imaging. Magnetic resonance imaging classically demonstrates a bright image on a T2-weighted study. Additionally, metaiodobenzylguanidine nuclear medicine scanning can help confirm and localize pheochromocytomas. The treatment of choice for most pheochromocytomas is surgical excision.

Successful surgical management of pheochromocytoma requires close collaboration among the surgeon, endocrinologist, and anesthesiologist.

It is essential to have an anesthesiologist familiar with pheochromocytoma, able to adequately manage blood pressure intra-operatively, and knowledgable about which anesthetic agents to avoid.

With increasing worldwide experience with laparoscopic adrenalectomy, pheochromocytoma is no longer considered a contraindication to laparoscopic surgery.

In the past, all pheochromocytomas were treated through an open approach, with early control of the adrenal vein. With increasing worldwide experience with laparoscopic adrenalectomy, pheochromocytoma is no longer considered a contraindication to laparoscopic surgery. In fact, laparoscopic adrenalectomy for pheochromocytomas has now been performed successfully at many centers of laparoscopic excellence and reported in several series (14–16).

Regardless of the surgical approach chosen, preoperative medical preparation is essential, and includes optimal control of blood pressure with alpha blockade or calcium channel antagonists (2). Beta-blockers may be used to control reflex tachycardia after initiation of alpha blockade. In addition, aggressive fluid expansion is necessary to increase circulating plasma volume and prevent postoperative hypotension. Close intra-operative monitoring includes careful attention to blood pressure, central venous pressure, and urinary output. An arterial line and central venous line are routinely used, and occasionally a Swan-Ganz catheter is employed. Severe hypertension can be controlled with sodium nitropusside or phentolamine, and hypotension controlled with fluid resuscitation and norepinephrine.

INDICATIONS FOR LAPAROSCOPIC ADRENALECTOMY

The indications for laparoscopic adrenalectomy have expanded as more surgeons have become proficient with the technique and the advantages of this approach have become apparent. In many centers, laparoscopic adrenalectomy has become the surgical procedure of choice for the management of functional tumors less than 6 cm in size. Although the presence of pheochromocytoma was a relative contraindication for laparoscopic adrenalectomy in the past, it is clear that the procedure can be performed safely as long as the same precautions are taken as those for open surgery (14). The current indications for performing a laparoscopic adrenalectomy are listed in Table 2.

There are few contraindications to laparoscopic adrenalectomy. Absolute contraindications to laparoscopic adrenalectomy include uncorrectable coagulopathy and severe cardiopulmonary disease precluding general anesthesia. Patients who may not tolerate an open operation are generally poor candidates for laparoscopic adrenalectomy.

Patients who may not tolerate an open operation are generally poor candidates for laparoscopic adrenalectomy.

Relative contraindications to laparoscopic adrenalectomy include previous abdominal surgery or significant morbidity. Lesions greater than 8 cm in size, even if not suspected to be primary adrenal carcinomas, should be approached cautiously because of the increased risk of hemorrhage and injury to surrounding viscera.

With increasing experience in performing laparoscopic adrenalectomy, relative contraindications become less of a factor. In addition, a variety of approaches to laparoscopic adrenalectomy, including transperitoneal and retroperitoneal, have further decreased some of the relative contraindications. It is generally felt that a known or suspected primary adrenal carcinoma, particularly with extension into surrounding organs, should be removed by an open technique. Given the aggressive nature of the disease, the open approach allows for en bloc resection and potential removal of surrounding organs (8).

RESULTS OF LAPAROSCOPIC ADRENALECTOMY FOR BENIGN DISEASE

Worldwide experience with laparoscopic adrenal surgery has increased since its original description in 1992. Several centers have reported large series documenting the decreased blood loss, shortened hospital stay, and faster return to normal activity. Selected recent series in the literature are summarized in Table 3.

Gagner et al. reported on 100 consecutive laparoscopic adrenalectomy procedures performed using the transperitoneal approach (31). The lesions removed included pheochromocytomas, aldosteronomas, Cushing's lesions, and others. Mean operative time was 123 minutes, and estimated blood loss 70 cc. In this series, the open conversion

TABLE 2 ■ Indications for Laparoscopic Adrenalectomy for Benign Disease

Aldosterone secreting adrenal gland, adenoma, or unilateral hyperplasia
Cushing's syndrome secondary to adrenocortical adenoma
Nonfunctional adrenal mass ≤8 cm with negative metastatic workup
Nonfunctional adrenal mass ≤8 cm with progressive growth on CT or MRI
Adrenal pheochromocytoma (benign) ≤8 cm

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging.

rate was 3%, average length of hospital stay was three days or less, and postoperative morbidity was experienced by 12% of patients.

In the largest reported series, a combined experience of surgeons in Italy and the Netherlands by Lezoche et al. (21), a total of 216 laparoscopic adrenalectomies were performed using the anterior transperitoneal, lateral transperitoneal, or the posterior retroperitoneal approaches. The average operating time of all approaches was 100 minutes with a conversion rate of only 1.9%. Average hospital stay for all approaches was three to four days.

Studies comparing laparoscopic and open adrenalectomy have been conducted to determine if there are significant benefits provided by the laparoscopic approach (28,29,34–40). Overall, laparoscopic surgery requires longer operative time, particularly early in the learning curve. However, operative time decreases with increasing surgeon experience. In addition, the laparoscopic approach provides less blood loss, significantly less postoperative narcotic use, overall shorter hospital stay, and a faster return to normal activity. In one study, the costs of a laparoscopic and open adrenalectomy were comparable (41).

SUMMARY

- ■ Unquestioned advantages of the laparoscopic approach include shorter hospitalization and convalescence. In addition, even hormonally active lesions such as pheochromocytomas can be safely approached laparoscopically.
- ■ Relative contraindications to the laparoscopic approach include very large benign lesions and primary adrenal carcinomas.
- ■ Both the transperitoneal and retroperitoneal techniques yield satisfactory results.
- ■ Laparoscopic adrenalectomy has been shown to be a safe and effective approach to many forms of adrenal pathology. It should be considered the standard of care in the management of benign lesions of the adrenal gland that require surgical removal.

LAPAROSCOPIC SIMPLE NEPHRECTOMY: TECHNIQUE

Simon V. Bariol and David A. Tolley

Scottish Lithotriptor Centre, Western General Hospital, Edinburgh, U.K.

INTRODUCTION

Laparoscopic nephrectomy for benign disease is now a simple procedure but may prove to be very challenging, depending on the indication for surgery.

Laparoscopic nephrectomy for benign disease is now a simple procedure but may prove to be very challenging, depending on the indication for surgery.

Although most cases of benign disease can be managed by simple nephrectomy, inflammation or previous surgery, especially in the obese patient, may obliterate normal dissection planes, and radical ablative surgery in these circumstances may be more judicious. This chapter describes the technique of laparoscopic simple nephrectomy for benign disease in detail, including a number of practical tips designed to facilitate the procedure, based on the authors' experience of over 500 procedures.

PATIENT SELECTION

Indications

Laparoscopic simple nephrectomy is indicated in the management of benign renal disease associated with significant loss of function or that contributes to patient morbidity. This includes chronic pyelonephritis, obstructive nephropathy, renovascular hypertension, cystic disease (congenital or acquired), nonfunction due to stone disease and reflux nephropathy.

Contraindications

Untreated infection and coagulopathy are the only absolute contraindications to laparoscopic nephrectomy. Complication and conversion rates are highest in patients undergoing laparoscopic nephrectomy for severe inflammatory conditions of the kidney (e.g., xanthogranulomatous pyelonephritis, pyonephrosis) and should be regarded as relative contraindications for the inexperienced laparoscopist (1–4). Renal tuberculosis can be dealt with safely by laparoscopy, although operating times are longer compared with nephrectomy for other benign conditions (5). Obesity and previous abdominal surgery do not preclude a laparoscopic approach (6,7).

PREOPERATIVE PREPARATION

Specific Investigations

Preoperative evaluation includes full history and physical examination, routine blood tests, including group and save, and anesthetic assessment. It should be appreciated

that despite the many advantages of the laparoscopic approach to the patient, laparoscopic nephrectomy is a major procedure with significant mortality. Abdominal contrast computed tomography provides information regarding the size of the kidney and renal pelvis, the presence of stones or inflammation, vascular anatomy, and the state of the contralateral kidney. A nuclear renogram and diethylenetriaminepentaacetic acid scan provides important functional information to determine whether ablative surgery is appropriate. Ultrasound performed immediately prior to surgery, to re-assess the size of the renal pelvis and renal movement with respiration (as a marker of perirenal fibrosis) may also be helpful.

Upper Urinary Tract Drainage
A grossly enlarged hydronephrotic kidney, especially in the presence of infection should be drained, either with stent or preferably nephrostomy tube placement, at least 4 weeks prior to ablative surgery. The resulting reduction in size facilitates dissection. A delay of at least six weeks in the infected kidney will permit much of the associated inflammation to settle, thus facilitating the dissection. Urine from the obstructed kidney, collected at the time of drainage, should be sent for culture, and antibiotics commenced as appropriate. Mid-stream specimen of urine test is unreliable as a predictor of upper urinary tract infection in the presence of upper urinary tract obstruction (8). Uncomplicated hydronephrosis may be drained with a ureteric catheter at the time of laparoscopic nephrectomy to decompress the kidney and facilitate ureteric identification (9), however this maneuver is not essential (10).

Bowel Preparation
This is not performed routinely for laparoscopic nephrectomy for benign diseases. If preoperative imaging is suggestive of xanthogranulomatous pyelonephritis, full bowel preparation is recommended in case bowel injury occurs or bowel resection is required.

Informed Consent
Patients must be warned of the (small) risk of conversion to open surgery, particularly those with inflammatory conditions in which the risk is even greater. The kidney to be removed should be confirmed with the patient, and the patient is marked with indelible ink. Side should be indicated clearly on the operating list and the patient's consent form.

TECHNIQUE

Description
Anesthetic Considerations
Laparoscopic nephrectomy requires general anesthesia with muscle relaxation and endotracheal intubation (Table 1).

Patient Positioning
An indwelling urethral catheter is inserted. The patient is placed in a modified lateral decubitus position with the umbilicus over the break of the operating table. The table is flexed as required. Lumbar and thoracic supports with padding are placed behind the patient to secure the position. The arm on the ipsilateral side is flexed with the shoulder at 90° to the chest in an armrest, with padding over bony prominences; the contralateral arm is similarly flexed and protected (Fig. 1). A peripheral warming blanket is applied.

After the patient's skin is prepared and draped, the surgeon and scrub nurse stand facing the patient. The camera stack is moved to a comfortable position directly opposite the surgeon, and the assistant sits to the side of the operator.

Insufflation and Trocar Placement
The first port is placed at the lateral edge of the rectus muscle, between the level of the umbilicus and the transpyloric plane (which lies approximately half-way between the xiphisternum and umbilicus, Fig. 2). The peritoneum is entered under vision with sharp and blunt dissection. In patients with a history of previous abdominal surgery, particular care should be taken when opening the peritoneum, and the surgeon should introduce their index finger into the peritoneal cavity to sweep any abdominal wall adhesions prior to introducing the trocar.

CO_2 insufflation is commenced at low flow (less than 2 L/min) after introducing a blunt (Hasson) 12 mm trochar. The intraabdominal pressure should be no more than

TABLE 1 ■ Technique of Laparoscopic Simple Nephrectomy

Anesthetic	General anesthesia with muscular relaxation and endotracheal intubation
Patient positioning	Modified lateral decubitus position with umbilicus over break of operating table
Insufflation and trocar placement	Hasson or Veress needle technique; three to four trocars in triangle or diamond formation, secured with silk sutures
Initial assessment	Visual inspection of the upper abdomen and division of adhesions
Initial dissection	Colon mobilized medially by incising its lateral attachment
Identification of the lower pole	Lower pole elevated while dividing medial tissue advancing in the direction of the pedicle
Pedicle control	Elevate lower pole; blunt dissection using right-angled forceps and the sucker-irrigator tip; avoid excessive use of clips close to main vein; artery clipped with laparoscopic clips and divided, followed by ligation and division of the vein using Endo-GIA
Mobilization of the upper pole	Dissection continued close to the kidney avoiding hilum; combination of sharp and blunt dissection; consider using clips, harmonic scalpel or endo-GIA for perforating vessels
Ureteric division	Ligated with Liga clips and divided; final step before specimen retrieval
Specimen retrieval	Kidney grasped with heavy laparoscopic forceps; inspection for hemostasis; kidney removed in laparoscopic catchment bag in tact or after morcellation
Wound closure	Consider drain; retrieval site closed in two layers using continuous 0 PDS; 12 mm port sites closed with 0 Vicryl on a J needle; skin closed with clips or subcuticular suture

FIGURE 1 ■ Patient position for laparoscopic simple nephrectomy.

4 or 5 mmHg at this stage. A sudden increase in pressure during initial insufflation signals incorrect trocar placement. In this situation, insufflation is stopped and the reason for the problem identified. After insufflation of 1 to 1.5 L of gas, flow can be increased to a high rate (approximately 6 L/min) and intraabdominal pressure maintained at 12 to 15 mmHg. Rapid initial insufflation occasionally results in a severe bradycardia.

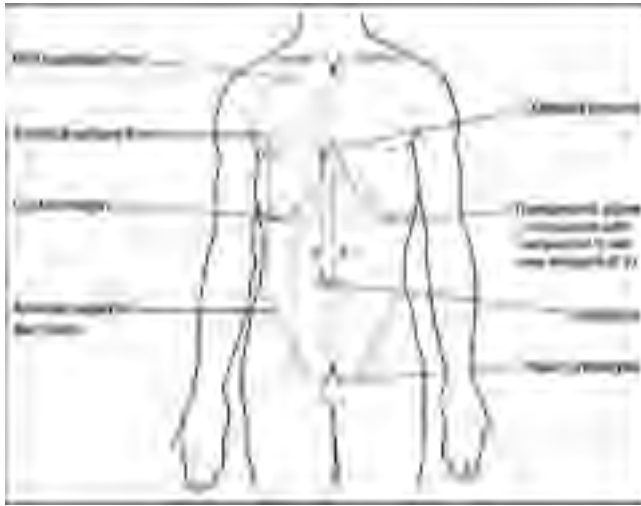
For right nephrectomy, two other main ports are inserted under laparoscopic control: a 5- to 12-mm port inferior to the costal margin and a 5-mm port at the level of the umbilicus, both in the anterior axillary line and roughly equidistant from the camera port; so the three ports form an isosceles triangle. For left nephrectomy, the 5- and 12-mm ports are reversed in position so that the larger port is always on the surgeon's right. This is to permit passage of 10-mm clip appliers and linear cutting/stapling devices. A fourth 5- to 12-mm port, if required for retraction, may be inserted in a lateral position, in line with the camera port near the tip of the 12th rib (Fig. 3). The trocars are secured using silk sutures through the skin.


FIGURE 2 ■ Surface anatomy.
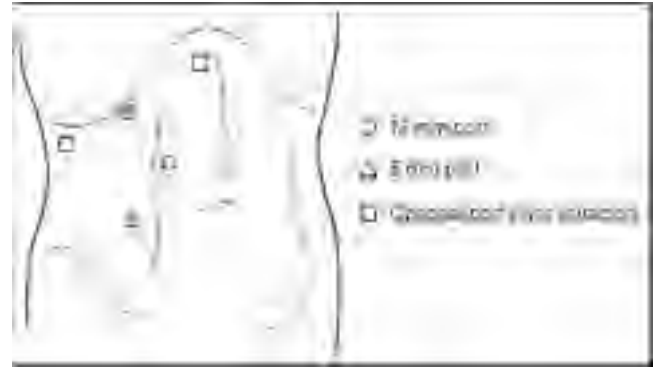

FIGURE 3 ■ Transperitoneal laparoscopic nephrectomy trocar placement.

Initial Assessment

Visual inspection of the upper abdomen is performed, and any adhesions are divided. Dissection is performed using laparoscopic scissors or the ultrasonic scalpel. The kidney is then identified, lying in the retroperitoneum behind the colon.

Initial Dissection

The colon is mobilized medially 4 to 5 cm below the lower pole by incising its lateral attachment; on the left side this corresponds with the white line of Toldt. Care should be taken during this mobilization: maintaining a safe distance from the colon to prevent diathermy injury and preserving the colonic mesentery. The different appearance of the fat associated with colonic mesentery (dark yellow/orange) and Gerota's fascia (pale yellow) is a useful guide to determining the correct plane. The mobilization should be carried caudally to expose the lower pole of the kidney. On the left side, mobilization should be extended cranially, sufficient to allow the spleen and tail of pancreas to fall medially and expose the hilum. On the right side, the colon should be mobilized above the hepatic flexure and the right triangular ligament incised. The duodenum, which lies immediately deep to the hepatic flexure, should also be mobilized medially.

Identification of the Lower Pole

After mobilization of the colon, Gerota's fascia is seen covering the renal outline. Using sharp and blunt dissection through Gerota's fascia in a craniocaudal direction, the lower pole is identified overlying the psoas muscle. The left-hand instrument is used to retract the lower pole in a lateral direction (that is, toward the abdominal wall), thus stretching the overlying tissue that is then divided by the right-hand instrument while advancing in the direction of the pedicle. A large window is opened up between the lower pole, psoas, and the kidney's medial attachments.

Occasionally, the surgeon encounters severe perinephric inflammatory reaction. In this case, the plane outside Gerota's fascia is often the better plane of dissection, and a radical excision may be the safest and easiest procedure, irrespective of the nature of the pathology.

Pedicle Control

Elevation of the lower pole of the kidney places the renal vessels "on the stretch" and facilitates identification (Fig. 4). Blunt dissection of the vessels using right-angled forceps and/or the sucker-irrigator tip is performed. The renal vein, lying more anterior, is normally identified first. On the left side, the renal vein may receive gonadal, adrenal, and lumbar branches that may require individual clipping.

The preoperative computed tomography scan may provide clues as to the position of the renal artery in relation to the vein; otherwise, further blunt dissection cranial, caudal, and deep to the vein, while observing for arterial pulsation, will clarify the vascular anatomy. The artery is clipped with laparoscopic clips (three on the "stay" side and two on the "go" side) and divided; this is followed by division of the renal vein

using an endovascular gastrointestinal anastomosis stapler, which fires four rows of clips before cutting the vein. It is important to ensure that the path of the stapling device is clear of any clips, because their inadvertent inclusion in the closed jaws of the instrument will result in a misfire of the linear cutting/stapling device.

Arterial division may occasionally be postponed until after division of the vein if necessary, although the authors strongly recommend that this is a maneuver of last resort because it may result in considerable swelling of the renal vein and oozing from the hilum, which can hamper dissection. A far safer approach when space is limited is to place a single clip on the artery first and to complete its dissection once the vein has been divided.

In general, dissection of the renal artery and vein medially, as close to the great vessels as possible, is simpler because lateral dissection close to the hilum will result in more bleeding, and dissection of the branches of the renal artery and tributaries of the renal vein is also more likely.

Mobilization of the Upper Pole

After ligation of the renal artery and vein, dissection is carried along the medial aspect of the kidney, maintaining a safe distance from the renal hilum. At the upper pole, the anterior layer of Gerota's fascia is entered and dissection continued close to the kidney to preserve the adrenal gland. The upper pole can be dissected using a combination of sharp and blunt dissection. The use of clips, harmonic scalpel, or endo-gastrointestinal anastomosis is encouraged, as capsular vessels are common at the upper pole. Dissection is then carried to the lateral aspect of the kidney, where blunt dissection is usually sufficient to free the kidney of all attachments except for the ureter.

Ureteric Division

The ureter is now identified, clipped, and divided. If a stent was placed preoperatively, the ureter is first incised longitudinally and the stent removed with right-angled graspers via the 5- to 12-mm port, prior to clipping and division. Division of the ureter should be the final step before specimen retrieval, because the relatively fixed position of the ureter allows it to be used as an anchor, which prevents rotation of the kidney during the final stages of the dissection. This significantly reduces operating time.

Specimen Retrieval

The kidney is grasped with heavy laparoscopic forceps (Babcock forceps introduced through the fourth port, if present, are ideal). The specimen is held away from the renal bed, which is then inspected for bleeding. This inspection should always be performed at low intra-abdominal pressure, to ensure that venous bleeding is not masked. Swabbing the renal bed with a gauze roll (mastoid swab) will demonstrate any small vessels that require control. The pneumoperitoneum is reestablished, and a laparoscopic entrapment bag is inserted through the inferior port and the specimen carefully placed within it. The bag is withdrawn and the specimen removed by extending the trocar site or morcellation.

Wound Closure

A drain should be placed if there is concern about excessive ooze following extensive dissection for removal of a large kidney or if leakage of potentially infected material from the specimen has occurred. The extended trocar site is closed in two layers using continuous 0 Polydiaxone, while the other 12-mm port sites can be closed with 0 Vicryl on a J needle. Five-millimeter port sites do not need muscle closure, nor do those placed on the costal margin. Skin is closed with clips or subcuticular suture, and local anesthetic (bupivacaine 0.5%) is injected into the port sites.

Technical Modifications

Veress needle insufflation is the preferred technique for establishing pneumoperitoneum in some institutions, with the Hasson technique reserved for difficult cases. Blind trocar insertion following this method of insufflation carries an increased risk of bowel or vascular injury that does not occur when all trocars are introduced under vision. The needle is inserted level with the umbilicus and lateral to the rectus muscle. Intra-abdominal pressure is increased to 20 mmHg prior to initial trocar placement and then maintained at 8 to 15 mmHg for the duration of the operation.

The retroperitoneal laparoscopic approach to nephrectomy, for benign and malignant conditions, is widely practiced. Hsu et al. (6) described the Cleveland Clinic

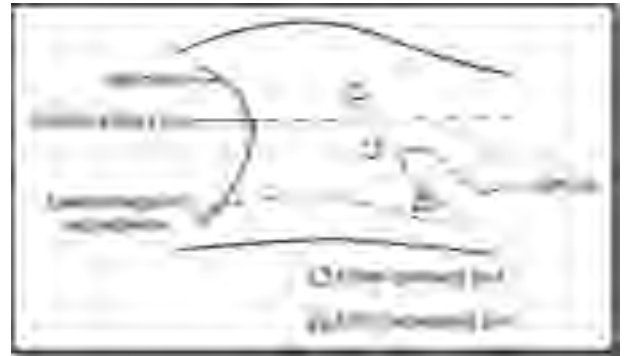
FIGURE 4 ■ Elevation of lower pole of kidney.


FIGURE 5 ■ Retroperitoneoscopic nephrectomy trocar placement.

technique in detail. The major technical considerations are (i) retroperitoneal access by an open method at the tip of the 12th rib, gently piercing the anterior thoracolumbar facia with finger tip or artery forceps after blunt dissection through the flank muscles; (ii) balloon dilation of the retroperitoneum using a trocar-mounted balloon device, which displaces the kidney anteromedially and facilitates identification of the renal artery; (iii) secondary port placement under laparoscopic or bimanual control, so that the three trocar sites are placed along the line of a conventional subcostal incision (Fig. 5); (iv) identification and control of the renal artery and vein; (v) kidney mobilization including clipping and division of the ureter; (vi) entrapment and piecemeal removal. Retroperitoneoscopy offers a number of advantages, avoiding adhesions in patients who have had previous abdominal surgery, and reducing the risk of bowel injury. On the other hand, operating in the more confined space of the retroperitoneum is a disadvantage, and orientation may be difficult.

Hand-assisted laparoscopic nephrectomy involves introducing the surgeon's or assistant's hand into the insufflated abdomen. It appears to have few advantages over standard or "pure" laparoscopy, but some authors claim safer retraction, reduced operating times, and a shorter learning curve. The incision required is larger than that for a wholly laparoscopic approach with morcellation of the kidney but smaller than that necessary for conventional open surgery. The technique may simplify the laparoscopic approach to chronically inflamed or scarred kidneys and shorten operating time (11,12) but is more suited to those patients in whom a larger incision is necessary, especially those undergoing donor nephrectomy.

Mass ligation of the renal artery and vein with the endo-gastrointestinal anastomosis has been described for use in patients with severe perinephric reaction, to avoid the risk of vascular injury when dissecting between renal artery and vein. Although there is a theoretical risk of fistula creation, this has not so far been observed (13).

POSTOPERATIVE CARE

Patients receive patient-controlled analgesia, which can usually be discontinued on the first postoperative day, when the catheter is also removed. Diet is progressed as tolerated, and the patients can mobilize without restriction. Heavy lifting is avoided for six weeks to allow muscular healing.

TECHNICAL TIPS

Preoperative Upper Tract Drainage
Patients with a grossly dilated collecting system are best served by a minimum four-week period of drainage prior to nephrectomy. Occasionally this is necessary to check function following relief of obstruction, before recommending ablative surgery over reconstruction, but it is certainly of benefit from a technical point of view because a tense, grossly dilated pelvis may otherwise overlap the renal vessels and make their identification and control more difficult.

Stay Suture

A stay suture inserted through the abdominal wall and into the pelvis, to support it and identify those structures deep to it, is also helpful in a patient with a grossly hydronephrotic kidney. A similar technique can be used to display the ureter.

Fourth Trocar

The use of an extra port for retraction purposes is encouraged. This decision should be made early at the first sign that additional organ retraction is likely to be needed. This trocar may be inserted near the tip of the 12th rib (a 5 to12 mm port), when operating on either side, or below the xiphoid (5 mm port) for hepatic retraction using a ratcheted grasper.

Harmonic Scalpel

This reduces bleeding during colonic reflection and mobilization of the kidney and facilitates dissection of inflammatory tissue. It can be used in close proximity to bowel and large vessels without risk of thermal injury.

Maximizing Use of Endovascular Stapler Device

The stiffness of laparoscopic endovascular staplers makes them very useful instruments for blunt dissection of the lateral attachments, after division of the pedicle and upper pole mobilization. Using a craniocaudal sweeping motion, and with the instrument closed, the kidney can be mobilized free of its lateral attachments very quickly.

Rolling the Patient

With the patient secured by lumbar and thoracic supports or surgical tape, the operating table may be tilted toward or away from the surgeon to facilitate exposure, in case the colon or adjacent organs fall into the operative field.

Obese Patients

Trocars should be positioned more laterally than usual. Consider using long trocars, and a purse string suture of the rectus sheath to facilitate closure at the end of the procedure.

Specimen Retrieval

This can be a surprisingly awkward step in the procedure, particularly when a larger catchment bag is used. Using a heavy grasping instrument (e.g., laparoscopic Babcock forceps, endo-gastrointestinal anastomosis) greatly improves the chances of success. The use of a Terumo guide wire to facilitate kidney entrapment when using the Lap Sac®[a], keeping the sac mouth stiff and open, has also been described (14).

Ribbon Gauze

Intracorporeal ribbon gauze strips can be used for temporary hemostatic control to absorb any blood or clot and to facilitate blunt dissection (15).

COMPLICATIONS

Intraoperative Complications

The major intraoperative complications are bleeding (usually from the renal vein, adrenal vein, or accessory branches), visceral injury (spleen, liver, bowel, or omentum), and vascular injury (superior mesenteric artery, aorta, and inferior vena cava) (16–18). While these occur uncommonly, they can cause serious morbidity or death. Rapid conversion may be necessary, although the experienced laparoscopist may be able to deal with bleeding from the renal and adrenal vein by judicious use of compression and retraction. There are reports of the linear cutting/stapling device failing to fire. This almost inevitably necessitates rapid conversion, but if the device can be rapidly closed and maintained in position, it may be possible to insert a second device medial to the first through an extra port placed just medial to the one carrying the failed device.

Open conversion rates vary between institutions, ranging from 0% to 16% (3,11,19,20), however this is affected by the indication for surgery and surgical experience.

[a]Cook Surgical, Spencer, IN.

In an analysis of factors, which predict the outcome of the laparoscopic approach, positive urine culture and renographic clearance (more than 10 mL/min) were found to increase the likelihood of conversion of both trans- and retroperitoneal laparoscopic nephrectomy for benign disease. In addition, learning curve and large kidney size were risk factors for conversion for trans- and retroperitoneal approaches, respectively (21). Conversion rates are also higher for inflammatory conditions (2–4).

Postoperative Complications

Major complications are unusual following laparoscopic nephrectomy but can occur particularly in patients with severe inflammation of the kidney and surrounding tissue. These include hematoma, intra-abdominal abscess, pulmonary embolus, pneumothorax, wound infection, and incisional hernia (20,22). Diathermy or dissection injury to the bowel may cause delayed abdominal signs due to a perforated viscus.

Avoiding Complications

As with all laparoscopic procedures, meticulous attention to detail and observation of surgical landmarks, particularly the major vessels and colon, should avoid most dangerous complications. However a few specific recommendations for avoiding complications in laparoscopic simple nephrectomy can be made.

Avoid the Hilum

There is a tendency to dissect close to the kidney when radical extirpation is not required. However renal vascular anatomy is far less complicated closer to the great vessels, and so it is more judicious to dissect and ligate them away from the renal hilum. Entering the hilum risks having to ligate and divide multiple vessels, and increases the risk of injury and conversion due to suboptimal control of bleeding.

Caution with Diathermy

Awareness of bowel position when using electrocautery within the peritoneal space avoids potential bowel necrosis, which can lead to immediate or delayed bowel perforation. The colon and duodenum are at particular risk due to their close proximity to the kidney. The use of disposable, nonmetallic trocars and bipolar diathermy will also minimize the risk of diathermy injury.

Renal Vein Control

The excessive use of clips to divide the gonadal or adrenal vessels close to the main vein should be avoided, because they can disrupt the firing mechanism of the endovascular gastrointestinal anastomosis stapler and cause it to fail, resulting in catastrophic bleeding. If the endovascular stapler fails to fire, placement of a second device proximal to the first while it is still closed may avoid the necessity of conversion.

Organ Retraction

Special purpose organ retractors (e.g., Fan retractor) are less likely to cause solid visceral injury, but should still be used with care. Alternatively, intracorporeal ribbon gauze can be used to prevent forceps trauma to solid organs (15).

Do Not Morcellate Infected Kidneys

Infected kidneys, secondary to obstruction or infected cysts, may contaminate the trocar site through which they are retrieved causing wound infection. As such we recommend removing them intact within a laparascopic catchment bag.

INTRODUCTION

> Today laparoscopy has become the standard of care for most patients requiring a simple nephrectomy.

Laparoscopic nephrectomy, since first performed by Clayman, has been shown to have various advantages over open nephrectomy (1). These advantages include decreased postoperative pain medication requirement, shorter hospital stay, quicker convalescence time, and potentially lower complication rates (2–6). More recently, laparoscopic approaches have been successfully employed to manage more complex cases such as xanthogranulomatous pyelonephritis and autosomal dominant polycystic kidney disease.

Today laparoscopy has become the standard of care for most patients requiring a simple nephrectomy.

INDICATIONS

> Laparoscopic simple nephrectomy is indicated in benign renal diseases where complete loss of the renal unit has occurred or is desired.

Laparoscopic simple nephrectomy is indicated in benign renal diseases where complete loss of the renal unit has occurred or is desired. Such conditions include but are not limited to:

- ■ Renovascular hypertension,
- ■ Obstructive or reflux nephropathy,
- ■ Chronic inflammatory/infection conditions including xanthogranulomatous and tuberculosis pyelonephritis (these are technically challenging),
- ■ Symptomatic ADPKD, and
- ■ Posttransplantation hypertension.

Simple nephrectomy is most commonly performed for symptomatic (pain, hypertension, and infections) and nonfunctioning renal units. The etiology of functional loss may be due to calculi, obstructive nephropathy, reflux nephropathy, polycystic kidney, pyelonephritis, and others. Laparoscopic nephrectomy for benign conditions has gained wide acceptance and has become the standard of care in many institutions.

> Benefits of laparoscopic simple nephrectomy over open nephrectomy include decreased need for pain medication, shorter hospital stay, and quicker convalescence time. Complication rates are equivalent or, as some reports suggest, less than the rates commonly associated with open nephrectomy.

Benefits of laparoscopic simple nephrectomy over open nephrectomy include decreased need for pain medication, shorter hospital stay, and quicker convalescence time (2–6).

Complication rates are equivalent or, as some reports suggest, less than the rates commonly associated with open nephrectomy.

Gill et al. reviewed 185 cases of laparoscopic nephrectomy from five centers (7). Overall, 83% of cases were performed for a benign cause. Complication rate was 16% and conversion rate was 5.4%. Fornara et al. reported a retrospective single center study of 249 patients; open simple nephrectomy was performed in 118 patients and laparoscopic

simple nephrectomy in 131 patients (3). The laparoscopic group experienced decreased pain medication requirement (12 mg vs. 20 mg morphine), shorter hospital stays (4 days vs. 10 days), and shorter time to convalescence (24 days vs. 36 days). Complication rate was 20.6% for the laparoscopic group and 25.4% for the open group, respectively. Open conversion rate during laparoscopy was 6.1%. In another comparison study in which 92 patients underwent open nephrectomy and 92 underwent laparoscopic nephrectomy, the laparoscopic group had shorter hospital stay (3.9 days vs. 5.9 days), shorter time to convalescence (12 days vs. 33 days), and lower complication rates (13% vs. 31%) (5). Open conversion rate during laparascopic nephrectomy was 0.8%. Other studies have supported these findings (2,4,6).

SPECIAL CONSIDERATIONS

Previous Procedures

Care must be taken when approaching patients who have undergone prior abdominal surgeries. These patients may have postsurgical adhesions, which increase the risk of bowel injury during Veress needle insertion, trocar placement, and dissection. In addition, the fibrosis secondary to prior surgery can make dissection more challenging. Veress needle placement should be as far from the previous incision site as possible.

In a series of 700 laparoscopic urologic procedures from a single center, comparison between patients with previous abdominal surgery (48%) and those with none (52%) revealed higher complication rates (9.4% vs. 4.8%) and higher open conversion rates (7.5% vs. 1.2%) in the previously operated patients. However, the differences were not statistically significant. The patients with prior surgery also had higher transfusion rates and slightly longer hospital stays, most likely due to higher medical comorbidity in this group (8).

Seifman et al. reported on 190 patients, of whom 40% had undergone previous abdominal surgery. The authors found that the group with prior abdominal surgery was associated with longer hospital stay (3.8 days vs. 2.6 days) and higher complication rates (16% vs. 5%). Specifically they reported that an upper midline and ipsilateral upper-quadrant scar were associated with a higher incidence of access complication (12% vs. 0%) (9).

In patients with a history of prior open abdominal surgery, an open Hassn trocar placement or a retroperitoneal approach should be considered (10).

Obesity

Obesity was initially believed to be a relative contraindication to laparoscopic surgery. An early multicenter series of 125 patients with a body mass index > 30 undergoing various laparoscopic procedures, including 14 laparoscopic nephrectomies, documented a complication rate of 22% intraoperatively and 26% postoperatively (11). With increased laparoscopic operative experience, more recent studies have shown otherwise (12). In a retrospective single center study involving 69 nonobese and 32 obese (body mass index > 30) patients undergoing laparoscopic nephrectomy, Fugita et al. reported equivalent operative times, complication rates, conversion rates, and postoperative recovery course (12). In another study involving 40 patients undergoing laparoscopic donor nephrectomy, outcomes and complication rates were similar between obese and nonobese patients (13).

Obesity is not a contraindication for laparoscopic nephrectomy. Laparoscopic nephrectomy is both feasible and efficacious in the obese patient.

Increased adipose tissue can make laparoscopic visualization more challenging. The increased distance to the kidney often necessitates the use of longer operative instruments and appropriate adjustments to trocar configuration.

Recommendations for operating upon obese patients include the use of higher insufflation pressures (20 mmHg) and repositioning of the midline trocars lateral to the rectus to improve visualization and dissection. The retroperitoneal laparoscopic approach for nephrectomy is particularly advantageous in the obese patient because of avoidance of pannus and direct access to the renal hilum.

Renal Units with Chronic Infection

Infectious conditions of the kidney provide significant challenges to laparoscopy. The inflammation causes the development of dense perinephric fibrosis around the kidney, with the possible involvement of the perihilar region. In such situations, a transperitoneal approach has been advocated over the retroperitoneal approach.

Care must be taken when approaching patients who have undergone prior abdominal surgeries. Veress needle placement should be as far from the previous incision site as possible.

In patients with a history of prior open abdominal surgery, an open Hassn trocar placement or a retroperitoneal approach should be considered.

Obesity is not a contraindication for laparoscopic nephrectomy. Laparoscopic nephrectomy is both feasible and efficacious in the obese patient.

Recommendations for operating upon obese patients include the use of higher insufflation pressures (20 mmHg) and repositioning of the midline trocars lateral to the rectus to improve visualization and dissection. The retroperitoneal laparoscopic approach for nephrectomy is particularly advantageous in the obese patient because of avoidance of pannus and direct access to the renal hilum.

Open conversion should be strongly considered if the perirenal fibrosis is dense and the dissection during laparoscopic nephrectomy is particularly challenging and not progressing.

The transperitoneal approach provides better exposure and larger working space for this potentially difficult dissection. One study evaluated laparoscopic nephrectomy in 12 patients with inflammatory renal conditions, including chronic inflammation/fibrosis (eight), xanthogranulomatous pyelonephritis (three), and tuberculosis (one) (14). Outcomes were compared to those of nine patients undergoing laparoscopic nephrectomy for noninflammatory conditions. Operative time was longer (284 minutes vs. 226 minutes) and conversion rate was higher (16% vs. 0%).

Open conversion should be strongly considered if the perirenal fibrosis is dense and the dissection during laparoscopic nephrectomy is particularly challenging and not progressing.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is an atypical form of chronic renal infection, usually associated with obstructive nephrolithiasis. *Proteus* and *Escherichia coli* are the most common organisms isolated from these kidneys. Lysis of tissue and phagocytosis of lipid material by histiocytes result in sheets of lipid-laden macrophages (xanthoma). Treatment traditionally involves open nephrectomy due to the dense fibrosis/inflammatory process involving the affected renal unit, the surrounding perinephric structures, and occasionally the adjacent organs. Nevertheless, several cases of laparoscopic nephrectomy have been performed in such patients, e.g., nine cases (five laparoscopic, four open) reported by Bercowsky et al. Two patients, of whom one was converted open, were approached retroperitoneally, and three transperitoneally (15). Mean operative time was 360 minutes compared to 154 minutes for the open procedure, while hospital stay (6 days vs. 5.7 days) was similar. Complications occurred in three patients in the laparoscopic group, including ileus (1), ileus and a pulmonary embolism (1), and an open conversion (1). In another study of three cases of laparoscopic transperitoneal nephrectomy for xanthogranulomatous pyelonephritis, mean operative time was 213 minutes and open conversion was necessary in one patient (14).

Laparoscopic nephrectomy for xanthogranulomatous pyelonephritis is feasible. The scant available data suggest longer operative times and no clear advantage over open nephrectomy. Laparoscopic simple nephrectomy in xanthogranulomatous pyelonephritis cases should only be attempted by the very experienced laparoscopist.

Laparoscopic nephrectomy for xanthogranulomatous pyelonephritis is feasible. The scant available data suggest longer operative times and no clear advantage over open nephrectomy. Laparoscopic simple nephrectomy in xanthogranulomatous pyelonephritis cases should only be attempted by the very experienced laparoscopist.

Tuberculosis

Tuberculosis of the kidney is usually caused by hematogenously spread organisms. Initial treatment involves antituberculous drugs such as isoniazid, rifampin, pyrazinamide, and ethambutol. Nephrectomy is indicated in cases of nonfunctioning kidneys, with extensive disease involving the entire kidney, causing hypertension, ureteropelvic junction obstruction, or coexisting renal carcinoma. Lee et al. reported the largest series of laparoscopic nephrectomy for tuberculosis of the kidney (16). Outcomes of laparoscopic nephrectomy in 31 patients with nonfunctioning kidney secondary to tuberculosis were compared to those of 45 patients who underwent laparoscopic nephrectomy for other benign causes. In the tuberculosis group, 10 were performed using the transperitoneal approach and 21 via the retroperitoneal approach. On comparing the tuberculosis group and the nontubercular group, no difference was noted as regards operative time (206 minutes vs. 200 minutes), length of hospital stay (5.3 days vs. 5.7 days), and complication rates (13% vs. 7%). There was one open conversion in the tuberculosis group.

Laparoscopic nephrectomy for tuberculosis is safe and, with sufficient laparoscopic experience, appears to provide the same benefits as for other benign noninflammatory conditions.

Laparoscopic nephrectomy for tuberculosis is safe and, with sufficient laparoscopic experience, appears to provide the same benefits as for other benign noninflammatory conditions.

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease, an inherited form of polycystic disease with nearly 100% penetrance, ultimately leads to renal failure requiring dialysis. The identified genes for polycystic kidney disease (*PKD1*) reside on the short arm of chromosome 16, which accounts for 85% to 90% of cases (17), and for *PKD2* on chromosome 4, which accounts for 5% to 10% of cases (18). Patients also have increased incidence of intracranial hemorrhages and hepatic and pancreatic cysts.

Patients may develop hypertension, back and flank pain, infection, intracystic hemorrhage, and malignancy. Laparoscopic cyst decortication has been shown to improve pain and hypertension with no compromise of renal function (19). Simple nephrectomy may provide dramatic relief to symptomatic patients with preexisting end-stage renal disease.

These patients generally have giant kidneys, which add unique challenges to the minimally invasive surgeon. Outcomes in 11 such patients undergoing laparoscopic nephrectomy showed a mean operative time of 6.3 hours, average hospital stay of three days, and convalescence time of five weeks (20). All patients had resolution of the preoperative pain at a mean follow-up of 31 months. In a comparison between 10 consecutive patients who underwent laparoscopic nephrectomy for autosomal dominant polycystic kidney disease and 10 consecutive patients who underwent open nephrectomy, the laparoscopic group had longer operative times (247 minutes vs. 205 minutes) but shorter mean hospital stay (2.6 days vs. 6.6 days) and lower complication rate (10% vs. 30%). In this study, the cysts were punctured and drained prior to hilar dissection in order to decrease the volume of the kidney and increase the working space. Preoperative embolization was necessary in only two cases. More importantly, all the patients had resolution of their preoperative pain at one-year follow-up (21). Laparoscopic bilateral simultaneous nephrectomy (22) and hand-assisted laparoscopic nephrectomy (23) in patients with autosomal dominant polycystic kidney disease showed similar results.

Although challenging, laparoscopic nephrectomy for autosomal dominant polycystic kidney disease is safe and efficient, and provides all the benefits associated with minimally invasive surgery.

> Although challenging, laparoscopic nephrectomy for autosomal dominant polycystic kidney disease is safe and efficient, and provides all the benefits associated with minimally invasive surgery.

SUMMARY

- ■ Laparoscopic simple nephrectomy for benign disease has become the standard of care.
- ■ Almost all symptomatic benign renal diseases can be treated laparoscopically, given appropriate training and laparoscopic experience.
- ■ Benefits of laparoscopic simple nephrectomy over open nephrectomy include decreased need for pain medication, shorter hospital stay, and quicker convalescence time.
- ■ Complication rates are equivalent to or less than open surgery.
- ■ Morbid obesity is not a contraindication for laparoscopic nephrectomy. Laparoscopic nephrectomy is both feasible and efficacious, and may actually be the preferred option in the obese patient.
- ■ Laparoscopic simple nephrectomy in xanthogranulomatous pyelonephritis cases should only be attempted by the very experienced laparoscopist.
- ■ Laparoscopic nephrectomy for tuberculosis and for autosomal dominant polycystic kidney disease is feasible and safe.

CHAPTER 19

LAPAROSCOPIC RENAL BIOPSY: TECHNIQUE AND RESULTS

Christopher A. Warlick and David Y. Chan

The James Buchanan Brady Urological Institute, Johns Hopkins Medical Institutions, Baltimore, Maryland, U.S.A.

INTRODUCTION

Renal biopsy is an important diagnostic tool in the medical evaluation of renal insufficiency, hematuria, and proteinuria, and in the assessment of renal allograft dysfunction (1,2). Currently, most renal biopsies are performed percutaneously with a local anesthetic under ultrasound guidance using an 18-gauge spring-loaded biopsy gun (3–6). As greater experience with percutaneous biopsies has accumulated, several former absolute contraindications to percutaneous biopsy have devolved into relative contraindications (3,7). However, in select patients, renal biopsy under direct vision may still be preferred.

Indications for direct-vision renal biopsy include patients with bleeding diatheses, those on chronic anticoagulation medications, morbidly obese patients, patients with failed prior attempts at percutaneous biopsy, uncooperative patients, patients with a solitary kidney, patients with uncontrolled hypertension, and those patients with anomalous anatomy (3,8,9).

Direct-vision renal biopsy can be accomplished by either an open (10,11) or laparoscopic technique including both transperitoneal (12,13) and retroperitoneal approaches (8,14). Transperitoneal approaches offer the advantage of familiarity, because most laparoscopists are comfortable with transperitoneal landmarks and orientation. This may be particularly true in obese patients where the large amount of adipose tissue may obscure traditional landmarks in the retroperitoneum. The advantage of a retroperitoneal approach, however, includes an intuitive decreased risk of visceral injury and postoperative ileus because the colon is not mobilized and the peritoneal cavity is not insufflated.

SURGICAL TECHNIQUE

While both transperitoneal and retroperitoneal approaches for laparoscopic renal biopsy have been described, our preference is the retroperitoneal approach and will be the surgical technique described herein (Table 1). Preprocedure ultrasound or computed tomography imaging should be obtained to ensure normal anatomy or to determine if one kidney should be biopsied over the other. While biopsies can be obtained from either kidney, access to the left kidney may be simpler due to absence of the liver.

After consent is obtained, the patient is administered general endotracheal tube anesthesia. A Foley catheter and an orogastric or nasogastric tube are placed. The patient is placed carefully in a lateral decubitus position with the umbilicus over the break of the table. Care is taken to appropriately pad all pressure points, securing the patient to the table with wide cloth tape. The patient and the table are then flexed to maximize the distance and thus the working space between the iliac crest and the 12th rib. Prophylactic antibiotics are administered prior to the start of the procedure. The patient is prepped and draped in standard sterile fashion.

One 10-mm and one 5-mm port are required for the retroperitoneal approach. A small transverse incision just large enough to accommodate a 10-mm port is made equidistant between the 12th rib and the iliac crest in the posterior axillary line, just

> Indications for direct-vision renal biopsy include patients with bleeding diatheses, those on chronic anticoagulation medications, morbidly obese patients, patients with failed prior attempts at percutaneous biopsy, uncooperative patients, patients with a solitary kidney, patients with uncontrolled hypertension, and those patients with anomalous anatomy.

TABLE 1 ■ Summary of Surgical Procedure

> Place patient in lateral decubitus position
> Place 10-mm port in posterior axillary line midway between 12th rib and iliac crest
> Insufflate to 15 mmHg
> Bluntly dissect retroperitoneal space with laparoscope
> Place 5-mm port in anterior axillary line at level of first port under direct vision
> Incise Gerota's fascia with scissors and clear perirenal fat from inferior pole of kidney
> Using laparoscopic toothed cup biopsy forceps, obtain one to five biopsies
> Obtain hemostasis with argon beam coagulator and Surgical
> Desufflate to 5 mmHg and observe for bleeding
> Evacuate all CO_2 and remove ports
> Close skin with absorbable suture

medial to the lateral border of the sacrospinalis muscle as indicated in Figure 1. Using the Visiport® introducer[a], the laparoscope is inserted through the incision and advanced sequentially through the fascial layers under vision. The tip of the scope should be maintained at an approximately 10° to 15° angle toward the umbilicus to achieve the correct trajectory to allow entrance into the retroperitoneum. An angle completely perpendicular to the body wall may result in an inadvertent penetration of the psoas muscle, while too dramatic of an angle may result in dissection of the layers of the abdominal wall musculature with the laparoscope and failure to enter the retroperitoneum. Once the retroperitoneum is entered, the Visiport device is removed, leaving the 10-mm trocar in place in the retroperitoneum. The trocar is then secured to the skin with sutures, and carbon dioxide insufflation is achieved to 15 mmHg. Blunt dissection with the laparoscope during insufflation may be necessary to further develop the retroperitoneal space anterior to the psoas muscle.

> The technique for the placement of the first trocar described here applicable to all patients, but is particularly useful in morbidly obese patients.

   The technique for the placement of the first trocar described above is applicable to all patients, but is particularly useful in morbidly obese patients.

   In fact, Chen et al. (15) described using this technique in conjunction with intraoperative transabdominal ultrasound to assist in the placement of the first trocar in patients in whom normal anatomic landmarks were obscured due to obesity, making placement of trocars dangerous. Ultrasound was used to identify bony landmarks such as the iliac crest and 11th and 12th ribs as well as the inferior pole of the kidney. Yap et al. (16) described a modification of the use of intraoperative ultrasound such that by obtaining transverse images through the liver, the authors were able to simultaneously view

Figure 1 ■ Port placement for retroperitoneal laparoscopic renal biopsy. A, location of 10 mm port: midpoint between the 12th rib and iliac crest in the PAL; B, location of 5 mm port: AAL at similar level to 10 mm port. *Abbreviations*: PAL, posterior axillary line; AAL, anterior axillary line.

Figure 2 ■ Transverse ultrasound images obtained through the acoustic window provided by the liver allow the simultaneous localization of the Visiport® device and the kidney. *Source*: From Ref. 16.

the tip of the Visiport device during advancement through the abdominal wall and the outline of the kidney thus ensuring that the trocar was being placed correctly (Fig. 2).

In patients without morbid obesity, an alternative technique can be applied wherein the retroperitoneum is first insufflated using a Veress needle prior to the placement of the first trocar. Capelouto et al. (17) first placed a Veress needle in the posterior axillary line 1 cm above the iliac crest at a 5° to 10° angle, and insufflated the retroperitoneum after confirming correct placement of the needle. Following insufflation, the Veress needle was removed, and a 1 cm incision was made in that location and the laparoscope was introduced into the retroperitoneum followed by balloon dissection of the retroperitoneum. Current modifications of this access technique have abandoned the balloon dilation, and the Visiport device is used to introduce the laparoscope following insufflation. Additional working space in the retroperitoneum is created by blunt dissection with the laparoscope.

Once in the retroperitoneum and insufflation established, the laparoscope is used to bluntly dissect tissue in the retroperitoneum revealing Gerota's fascia overlying the kidney. After sufficient space has been created, a 5-mm port is placed under direct vision in the anterior axillary line between the level of the first port and the level of the iliac crest (Fig. 1) and secured to the skin with suture. In general, the 5-mm trocar is the working port. However, if a 5-mm laparoscope is also available, the 10-mm trocar can also serve as a working port.

After the kidney has been positively identified, Gerota's fascia is incised with laparoscopic scissors and the perinephric fat dissected away to reveal the inferior pole of the kidney.

Proper identification of the kidney can sometimes be challenging, particularly if there is a large amount of perinephric fat. In these cases, intraoperative laparoscopic ultrasound using a 10-mm probe can be used to help identify the kidney prior to harvesting the biopsies (8). If intraoperative ultrasound is used, a 5-mm laparoscope is placed medially in the working port and the ultrasound probe is placed in the 10-mm trocar.

After positive identification of the surface of the kidney, laparoscopic biopsy forceps (Fig. 3) are used to obtain one to five cortical biopsies from the surface of the kidney taking care to avoid deep samples containing medullary tissue.

Frozen sections of the tissue are sent for pathological analysis to confirm renal origin of the biopsy sample and to determine adequacy of harvested tissue.

Bleeding from the biopsy sites is controlled under direct vision using a 5-mm argon beam coagulator and by packing the sites with oxidized cellulose.

When the argon beam coagulator is used, it is important to vent the retroperitoneum to avoid overinsufflation. While awaiting the results of the frozen sections, insufflation pressure should be decreased to 5 mmHg and the biopsy site observed for adequate hemostasis for 5 to 10 minutes. After acquiring confirmation that adequate renal samples were obtained and complete hemostasis achieved, the carbon dioxide gas is evacuated from the retroperitoneum and the ports removed. Fascia does not need to be closed in this location, thus only the skin is closed using an absorbable suture. The patient is then awakened and brought to the recovery room. Patients are observed overnight with the vast majority of patients discharged the following day.

After the kidney has been positively identified, Gerota's fascia is incised with laparoscopic scissors and the perinephric fat dissected away to reveal the inferior pole of the kidney.

After positive identification of the surface of the kidney, laparoscopic biopsy forceps are used to obtain one to five cortical biopsies from the surface of the kidney, taking care to avoid deep samples containing medullary tissue.

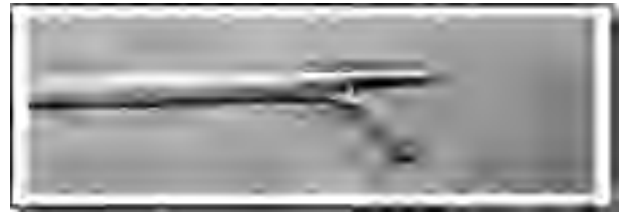
Bleeding from the biopsy sites is controlled under direct vision using a 5-mm argon beam coagulator and by packing the sites with oxidized cellulose.


Figure 3 ■ Laparoscopic cup biopsy forceps.

Laparoscopic ultrasound to positively identify the kidney can avoid the complication of inadvertent biopsy of nonrenal tissue. It is also important to take superficial biopsies of the cortex. Deeper bites may result in the acquisition of mainly medullary tissue, increased bleeding, increased risk of arteriovenous fistula formation, or inadvertent violation of the collecting system, which increases the risk of urinary leak and fistula formation.

While this procedure is safe and is associated with relatively few complications, several points should be kept in mind to minimize the risk of complications. As noted above, gaining access to the retroperitoneum can be challenging, particularly in obese patients. The use of intraoperative ultrasound to identify landmarks to facilitate the safe placement of trocars is invaluable. Using this technique, Chen et al. (15) reported successful biopsy in eight patients with a mean body mass index of 52.8 in a mean operative time of 118 minutes and with an estimated blood loss of 71 mL.

The use of laparoscopic ultrasound to positively identify the kidney in equivocal cases can avoid the complication of inadvertent biopsy of nonrenal tissue. It is also important to take superficial biopsies of the cortex. Deeper bites may result in the acquisition of mainly medullary tissue, increased bleeding, increased risk of arteriovenous fistula formation, or inadvertent violation of the collecting system, which increases the risk of urinary leak and fistula formation.

After obtaining hemostasis, it is prudent to decrease the insufflation pressure from 20 to 5 mmHg before removing the trocars to ensure that complete hemostasis has been achieved, because high insufflation pressures can mask bleeding.

RESULTS

Several authors have published reports on laparoscopic renal biopsy by both transperitoneal (12,13) and retroperitoneal (8,14,18–20) approaches, including biopsies in children involving minor technical modifications (21). The largest series is reported by Shetye et al. (8) in which 74 patients underwent retroperitoneal laparoscopic renal biopsy over a nine-year period from 1991 to 2000. These authors obtained adequate tissue in 96% of their cases, which is similar to 100% rates of recovery from other published series (13,14). Shetye et al. reported an overall complication rate of 13.5%, the most common complication being bleeding, which was observed in 3 of 74 (4%) patients (8). Only one bleed was significant, involving a 2000 mL blood loss. These authors also reported one death seven days following uneventful biopsy in a patient with a lupus flare who was treated with high-dose steroids after the renal biopsy and subsequently died of a perforated gastric ulcer after refusing transfusion or surgery to explore the source of her abdominal pain (8). Complication rates from other reported series range from 11.8% (14) to 50% (13) and include subcutaneous emphysema (13), transient postoperative gross hematuria (14), perinephric hematoma (not requiring transfusion) (8), initial biopsy of nonrenal tissue (8), and inability to obtain tissue (8). Caione et al. (21) reported a single intraoperative complication (5%) of a peritoneotomy and one open conversion in 20 pediatric patients. While most reported complications in the literature have been minor, there is one case report of pneumocephalus following retroperitoneal laparoscopic renal biopsy, which is hypothesized to have resulted from an inadvertent disruption of the dura mater along an intercostal nerve or the lumbar plexus, which presumably occurred during placement of the 5-mm trocar (22). In addition, this same patient also suffered new-onset right lower extremity numbness and paralysis following the procedure, which was believed to have resulted from positioning during the procedure. The patient's pneumocephalus resolved without further intervention, and her paralysis resolved following aggressive physical therapy (22).

Laparoscopic renal biopsy is generally well tolerated. The majority of patients return home within 24 hours, with most of the remaining patients being discharged within 48 hours. Most patients who remain longer than this duration do so secondary to medical comorbidities or to reinitiate anticoagulation (8,15).

Laparoscopic renal biopsy is generally well tolerated. The majority of patients return home within 24 hours, with most of the remaining patients being discharged within 48 hours.

DISCUSSION

Renal biopsy remains indispensable in the diagnosis of medical renal disease manifesting as proteinuria, hematuria, or renal failure. Most biopsies can be accomplished percutaneously with ultrasound guidance and a spring-loaded biopsy gun. Reported

complications rates with this procedure including postoperative bleeding (the most common complication) are between 11% (23) and 34.1% (24). Manno et al. (24) reported a major complication rate of 1.2% in their series of 471 patients including 1 nephrectomy. Rates might be expected to be higher among high-risk patients. In such cases where percutaneous biopsy is contraindicated, alternative methods must be employed to obtain the biopsy. Several other methods have been reported. Percutaneous computed tomography-guided biopsy (25,26) is an alternative to ultrasound-guided percutaneous biopsy, which, similar to ultrasound guidance, does not involve general anesthesia, but is not appropriate for extremely obese patients who do not fit in the scanner. Another option is transjugular kidney biopsy (27,28). While this procedure provides diagnostic biopsies approximately 90% of the time, it involves capsular perforations between 13.5% (28) and 73.9% (27) of the time, increasing the risk of bleeding into the retroperitoneum, or the collecting system. In the study by Fine et al. (28), 1 of 37 patients required transfusion, while in Thompson et al.'s report (27), 1 of 25 patients developed an arteriocalyceal fistula, and another patient developed a renal vein thrombosis (27). There is also a report of transureteral renal biopsy through an upper pole calyx accomplished with an 18-gauge needle sheathed in an 8 French catheter inserted through a 10 French transureteral catheter (29).

Open biopsy and laparoscopic biopsy are the two methods that allow direct vision both during biopsy and during subsequent achievement of hemostasis, which is important in patients who may be at high risk of bleeding. Laparoscopy has the advantage of being less invasive and less morbid than open biopsy.

Many patients who are candidates for laparoscopic renal biopsy have significant medical comorbidities. Shetye et al. (8) reported that 47 of 74 patients in their series had American Society of Anesthesiologists physical status scores of 3 or 4. Thus a disadvantage of laparoscopic renal biopsy compared to percutaneous biopsy is the need for general anesthesia. However, Micali et al. (30) reported the successful use of epidural anesthesia in a patient requiring laparoscopic renal biopsy with severe comorbidities that made him a poor candidate for general anesthesia. Therefore, general anesthesia may not be absolutely necessary for this procedure, particularly if it can be performed quickly thus minimizing the risk of hypercarbia.

Renal biopsy remains essential in the diagnosis of medical renal pathology. In most cases, this can be accomplished with image-guided percutaneous biopsy. However, in the rare instance that direct-vision biopsy is required, laparoscopic renal biopsy is a safe and minimally invasive technique for obtaining renal tissue in high-risk patients. Careful patient selection and counseling, with meticulous intraoperative hemostasis, and careful resumption of anticoagulation medication after the procedure help ensure a safe outcome following renal biopsy in what can be a challenging group of patients.

SUMMARY

- Renal biopsy remains indispensable in the diagnosis of medical renal disease manifesting as proteinuria, hematuria, or renal failure.
- Indications for direct-vision renal biopsy include patients with bleeding diatheses, those on chronic anticoagulation medications, morbidly obese patients, patients with failed prior attempts at percutaneous biopsy, uncooperative patients, patients with a solitary kidney, patients with uncontrolled hypertension, and those patients with anomalous anatomy.
- Open biopsy and laparoscopic biopsy are the two methods that allow direct vision both during biopsy and during subsequent achievement of hemostasis, which is important in patients who may be at high risk of bleeding. Laparoscopy has the advantage of being less invasive and less morbid than open biopsy.
- Laparoscopic renal biopsy is generally well tolerated. The majority of patients return home within 24 hours, with most of the remaining patients being discharged within 48 hours.

LAPAROSCOPIC NEPHROPEXY

Lewis CH. Liew and Adrian D. Joyce
St. James's University Hospital, Leeds, U.K.

INTRODUCTION

Nephroptosis, also called hypermobile
or floating kidney, is characterized by an
abnormal caudal movement of the
kidney by more than two vertebral
bodies or 5 cm when the patient
changes from the supine to the
erect position.

Nephroptosis, also called hypermobile or floating kidney, is characterized by an abnormal caudal movement of the kidney by more than two vertebral bodies or 5 cm when the patient changes from the supine to the erect position.

The condition was first described by Franciscus de Pedemantanus in the 14th century. Subsequently, Rayer described the characteristic symptoms attributable to a ptotic kidney in 1841(1). Historically, nephroptosis occurs more frequently in lean young females with a female-to-male ratio of about 5 to 10:1. The right kidney is affected in 70% of the cases. However, such data have to be evaluated cautiously because in approximately 20% of normal, asymptomatic females, the intravenous urogram was observed to have significant renal descent consistent with a diagnosis of nephroptosis (2,3). As such, from a practical standpoint, true symptomatic nephroptosis is a rare condition, and the diagnosis should be made with due circumspection.

The symptoms of nephroptosis usually include pain, which is exacerbated by sitting or standing. Sometimes, when the patient is upright, the kidney can be palpated in the lower abdomen. Nephroptosis may also present with pyelonephritis, renal calculi, hematuria, hypertension, and renal ischemia (2). The most severe presentation of nephroptosis is a syndrome of multiple symptoms including intermittent, severe colicky pain, nausea, tachycardia, oliguria, proteinuria, and/or hematuria, known as Dietl's crisis. On physical examination, the kidney may appear palpably enlarged and tender. The pain can be acutely relieved by upward manual reduction of the kidney into the renal fossa, with the patient in the supine position. Also the knee-chest or supine position assumed by the patient with the head down and feet elevated may help relieving the pain (4,5). Hypotheses for the pathogenesis of symptoms due to nephroptosis include kidney descent causing intermittent ureteral obstruction at the ureteropelvic junction with consequential hydronephrosis. Alternative explanations include traction on the renal pedicle combined with hilar vessel kinking leading to renal ischemia. Stretching of the peripelvic nerves is also considered to be a possible mechanism responsible for the pain.

Nephropexy, an organ-preserving
modality, was first per-formed by Hahn
in 1881, and was technically refined,
innovated, and popularized by
Edebohls, a gynecologist.

Nephropexy, an organ-preserving modality, was first performed by Hahn in 1881 (6), and was technically refined, innovated, and popularized by Edebohls, a gynecologist.

Most of the proposed therapeutic options for nephroptosis are no longer popular because of their degree of invasiveness. In the 1870s, nephrectomy was advocated for the relief of symptomatic renal ptosis. However, such radical therapy was swiftly condemned due to its high mortality and lack of evidence of pathologic changes in the excised specimen (2).

Edebohls published a series of 12 cases in 1893, in which he described his technique comprising incision and back stripping of the renal capsule along the entire convexity of the kidney, and the placement of five or six deep sutures through the skin, the superficial fat, the tendons of the abdominal muscles, and the edges of the renal capsule and parenchyma (7).

Since then, a multitude of different procedures for symptomatic nephroptosis have been described including various "pexy" procedures, decapsulation of the kidney,

and fixation of the kidney to the 12th rib. However, due to the lack of objective diagnostic studies and the lack of clear-cut indications for surgery, the diagnosis of nephroptosis and its surgical treatment have passed through cycles of intense popularity and equally intense disfavor during the past century (8).

In the last decade, the availability of laparoscopic surgery has led to a revival of interest in nephroptosis and nephropexy.

Urban et al. from the Washington University School of Medicine reported the initial laparoscopic nephropexy performed in a severely symptomatic woman with a palpable ptotic kidney and hydronephrosis in 1993 (9). Two years later, the same group updated their experience including five additional cases managed with laparoscopic nephropexy. The procedure was well tolerated with reported low morbidity, rapid recovery, and successful improvement of symptoms (10).

PATIENT SELECTION AND DIAGNOSIS

A history of flank or loin pain, relieved by lying down, is the most common symptom of patients with nephroptosis.

Sometimes, the full range of symptoms of Dietl's crisis may be seen as the initial presentation. Physical examination, especially with the patient in the upright position, usually reveals palpation of a mobile mass in the lower abdomen. Reduction of the mobile mass back to its normal position in the retroperitoneum with relief of symptoms is highly suggestive of the diagnosis.

Intravenous urography, usually performed in the supine and erect positions, has been the primary diagnostic tool for the assessment of nephroptosis. The ability to reproduce symptoms after the administration of a diuretic, with the patient upright, assists in confirming the diagnosis.

Erect and supine diuretic renography-documented renal obstruction, decreased renal perfusion, and/or changes in the degree of renal function has been used to identify patients with functional nephroptosis and has been recommended as the most definitive diagnostic study.

Retrograde pyelography in both supine and erect positions has also been used as an alternative diagnostic tool, but is more invasive than renography. Ultrasonography can also be used to confirm a mobile, ptotic kidney and can reveal hydronephrosis, with positional change. Recently, the use of ultrasound Doppler was proposed as a diagnostic tool for patient with nephroptosis by detection of changes in renal blood flow. The resistive index was measured in the segmental arteries, with the patient in both the supine and the erect position. In comparison with isotope renogram, resistive index measurement by Doppler ultrasound appears to be significantly more sensitive in detecting renal blood flow impairment (10).

SURGICAL TECHNIQUE

Patient Preparation

Patients may be typed and crossmatched for blood and are given a dose of broad-spectrum antibiotics before the procedure. No specific bowel preparation is required. Patients undergoing laparoscopic nephropexy, like all other laparoscopic surgery, should have a general endotracheal anesthetic, because controlled ventilation is necessary to ensure adequate oxygenation and to avoid hypercarbia. A nasogastric tube is placed to keep the stomach and bowels decompressed, and a Foley catheter is inserted to allow drainage of the bladder prior to commencement of the procedure. Pneumatic compression stockings are applied to both legs.

Transperitoneal Approach

Positioning

After intubation and placement of all appropriate tubes and lines, the patient is rolled onto the lateral decubitus position, allowing the torso to fall back to an angle of 70° from the horizontal, with the side of the lesion in the nondependent position. The operating table is flexed in order to help distract the kidney from the nearby structures. The bottom leg is flexed at the hip and knee, whereas the upper leg remains straight. It is important to fully pad all pressure points, including both the top and the bottom legs and to ensure the patient is adequately secured to the operating table.

A history of flank or loin pain, relieved by lying down, is the most common symptom of patients with nephroptosis.

Erect and supine diuretic renography–documented renal obstruction, decreased renal perfusion, and/or changes in the degree of renal function has been used to identify patients with functional nephroptosis and has been recommended as the most definitive diagnostic study.

Port Placement

Transperitoneal access can be obtained, and the primary port is inserted at the lateral border of the rectus muscle just above the level of the umbilicus. We prefer a 12-mm blunt tip trocar as our primary port. Carbon dioxide is insufflated to create a pneumoperitoneum up to 15 mmHg. A 10-mm 0° laparoscope is inserted, and the underlying bowel is inspected for any injury that may have occurred inadvertently during port placement. Subsequently, two additional 5-mm ports are placed under direct laparoscopic vision. A second port is placed 2 cm below the costal margin in the midclavicular line. The third port is placed in the anterior axillary line between the costal margin and iliac crest.

Step 1: Peritoneal Incision and Pararenal Dissection

The line of Toldt is incised, and the colon is reflected medially to expose the entire kidney. In general, the descending colon needs to be mobilized up to the aorta and the ascending colon up to the duodenum. At this point, the Gerota's fascia is incised and both the Gerota's fascia and the perinephric fat are reflected. The kidney is then completely mobilized, and the renal pelvis and ureter exposed. Blunt dissection is performed along the posterior wall of the retroperitoneum to expose the fascia overlying the psoas and quadratus lumborum muscles.

Step 2: Fixation of the Kidney

The patient is placed in a steep, Trendelenburg (head down) position, thereby facilitating cephalad displacement of the kidney. Using either the intra- or the extracorporeal knot-tying techniques, the kidney is fixed high on the posterior abdominal wall. According to surgeon preference, a vertical or horizontal row of sutures may be employed. Initially the upper pole of the kidney is affixed to the psoas or quadratus lumborum muscle with 2/0 nonabsorbable polyester suture on a round-bodied needle. Care must be taken to ensure that the suture only catches the renal capsule without penetrating the renal parenchyma

> Care must be taken to ensure that the suture only catches the renal capsule without penetrating the renal parenchyma

Two to three further sutures are placed in the similar manner at the middle and lower pole of the kidney (Fig. 1). Once all the sutures are secured, intra-abdominal pressure is decreased to 5 mmHg for inspection of the operative field and port sites for bleeding. After hemostasis is achieved, the ports are removed and port sites closed.

Retroperitoneal Approach

Positioning

The patient is put in a lateral decubitus position, with the operating table flexed. The bottom leg is flexed at the hip and knee, whereas the upper leg remains straight with a pillow between the legs. It is important to ensure all pressure points are fully padded and the patient is secured safely on the table.

FIGURE 1 ■ Kidney is pressed to the sidewall with non-absorbable sutures.

Port Placement

A 15-mm incision is made in the lumbar triangle between the 12th rib and the iliac crest. Using a hemostat, the tissue is bluntly spread away until the anterior thoracoabdominal fascia is exposed. A finger or hemostat is used to penetrate through this fascial layer as well as the lumbodorsal fascia to enter the retroperitoneum. Using the finger for blunt dissection, the retroperitoneal space is developed anterior to the psoas muscle and posterior to the Gerota's fascia. A balloon dilator device is inserted to create a working space in the retroperitoneum. Typically, about 800 to 1000 mL of air is instilled into the balloon to displace the kidney anteromedially.

> The laparoscope can be inserted within the inflated transparent balloon to confirm appropriate balloon placement and adequate expansion of the retroperitoneum.

The laparoscope can be inserted within the inflated transparent balloon to confirm appropriate balloon placement and adequate expansion of the retroperitoneum.

Following balloon dilation and removal, a 10-mm blunt tip trocar is placed as the primary port. After creation of pneumoretroperitoneum (15 mmHg) and the insertion of a 10-mm 30° laparoscope, the psoas muscle and Gerota's fascia are identified. Two secondary ports are placed under direct laparoscopic visualization. A 5-mm port is placed at lateral border of the erector spinae muscle just below the 12th rib (Fig. 2). Another 5-mm port is placed at the anterior axillary line 2 cm below the costal margin.

> During insertion of the third port, care must be taken to prevent breaching of the peritoneum. If required, the lateral reflection of the peritoneum can be further mobilized anteromedially before the port is inserted.

During insertion of the third port, care must be taken to prevent breaching of the peritoneum. If required, the lateral reflection of the peritoneum can be further mobilized anteromedially before the port is inserted.

Step 1: Kidney Mobilization

Gerota's fascia is incised longitudinally, and the kidney is dissected along its anterior, posterior, and lateral aspects. The kidney is fully mobilized after reflecting the perinephric fat. The posterior wall of the retroperitoneum is bluntly dissected to expose the fascia overlying the psoas and quadratus lumborum muscles.

Step 2: Fixation of the Kidney

The kidney is then fixed in an optimal position in the same manner described above. At the end of the surgery, hemostasis is confirmed under lowered retropneumoperitoneum pressure, and all the ports are removed under laparoscopic visualization. Fascial closure is performed for the 12-mm port site.

Postoperative Care

The patient is allowed to begin oral intake as tolerated from postoperative day 1. Intravenous ketorolac 15 mg is administered every six hours as required, and the patient is instructed to lie flat in bed for the initial three days. Antithrombotic stockings and low-molecular-weight heparin is given until the patient is ambulating. The average length of hospital stay is between three and five days. After discharge, the patient is followed up with an intravenous urogram at about three months.

RESULTS

Nephropexy is one of the oldest surgical procedures performed for symptomatic nephroptosis. Nevertheless, there is a continuing debate with regard to the indication and necessity of this procedure. Earlier, limited diagnostic studies prevented careful selection of patients with respect to the exclusion of other nonurological causes. With the advent of intravenous urography, a better understanding of this complex disorder

FIGURE 2 ■ Placement for the retroperitoneal approach.

TABLE 1 ■ Worldwide Experience with Laparoscopic Nephropexy

Study	Year	Number of patients	Approach	Fixation	Follow up (months)	Results
Hubner et al.	1994	10	Transperitoneal	Polygactin net	1–9	100% Asymptomatic
Elashry et al.	1995	6	Transperitoneal	Quadratus lumborum	2–30	100% Asymptomatic
Fornara et al.	1997	23	Transperitoneal	Psoas/ quadratus lumborum	12–27	91% Asymptomatic
McDougall et al.	2000	14	Transperitoneal	Quadratus lumborum	4–75	80% Asymptomatic
Rassweiler et al.	2001	31	Retroperitoneal	Psoas muscle	24 (mean)	83% Asymptomatic
Plas et al.	2001	13	Transperitoneal	Polypropylene net	63–93	92% Asymptomatic
Chueh et al.	2002	23	Retroperitoneal	Psoas/ quadratus lumborum	2–84	84% Asymptomatic
Ichikawa et al.	2003	5	Retroperitoneal	Psoas/ quadratus lumborum	5–22	80% Asymptomatic

Overall, about 130 patients with symptomatic nephroptosis have been treated laparoscopically. The transperitoneal approach seems to be favored over the retroperitoneal approach.

Early postoperative results after laparoscopic nephropexy vary from 80% to 100% success rate after one year and complete relief of symptoms in most cases. Long-term results up to five years following laparoscopic nephropexy showed complete remission in the vast majority of patients.

with associated functional changes could be demonstrated. As a result, nephropexy became established as the treatment of choice for symptomatic nephroptosis.

Overall, about 130 patients with symptomatic nephroptosis have been treated laparoscopically. The transperitoneal approach seems to be favored over the retroperitoneal approach.

Laparoscopy has brought to the surgical realm a minimally invasive method of approaching surgical problems with certain advantages over conventional open surgery. With the advent of intracorporeal suturing, reconstructive procedures have begun to come into the realm of minimally invasive therapy. Various authors have reported their experiences with laparoscopic nephropexy over the last decade (11–20). Table 1 summarizes all the reported series of laparoscopic nephropexy in the English literature.

Success of the surgery is usually defined as resolution of the symptoms associated with nephroptosis. Postoperative intravenous urogram assessment should reveal minimal descent of the kidney in majority of the patients. In additional, the ureteral obstruction associated with the kidney ptosis should also be resolved.

Early postoperative results after laparoscopic nephropexy vary from 80% to 100% success rate after one year and complete relief of symptoms in most cases. Long-term results up to five years following laparoscopic nephropexy showed complete remission in the vast majority of patients (18,19).

Few cases of symptomatic recurrence were observed after the initial success (18). Nonabsorbable materials (suture or mesh) should be used for the fixation of the mobile kidney to the retroperitoneum muscles. After concluding that the use of absorbable polygactin mesh for fixation was responsible for the recurrences seen, the authors subsequently changed to nonabsorbable polypropylene mesh, and no further symptomatic recurrences were noted.

SUMMARY

■ Symptomatic nephroptosis requires standard evaluation, including intravenous urogram assessment and isotope renogram with patients supine and upright.

■ Nephropexy should only be offered in symptomatic patients with proven deterioration of split renal function at orthostasis.

■ The good clinical outcome, minimal invasiveness, and rapid convalescence with long-term resolution of symptoms support the observation for laparoscopic nephropexy as the treatment of choice.

■ Nonabsorbable materials (suture or mesh) should be used for the fixation of the mobile kidney to the retroperitoneum muscles.

LAPAROSCOPIC RENAL CYST ABLATION: TECHNIQUE AND RESULTS

Li-Ming Su

Brady Urological Institute, The Johns Hopkins University School of Medicine, Baltimore, Maryland, U.S.A.

INTRODUCTION

Renal cysts are common benign lesions of the kidney estimated to occur in at least 24% of individuals older than 40 years and 50% of individuals older than 50 years, who are evaluated by abdominal computed tomography for nonurologic indications (1). With the recent widespread and increase use of abdominal cross-sectional radiographic imaging, the incidence of asymptomatic renal cysts is likely higher than previous estimates. Although renal cyst may be congenital or acquired, most are simple, asymptomatic, and of unknown etiology. However, some patients develop abdominal and/or flank pain, hematuria, hypertension, recurrent infection, or obstructive uropathy as a result of a renal cyst (2).

Open surgical exploration and treatment of renal cysts have been reported since the early 1900s. One of the earliest formal reviews of the literature and descriptions of open surgical management of renal cysts was performed by Kretschmer in 1920 (3). Of 35 patients who were explored through flank or abdominal incisions, 18 underwent excision or resection of a renal cyst, 16 required nephrectomy, and in one patient the cyst was marsupialized. He concluded that surgical resection of the cyst should be performed when possible. Open renal cyst ablation, although effective, was not without morbidity. In 1967, Kropp et al. reported a 37% complication rate in 126 patients undergoing open renal exploration for cyst, including two patients dying in the postoperative period (4). Because the surgical treatment of a benign condition such as a renal cyst did not generally require organ extirpation but rather only excision of the cyst wall and evacuation of its fluid contents, less invasive means of treating symptomatic renal cysts without requiring a large flank or abdominal incision were searched. Open renal cyst ablation remained the gold-standard approach until the late 1980s when minimally invasive methods were introduced.

In 1989, Holmberg and Hietala described percutaneous puncture and drainage of peripheral renal cysts under local anesthesia followed by instillation of bismuth–phosphate sclerosant (5). Although short-term success was high, limitations of this technique included a high cyst recurrence rate (54%) and the risk of collecting system strictures as a result of scarring caused by the sclerosing agent, making this technique ill advised for cysts located in the peripelvic region. Percutaneous resection and fulguration was proposed to address symptomatic renal cysts not amenable to aspiration and sclerosis (6). However, this technique required high technical skill, a large nephrostomy tract with

> Open renal cyst ablation remained the gold-standard approach until the late 1980s when minimally invasive methods were introduced.

the need for multiple tracts to treat multiple renal cysts, the placement of a ureteral stent and was associated with the risk of electrolyte disturbances secondary to irrigant absorption. Finally, retrograde endoscopic marsupialization of renal cysts using a flexible ureteroscope was described. Limitations of this technique included technical difficulty, a secondary procedure required to remove an indwelling ureteral stent, and its indications restricted to the treatment of peripelvic cysts only (7). Although each of these three minimally invasive approaches was effective for selected unilateral cysts, none provided the ability to easily address all types of cysts or complex cysts (multiple, bilateral, and/or peripelvic cysts) in one setting.

Hulbert and coworkers presented the first description of The advantage laparoscopic decortication of symptomatic renal cysts in 1992 (8) this technique included the ability to address multiple, peripelvic, and bilateral renal cysts in a single operation, while minimizing incisional morbidity.

Since its description, both transperitoneal and retroperitoneal laparoscopic approaches have been evaluated with excellent success rates (9–16).

PATIENT SELECTION

Selecting a proper candidate for laparoscopic renal cyst ablation depends on the following criteria:

- Radiographic diagnosis of a renal cyst
- Presence of symptoms attributable to the renal cyst
- Specific indications and contraindications

Radiographic Evaluation

The radiologic diagnosis of renal cysts can be made by renal ultrasonography, computed tomography, or magnetic resonance imaging. Although intravenous pyelography with tomographic views may show splaying of the collecting system or rotation of the kidney about its normal axis suggesting the presence of a renal mass, further confirmation radiologic studies are required in order to differentiate cyst versus neoplasm.

Ultrasonography

Ultrasonographic appearance of simple renal cyst is that of a sonolucent, round lesion with thin walls, smooth contour, displaying through transmission (Fig. 1). The presence or absence of septations, calcifications, thickening of the cyst wall, and soft-tissue nodules can be assessed using ultrasonography.

Computed Tomography

With the increase in cross-sectional imaging studies, computed tomography has become a more reliable modality for diagnosing renal cysts and differentiating them from other renal lesions such as a solid neoplasm.

The advantage of laparoscopic decortication of symptomatic renal cysts. Include the ability to address multiple, peripelvic, and bilateral renal cysts in a single operation, while minimizing incisional morbidity.

Since its description, both transperitoneal and retroperitoneal laparoscopic approaches have been evaluated with excellent success rates.

FIGURE 1 ■ Renal ultrasound of a patient with multiple simple renal cysts. Note the sonolucent nature of cysts displaying through transmission with thin walls, absence of nodules, septations, or calcifications.

FIGURE 2 ■ Contrast enhanced computed tomographic image of a patient with left peripheral renal cyst and right peripelvic renal cysts. Note: The peripelvic cysts are causing compression and obstruction of the collecting system. No enhancement within these cysts was noted after intravenous contrast administration.

The computed tomography criteria for a simple renal cyst include

- Homogeneous appearance of near water density;
- Thin or imperceptible wall when the cyst projects beyond the renal outline;
- No enhancement with intravenous contrast; and
- A smooth cyst–parenchymal interface (Fig. 2).

Measurement of Hounsfield units within a simple renal cyst confirms the presence of water density (Hounsfield units of 0–20). Comparison of Hounsfield units prior to and following intravenous contrast is also helpful in differentiating a simple fluid-filled cyst (no significant enhancement postcontrast) from a hyperdense cyst (precontrast Hounsfield units higher than water density but no significant enhancement postcontrast) or a solid-enhancing mass (postcontrast enhancement difference of > +10 Hounsfield units). Like with ultrasound, computed tomography provides information regarding the presence or absence of septations, mural nodules, and calcifications. Bosniak classification makes use of this information for categorizing renal cystic lesions with respect to risk of malignancy (Table 1) (17). Such classification ranges from Bosniak I lesions (i.e., simple benign renal cyst) to Bosniak IV lesions (i.e., highly suspicious for cystic renal neoplasm). For patients with a known history of autosomal dominant polycystic kidney disease, von Hippel-Lindau syndrome, tuberous sclerosis, or acquired cystic renal disease, each cyst should be evaluated separately to determine the likelihood of malignancy. Two- and, more recently, three-dimensional computed tomography images provide excellent anatomic information of renal units as well as the proximity of the renal cyst(s) to surrounding structures (e.g., spleen, liver, lung, adrenal, small and large bowel, renal vessels, or collecting system). Review of such information can prove useful when planning therapeutic intervention such as percutaneous, laparoscopic, or open surgical drainage of a renal cyst.

Magnetic Resonance Imaging

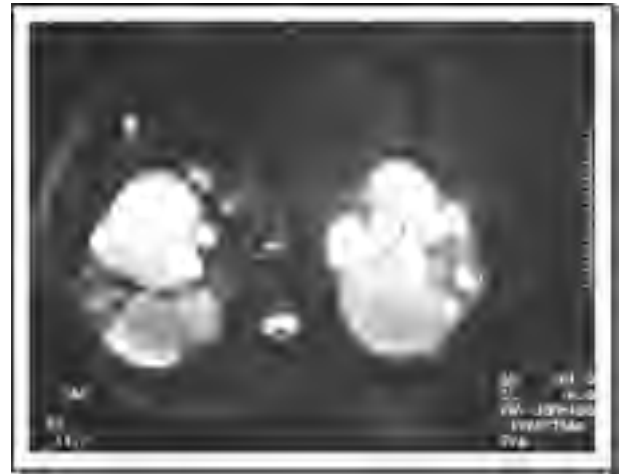
Magnetic resonance imaging with intravenous gadolinium can be used in patients who are unable to receive iodinated contrast due to renal insufficiency or dye allergy.

Enhancement of a renal lesion following the administration of gadolinium suggests the likelihood of a solid neoplasm, whereas a simple renal cyst does not enhance and appears homogeneous with low signal on T1-weighted images and high signal on T2-weighted images (Fig. 3).

> Enhancement of a renal lesion following the administration of gadolinium suggests the likelihood of a solid neoplasm, whereas a simple renal cyst does not enhance and appears homogeneous with low signal on T1-weighted images and high signal on T2-weighted images.

TABLE 1 ■ Bosniak Criteria for Classification of Renal Cysts Based on Computed Tomographic Findings

Type	Calcifications	Septations	Wall	Enhancement
I	None	None	Thin	None
II	Minimal	Few	Thin	None
III	Moderate	Multiple	Increased thickness	None
IV	Coarse with nodules	Numerous and irregular	Thick	Yes

FIGURE 3 ■ T2-weighted magnetic resonance image of a patient with autosomal dominant polycystic kidney disease. *Note*: The cysts appear homogeneous and bright, consistent with fluid density similar to the cerebral spinal fluid. Note that virtually the entire renal parenchyma of both kidneys is replaced by numerous cysts of varying sizes. No enhancement was noted within these cysts after gadolinium administration.


Recent reports suggest that magnetic resonance imaging may in fact identify additional findings (e.g., septations, wall thickening, or enhancement) not seen on computed tomography, which may lead to an upgraded Bosniak classification and therefore affect clinical management (18).

Symptoms

The vast majority of renal cysts are asymptomatic and ordinarily do not require treatment. Renal cysts that grow and obstruct portions of the collecting system, compress normal renal parenchyma, stretch the renal capsule, or spontaneously hemorrhage can cause symptoms. These symptoms include flank or abdominal pain, hematuria, hypertension, infection, or obstructive uropathy (2). In cases of extremely large and/or multiple cysts, such as in patients with autosomal dominant polycystic kidney disease, a palpable abdominal mass may be appreciated on physical examination.

Indications and Contraindications

Laparoscopic renal cyst ablation is indicated in patients with symptomatic, simple renal cysts, who have failed medical management (i.e., analgesics, nonsteroidal anti-inflammatory agents, narcotics, etc.). An initial attempt at percutaneous drainage with or without sclerosis should be performed prior to laparoscopic exploration and ablation.

Because of the high incidence of cyst recurrence following simple percutaneous drainage, multiple sclerosing agents have been proposed, including the use of alcohol, tetracycline, minocycline, or povodine–iodine with variable success (5,19,20). These sclerosing agents should, however, be avoided in parapelvic cysts as scarring and strictures of the collecting system have been reported (5).

Assessing change in symptoms following the reduction of cyst volume: initial percutaneous aspiration of the renal cyst(s) also determines which patients are more likely to gain benefit from laparoscopic ablation if the cyst and symptoms recur (11).

A suggested treatment algorithm for managing symptomatic peripheral and peripelvic renal cysts is shown in Figure 4.

Patients with complex renal cystic disease such as autosomal dominant polycystic kidney disease, von Hippel-Lindau, acquired renal cystic disease, or tuberous sclerosis have a predisposition to malignancy. In addition, patients with autosomal dominant polycystic kidney disease frequently have flank/abdominal pain or worsening hypertension associated with enlargement of their renal cysts. Laparoscopy is an effective means of treating autosomal dominant polycystic kidney disease patients who suffer from painful renal cysts and evaluating indeterminate (Bosniak class II and III) renal cysts (21–24).

Laparoscopic renal cyst ablation is contraindicated in patients with uncorrectable bleeding diatheses and those with comorbid medical conditions that preclude general anesthesia.

Prior abdominal surgery is not an absolute contraindication, but rather the site of prior surgery may alter the route of laparoscopic access (transperitoneal vs. retroperitoneal) that is chosen.

Even in patients with a history of extensive prior abdominal surgery, a retroperitoneal access may be preferred as entry into and dissection within the peritoneal cavity is not necessary. Although extreme obesity may make transperitoneal

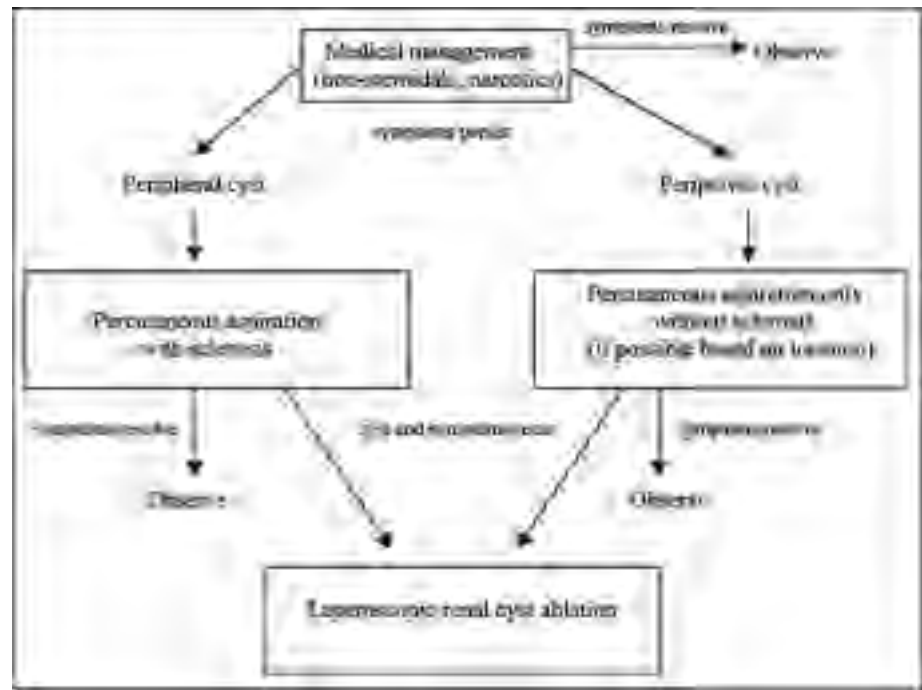
---

Sidebar notes (left margin):

Laparoscopic renal cyst ablation is indicated in patients with symptomatic, simple renal cysts, who have failed medical management (i.e., analgesics, nonsteroidal anti-inflammatory agents, narcotics, etc.). An initial attempt at percutaneous drainage with or without sclerosis should be performed prior to laparoscopic exploration and ablation.

Assessing change in symptoms following the reduction of cyst volume: initial percutaneous aspiration of the renal cyst(s) also determines which patients are more likely to gain benefit from laparoscopic ablation if the cyst and symptoms recur.

Prior abdominal surgery is not an absolute contraindication, but rather the site of prior surgery may alter the route of laparoscopic access (transperitoneal vs. retroperitoneal) that is chosen.

FIGURE 4 ■ Treatment algorithm for symptomatic simple peripheral and peripelvic renal cysts.


access more difficult, often a retroperitoneal approach is still feasible because patients typically have relatively less fat along their retroperitoneum. Unlike with Bosniak class II or III (i.e., indeterminate lesions), Bosniak IV lesions (i.e., renal cystic lesion found radiographically to be highly suspicious for malignancy) should not be approached by laparoscopic ablation, but rather by laparoscopic or open, partial, or radical nephrectomy.

Laparoscopic renal cyst ablation should not be performed in the setting of an active urinary tract infection, pyelonephritis, or renal abscess.

PREOPERATIVE PREPARATION

Laboratory and Radiologic Tests

All patients should undergo routine laboratory testing including a complete blood count, platelet count, serum electrolytes, coagulation profile, urinalysis, and a type and screen. Any coagulopathy or urinary infection should be treated prior to proceeding with surgery. An electrocardiogram and chest radiograph should be obtained if indicated. All necessary radiologic tests (i.e., sonogram, computed tomography, and magnetic resonance imaging) should be made available for reference during the operation.

Special attention must be made to confirm the presence of a normal contralateral renal unit especially in cases where partial or radical nephrectomy may be required.

Patients should be instructed to discontinue all aspirin, ibuprofen, vitamin E, warfarin, and any other blood thinners at least 7 to 10 days prior to surgery.

Bowel Preparation

In cases of symptomatic simple renal cysts, no specific bowel preparation is required prior to surgery. However in patients with autosomal dominant polycystic kidney disease, the typically large-sized kidneys can at times occupy the majority of the peritoneal cavity. Therefore, use of a preoperative bowel preparation (e.g., citrate of magnesium) is advised to decompress the bowel and provide more working space during laparoscopy. Patients should partake of only clear liquids 24 hours prior to surgery and remain fasted after midnight the evening prior to surgery.

Informed Consent

Prior to performing laparoscopic renal cyst ablation, patients must be counseled on the possibility of bleeding, transfusion, anesthetic risks, infection, urinoma, adjacent organ injury (e.g., bowel, adrenal, liver, spleen, ureter, and renal vessels) as well as renal loss.

Side margin notes:

Laparoscopic renal cyst ablation should not be performed in the setting of an active urinary tract infection, pyelonephritis, or renal abscess.

Special attention must be made to confirm the presence of a normal contralateral renal unit especially in cases where partial or radical nephrectomy may be required.

Patients must be aware of the possibility of failure to ablate all cysts, recurrence of cysts, and persistence of symptoms despite successful ablation of cyst(s). The possibility of partial or radical nephrectomy should be discussed, especially in cases of indeterminate renal cystic lesions in which the possibility of malignancy is suspected.

Patients must be aware of the possibility of failure to ablate all cysts, recurrence of cysts, and persistence of symptoms despite successful ablation of cyst(s). The possibility of partial or radical nephrectomy should be discussed with the patient especially in cases of indeterminate renal cystic lesions in which the possibility of malignancy is suspected.

As with any laparoscopic procedure, patients must understand the possibility of requiring conversion to an open surgery if deemed necessary.

Personnel and Equipment Configuration

In addition to the operating surgeon, laparoscopic renal cyst ablation requires the following personnel: a surgical assistant, scrub technician, circulating nurse, and anesthesia team. During the transperitoneal approach, both the operating surgeon and the assistant stand on the abdominal side of the patient, contralateral to the targeted kidney. A typical operating room configuration for a left transperitoneal laparoscopic renal cyst ablation is shown in Figure 5. The scrub nurse and equipment table are situated near the surgical team at the foot of the table. The operating table must be adjustable and allow for lateral rotation. Two towers or cabinets equipped with a color video monitor mounted at eye level, light source, and carbon dioxide gas insufflator are placed on either side near the head of the table to allow the operating surgeon, assistant, and scrub technician to view and continuously monitor the surgical procedure. A video camera is attached to the laparoscope and its display projected on both video monitors. A standard electrocautery unit is placed either in front or behind the operating surgeon. If the AESOP[®a] robotic arm is employed to stabilize and control the laparoscope, it should be attached to the operating table on the side contralateral to the kidney of interest and at the level of the patient's shoulders, taking great care to ensure that it does not come in contact with the patient's hands, arms, or shoulder during maneuvering of the robotic arm.

During the retroperitoneal approach, the surgeon and assistant stand facing the posterior flank of the patient with the side of the kidney of interest facing upward (Fig. 6). An operating table equipped with a kidney rest and that allows for flexion is important for the retroperitoneal technique.

Patient Positioning

Prior to patient positioning, the entire operating table is padded to reduce the risk of neuromuscular injuries. Sequential compression stockings are placed on the lower

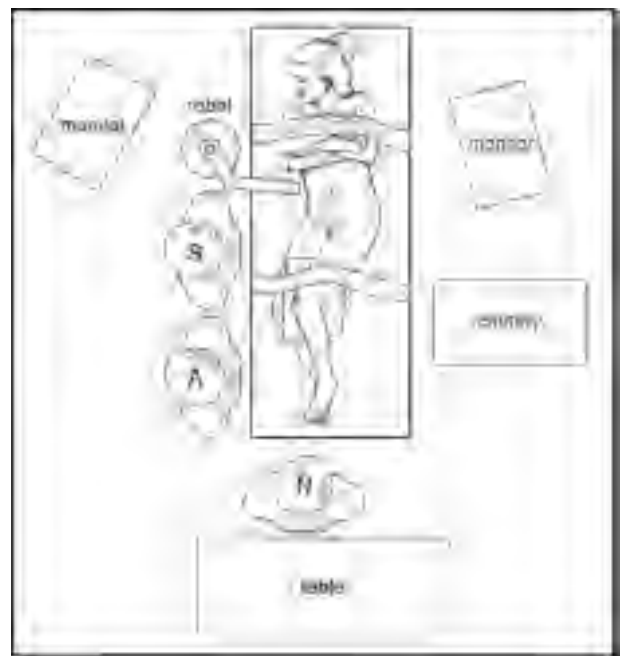
FIGURE 5 ■ Operating room configuration for left transperitoneal laparoscopic renal cyst ablation. *Abbreviations*: S, surgeon; A, assistant; N, scrub nurse/technician.


FIGURE 6 ■ Patient positioning and trocar configuration for right retroperitoneal laparoscopic renal cyst ablation. *Note*: X, 5-mm trocar; 0, 10/12-mm trocar.

FIGURE 7 ■ Patient positioning and trocar configuration for left transperitoneal laparoscopic renal cyst ablation. *Note*: X, 5-mm trocar; 0, 10/12-mm trocar.

extremities at the beginning of the operation and a single dose of intravenous cephazolin (1 g) is administered. Following induction of general endotracheal anesthesia, an orogastric tube and urethral catheter are placed to decompress the stomach and bladder, respectively.

Transperitoneal Approach

For the transperitoneal approach, the patient is placed in a modified flank position at an angle of 45° with the operating table, with the side of the kidney of interest facing upward. A sand bag is placed posterior to the ipsilateral flank for support. The arms are crossed over the chest and padded with egg crate padding or pillows (Fig. 7). This is to ensure that the patient's hands and arms do not rest upon the AESOP robotic arm. Alternatively if the AESOP robotic arm is not utilized, the arms can be kept outstretched on an arm board with sufficient padding placed between the arms. Neither an axillary roll nor flexion of the table is required.

The dependent leg is gently flexed at the knee, and pillows are placed between the legs. The patient is secured to the operating table with heavy cloth tape at the level of the shoulders and thighs. Additional egg crate sponge padding is placed over the shoulder and thighs to prevent abrasion and compression injuries as a result of the cloth tape. The operating room table is rotated to the extreme lateral limits to ensure that the patient is adequately secured to the table.

> In the transperitoneal approach, neither an axillary roll nor flexion of the table is required.

Retroperitoneal Approach

For the retroperitoneal approach, the patient is placed in a 90° full flank position, with the side of the targeted kidney facing upward. The patient's hips are positioned just below the break in the operating table. Flexion of the operating table at its break point is helpful in expanding the distance between the 12th rib and the iliac crest, thus providing the necessary room for trocar insertion. The kidney rest may also be elevated if needed (Fig. 6).

SURGICAL TECHNIQUE

Instrumentation and Equipment

Table 2 lists the laparoscopic instrumentation, equipment, and optional items recommended when performing laparoscopic renal cyst ablation.

Cystoscopy and Ureteral Stent Placement

Cystoscopy and ureteral stent placement is generally not required prior to laparoscopic cyst ablation of solitary, peripheral renal cysts. In patients with peripelvic cysts or autosomal dominant polycystic kidney disease, the location of the renal cyst(s) are often in close proximity to the collecting system in which case the ability to perform retrograde injection of indigo carmine or methylene blue–stained saline is useful to

TABLE 2 ■ Recommended and Optional Instrumentation and Equipment for Laparoscopic Renal Cyst Ablation

Recommended:
- 30° cystoscope lens, 20 French cystoscope sheath, and 5 French open-ended ureteral catheter (if cystoscopy and stent placement required)
- 7 French × 24 cm or 26 cm double pigtail ureteral stent
- Veress needle
- Visiport device™[a]
- 10/12-mm laparoscopic trocars (2 Nos.)
- 5-mm laparoscopic trocars (2 Nos.)
- 10-mm 0° and 30° laparoscopic lens
- Laparoscopic trocar-mounted dilator balloon
- Antifog lens solution and/or sterile hot water thermos
- 5-mm laparoscopic Debakey forceps
- Laparoscopic suction/irrigator device and probe
- Laparoscopic monopolar electrocautery scissors
- Laparoscopic articulating ultrasound probe and unit
- 5-mm laparoscopic needle aspirator and 20–30 cc syringe
- 5-mm laparoscopic biopsy forceps
- 3-mm laparoscopic trocar and 2-mm blunt-tip grasper (for elevation of liver during right-sided transperitoneal technique)
- Laparoscopic argon beam electrocoagulator
- Oxidized cellulose gauze
- Fibrin glue sealant (in cases of collecting system injury)
- 10-mm laparoscopic vascular clip appliers
- Hand-held electrocautery device
- Carter-Thomason®[b] fascial closure device
- 2-0, 3-0, 4-0, and 0-polyglactin suture (4-6)
- Steri-strips
- No. 15 scalpel blade
- 16 French urethral catheter
- 16 French orogastric tube
- Standard open nephrectomy tray and instrumentation with Bookwalter or Omni retractor (in case of open conversion)

Optional:
- 10-mm balloon-cuffed trocar
- 18-G spinal needle (for aspiration of renal cyst fluid)
- AESOP®[c] Robotic Arm
- Electrocautery hook
- Bipolar electrocautery forceps
- Ultrasonic shears

[a]United States Surgical Corporation, Norwalk, Connecticut, U.S.A.
[b]Inlet Medical, Eden Prairie, Minnesota, U.S.A.
[c]Intuitive Surgical, Inc., Sunnyvale, California, U.S.A.

rule out entry into the collecting system. In such cases, an open-ended ureteral stent can be placed cystoscopically under fluoroscopic guidance prior to positioning the patient for laparoscopy.

Operative Steps

Left Transperitoneal Laparoscopic Technique
Table 3 lists the operative steps for a transperitoneal laparoscopic ablation of a simple renal cyst.

Step 1: Trocar Configuration and Insertion
Transperitoneal laparoscopic renal cyst ablation typically requires three trocars (5-mm, 10/12-mm, and 10/12-mm) as depicted in Fig. 7. After Veress needle insertion at the umbilicus and insufflation of the abdomen, a 10/12-mm trocar is placed at the umbilicus with the use of a Visiport®[b] device and is utilized predominately for the laparoscope. Alternatively, an open Hasson technique can be used for initial trocar

TABLE 3 ■ Operative Steps for Transperitoneal Laparoscopic Renal Cyst Ablation

Step 1	Abdominal access and trocar placement
Step 2	Reflection of ipsilateral colon and exposure of kidney
Step 3	Exposure of renal cyst(s)
Step 4	Needle aspiration of renal cyst fluid
Step 5	Excision of renal cyst wall
Step 6	Biopsy of renal cyst base (if required) and coagulation of cyst base
Step 7	Packing of cyst defect
Step 8	Placement of retroperitoneal drain (if required)
Step 9	Retroperitonealization of kidney
Step 10	Exiting the abdomen and skin closure

insertion. Under laparoscopic view, a 5-mm trocar is place below the xiphoid process in the abdominal midline, halfway between the umbilicus and xiphoid process. A second 10/12-mm trocar is placed just lateral to the rectus muscle at the level of the umbilicus to avoid injury to the epigastric vessels. These two trocars serve as the main working trocars. A 10-mm 30° laparoscopic lens is utilized during transperitoneal laparoscopic renal cyst ablation.

Step 2: Reflecting the Ipsilateral Colon and Exposure of the Kidney

With Debakey forceps in the 5-mm trocar and laparoscopic electrocautery scissors placed in the left lower quadrant 10/12-mm trocar, the line of Toldt along the descending colon is sharply incised from the splenic flexure down to the pelvic inlet.

Electrocautery should be minimized during dissection of the colon in order to avoid accidental cautery injury to the bowel.

The colon and its associated mesentery are bluntly dissected with a suction irrigator device in a medial direction, exposing Gerota's fascia overlying the kidney. Great care must be taken to release the colorenal ligaments and develop the precise plane between Gerota's fascia and the mesentery of the colon.

Dissecting too close to the colonic mesentery can result in inadvertent injury to the mesenteric vessels and creation of a defect in the mesentery. If unrecognized or not repaired at the time of surgery, a mesenteric defect can result in an internal hernia in the postoperative period.

It may be necessary to divide the phrenocolic, lienorenal, and splenocolic ligaments in order to adequately expose the upper pole of the kidney and access superiorly located renal cysts. The operating table is maximally rotated toward the operating surgeon to allow the colon and small bowels to fall medial and away from the kidney, thus providing optimum exposure of the kidney and renal cyst(s) (Fig. 8).

When treating anteriorly located renal cysts, division of the lateral attachment of the kidney is not necessary and therefore these attachments should be maintained. For lateral or posteriorly located renal cysts, the lateral attachments of the kidney are released allowing the kidney to be rotated medially about its hilum. This provides the necessary exposure of the posterolateral surface of the kidney.

Alternatively, the retroperitoneal technique may be used for renal cysts located strictly at the posterior surface of the kidney (see the section entitled Retroperitoneal Laparoscopic Technique). Dissection and exposure of the renal vessels, pelvis, and ureter are typically not required during management of simple, nonhilar, peripheral renal cysts.

Step 3: Exposure of Renal Cyst(s)

For an exophytic renal cyst, the location of the cyst is often denoted by a bulge in the contour of the kidney. Gerota's fascia and perirenal fat overlying the renal cyst is excised sharply using electrocautery scissors, leaving an approximately 1-cm rim of exposed renal parenchyma around the cyst (Fig. 9).

For treatment of multiple renal cyst (e.g., autosomal dominant polycystic kidney disease), excision of most if not all of Gerota's fascia and perirenal fat may be required to expose all parenchymal surfaces and identify optimally all renal cysts.

For intraparenchymal cysts, intraoperative laparoscopic ultrasound may be required to identify their precise location.

Step 4: Needle Aspiration of Renal Cyst Fluid

For large renal cysts, needle aspiration of cyst fluid allows for decompression of the cyst and cytologic analysis of the aspirate. A 5-mm needle aspiration device is inserted and

---

Side notes:

Electrocautery should be minimized during dissection of the colon in order to avoid accidental cautery injury to the bowel.

Dissecting too close to the colonic mesentery can result in inadvertent injury to the mesenteric vessels and creation of a defect in the mesentery. If unrecognized or not repaired at the time of surgery, a mesenteric defect can result in an internal hernia in the postoperative period.

When treating anteriorly located renal cysts, division of the lateral attachment of the kidney is not necessary and therefore these attachments should be maintained. For lateral or posteriorly located renal cysts, the lateral attachments of the kidney are released allowing the kidney to be rotated medially about its hilum. This provides the necessary exposure of the posterolateral surface of the kidney.

For treatment of multiple renal cyst (e.g., autosomal dominant polycystic kidney disease), excision of most if not all of Gerota's fascia and perirenal fat may be required to expose all parenchymal surfaces and identify optimally all renal cysts.

FIGURE 8 ■ Mobilization of colon and exposure of Gerota's fascia and kidney. The contour of a small middle pole and large lower pole renal cyst can be seen.

FIGURE 9 ■ Excision of Gerota's fascia and perirenal fat overlying lower pole renal cyst.

Aspirated fluid from a benign renal cyst is typically straw colored and if bloody or purulent, the possibility of a malignancy or infection should be considered, respectively.

Only the anterior wall (i.e., extrarenal portion) of the cyst is generally excised, because efforts to remove the lining of the base of the cyst can result in parenchymal bleeding.

the fluid is aspirated using a 20 to 30 cc syringe (Fig. 10). Alternatively, an 18-G spinal needle may be placed percutaneously under laparoscopic view to drain the cyst.

Aspirated fluid from a benign renal cyst is typically straw colored and if bloody or purulent, the possibility of a malignancy or infection should be considered, respectively.

Step 5: Excision of Renal Cyst Wall
With the cyst decompressed, the exposed anterior wall of the renal cyst is excised sharply with electrocautery scissors at its junction with the renal parenchyma (Fig. 11). Point electrocautery may be required for hemostasis. The cyst wall is then sent for permanent histopathologic analysis.

Only the anterior wall (i.e., extrarenal portion) of the cyst is generally excised, because efforts to remove the lining of the base of the cyst can result in parenchymal bleeding.

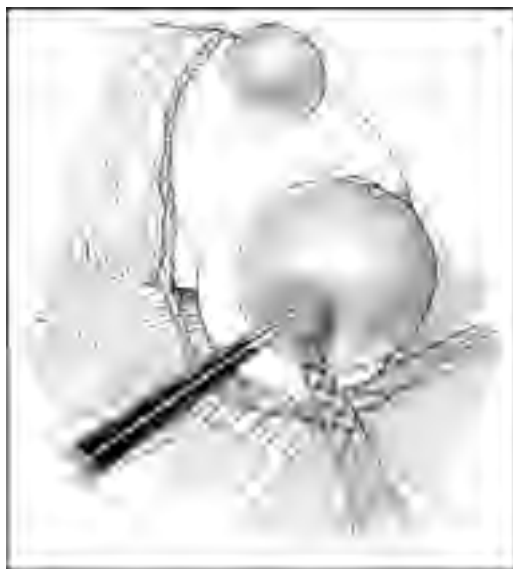
Step 6: Biopsy and Coagulation of Renal Cyst Base
Following excision of the cyst wall, the base of the cyst should be inspected carefully for the presence of suspicious lesions or nodules. These regions may be biopsied


FIGURE 10 ■ Needle aspiration of renal cyst fluid.

FIGURE 11 ■ Excision of exposed renal cyst wall.

Great care must be taken to avoid entry into the collecting system when performing biopsies, especially in cysts in close proximity to the collecting system. If violation of the collecting system is suspected, retrograde instillation of methylene blue or indigo carmine–stained saline via a previously placed ureteral stent can be performed and the collecting system sutured closed with 2–0 or 3–0 polyglactin suture.

In cases where malignancy is noted on frozen section analysis, a partial or radical nephrectomy can be immediately performed either laparoscopically or by open surgery, depending on the skill and experience of the surgeon.

The kidney, ablated renal cyst(s), and drain are thus retroperitonealized, aiding in the containment and management of a postoperative urinoma or hematoma if one were to occur in the postoperative setting.

using a 5-mm laparoscopic biopsy forceps (Fig. 12) and sent for frozen section histopathologic analysis.

Great care must be taken to avoid entry into the collecting system when performing biopsies, especially in those cysts that are in close proximity to the collecting system. If violation of the collecting system is suspected, retrograde instillation of methylene blue or indigo carmine–stained saline via a previously placed ureteral stent can be performed and the collecting system sutured closed with 2–0 or 3–0 polyglactin suture.

If the collecting system defect is large, fibrin glue sealant may also be applied as a secondary measure following suture placement. In cases where collecting system entry is confirmed, a closed-suction drain is left at the conclusion of the operation and the open-ended ureteral stent is exchanged for an indwelling stent. Limited coagulation of the base of the renal cyst may be performed using either monopolar electrocautery or a laparoscopic argon beam coagulator (Fig. 13), avoiding direct fulguration of the collecting system.

In cases where malignancy is noted on frozen section analysis, a partial or radical nephrectomy can be immediately performed either laparoscopically or by open surgery, depending on the skill and experience of the surgeon.

Step 7: Packing of Renal Cyst Defect
Suture fixation of perirenal fat or omentum into the cyst cavity can act as a wick to prevent reaccumulation of cyst fluid. Alternatively oxidized cellulose gauze can be placed within the cyst defect (Fig. 14).

Step 8: Drain Placement
For large cysts, infected cysts, or if entry into the collecting system is suspected, a closed suction drain can be left in place for one to two days. The drain can be inserted through a preexisting 10/12-mm trocar and brought out through a separate posterolateral incision site. The drain holes should rest in a dependent position relative to the renal cyst (Fig. 14).

Step 9: Retroperitonealization of Kidney
Upon completion of the renal cyst ablation and after meticulous hemostasis is accomplished, the ipsilateral colon can be brought back over the kidney and reattached to the abdominal sidewall, reconstituting the line of Toldt. This can be accomplished using 2-0 polyglactin sutures (Fig. 15).

The kidney, ablated renal cyst(s), and drain are thus retroperitonealized, aiding in the containment and management of a postoperative urinoma or hematoma if one were to occur in the postoperative setting.

FIGURE 12 ■ Biopsy of lesion at cyst base using laparoscopic biopsy forceps.

FIGURE 13 ■ Argon beam coagulation of renal cyst base.

FIGURE 14 ■ Packing of renal cyst defect with oxidized cellulose gauze. The smaller midpole cyst has already been ablated and packed. A retroperitoneal drain can be placed medial and inferior to the kidney, if entry and repair of the collecting system are required.

FIGURE 15 ■ Retroperitonealization of kidney and drain.

Step 10: Exiting the Abdomen and Skin Closure

Final inspection of the surgical site is performed under low insufflation pressures (e.g., 5–10 mmHg) to assess for residual bleeding. The 5-mm trocar is removed under laparoscopic view and all 10/12-mm trocar sites are closed using the Carter-Thomason®c fascial closure device with 0-polyglactin suture. The skin incisions are closed with continuous 4-0 polyglactin subcuticular sutures followed by steristrips.

Right Transperitoneal Laparoscopic Technique

For a right-sided transperitoneal laparoscopic renal cyst ablation, trocar configuration is the mirror image of that used for a left-sided technique (i.e., the second 10/12-mm trocar is placed lateral to the right rectus muscle with all other trocars remaining the same). The ascending colon is reflected medially and for cysts located near the hilum, reflection of the duodenum may be required. A combination of blunt and sharp dissection of the attachments between the duodenum and kidney (Kocher maneuver) is performed with avoidance of electrocautery. For cysts located along the superior pole of the kidney, sharp release of the coronary ligament of the liver allows for anterior retraction of the right lobe of the liver for exposure to the upper pole of the kidney. A 3-mm or 5-mm additional trocar may be placed two to three fingerbreadths superior to the existing 5-mm trocar to allow for insertion of a laparoscopic instrument or grasper for liver retraction. The subsequent steps follow that of a left-sided dissection. Figure 16 demonstrates the computed tomography images of a patient with bilateral, multiple renal cysts causing hydronephrosis and symptoms of right flank pain, who underwent right laparoscopic renal cyst ablation of a parapelvic and large peripheral cyst with prompt resolution of obstruction and symptoms.

Retroperitoneal Laparoscopic Technique

The retroperitoneal technique requires the use of three trocars (5-mm, 10/12-mm, and 10/12-mm) and a 10-mm 0° laparoscopic lens. A 1.5-cm transverse incision is made just below the tip of the 12th rib using a No. 15-scalpel blade. After entry into the retroperitoneal space, blunt finger dissection can be used to sweep the peritoneum medially and retroperitoneal fat away from the tract in all directions. A 0° 10-mm laparoscopic lens loaded into a trocar-mounted balloon dilator device is inserted into the tract keeping anterior to the psoas muscle and posterior to Gerota's fascia. Approximately 800 to 1000 cc of air is inflated into the balloon (approximately

---

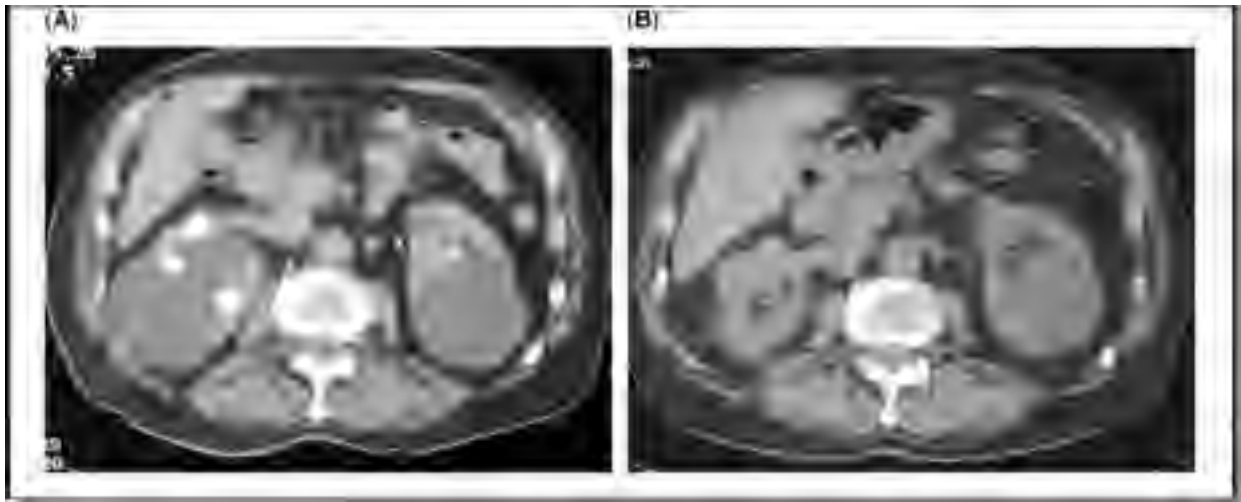

FIGURE 16 ■ Computed tomographic images before (**A**) and one month after (**B**) right laparoscopic renal cyst ablation of a peripelvic and large peripheral cyst causing obstruction and symptoms of right flank pain. Note complete ablation of right-sided cysts and resolution of obstruction. Left-sided cysts were left untreated because these were asymptomatic.

> During the retroperitoneal approach, identification of as many of the retroperitoneal landmarks including the psoas and quadratus lumborum muscles, pulsations of the renal artery, ureter, vena cava (right-sided dissection), and aorta (left-sided dissection) is important to properly orient the surgeon to the location of the kidney and associated cysts.

40 pumps of the sphygmomanometer bulb) under laparoscopic view to develop the retroperitoneal working space. A second more cephalad inflation with the balloon dilator may be required to gain exposure and access upper-pole renal cysts. After removal of the balloon dilator, a 10-mm balloon-cuffed trocar can be inserted and inflated (30 cc air) snug beneath the abdominal fascia to prevent gas leakage during the operation. Alternatively, a standard 10/12-mm trocar may be inserted with 2-0 polyglactin sutures used to cinch the abdominal fascia snug with the trocar to minimize loss of pneumoperitoneum. A second 10/12-mm trocar is placed under laparoscopic view or alternatively digital guidance, along the anterior axillary line and three fingerbreadths cephalad to the iliac crest. One must be sure that the peritoneum has been adequately mobilized medially to prevent transperitoneal placement of this trocar. Lastly, a 5-mm trocar is placed at the junction of the lateral border of the erector spinae muscle and the underside of the 12th rib. The final trocar configuration is as shown in Fig. 6. The distance between trocars should ideally be at least three to four fingerbreadths to minimize trocar and instrument collision.

During the retroperitoneal approach, identification of as many of the retroperitoneal landmarks including the psoas and quadratus lumborum muscles, pulsations of the renal artery, ureter, vena cava (right-sided dissection), and aorta (left-sided dissection) is important to properly orient the surgeon to the location of the kidney and associated cysts.

As the working space is smaller and landmarks less distinct as compared to the transperitoneal technique, great care must be taken to avoid mistaking the liver (during right-sided dissection) or spleen (during left-sided dissection) for renal parenchyma. During the retroperitoneal technique, reflection of the colon is unnecessary and therefore following trocar placement and development of the retroperitoneal working space, the operative steps follow that are listed in Table 3 starting with Step 3.

Pros and Cons of Transperitoneal vs. Retroperitoneal Approach

The choice of the transperitoneal versus retroperitoneal approach relies on a number of factors including

1. The location and number of renal cyst(s)
2. History of prior abdominal surgery
3. Working space and familiarity with the surrounding anatomy
4. The surgeon's experience

Location and Number of Renal Cysts

The location of the renal cyst(s) is perhaps the most important factor in determining the surgical approach. The transperitoneal approach is best utilized for management of simple renal cysts located along the anterior surface of the kidney and peripelvic cysts.

Cysts located along the posterolateral surface of the kidney can be managed by the transperitoneal approach, but may be more efficiently approached by retroperitoneal access. For patients with multiple renal cysts (e.g., autosomal dominant polycystic kidney disease), exposure of the entire renal surface may be necessary and therefore the transperitoneal approach is preferred.

Prior Abdominal Surgery

In patients with a history of prior abdominal surgery, dense, complex adhesions may at times be encountered during transperitoneal dissection with difficulty in accessing and exposing the renal cysts as well as the potential for bowel injury. In such cases, a retroperitoneal approach may be advisable to avoid the need for intraperitoneal dissection and lysis of adhesions in a previously operated field.

Working Space, Familiarity with the Surrounding Anatomy, and Surgeon Experience

In general, the transperitoneal approach provides a larger working space as compared to that of retroperitoneoscopy. In addition, the transperitoneal approach may provide an operative view that is more familiar to most surgeons as compared to that of the retroperitoneal approach. However with experience, retroperitoneoscopy provides a more direct and rapid access especially to posteriorly located renal cysts, avoids violation of the peritoneum, and thus reduces the chances of intraperitoneal organ injury.

Technical Modifications for the Management of Complex Renal Cysts

The laparoscopic approach to ablating simple renal cysts is relatively straightforward; however for complex renal cystic lesions, there are technical modifications worthy of mention.

Peripelvic Renal Cysts

Although for peripelvic cysts both transperitoneal and retroperitoneal laparoscopic techniques are feasible, the transperitoneal approach provides optimum exposure of the renal hilum, a larger working space, and is therefore the approach of choice. Excision of Gerota's fascia and perirenal fat overlying the anteromedial aspect of the kidney is necessary to provide optimal visualization of the renal hilar structures.

Due to the close proximity of peripelvic cysts to the renal vasculature and collecting system, meticulous dissection must be carried out to avoid injury to these structures.

The branches of the renal vasculature and collecting system are often distorted and splayed by the peripelvic cysts, making them difficult to identify and differentiate from the cyst itself. Prior attempts at percutaneous drainage can also result in inflammation and scarring, making the tissue planes between the peripelvic cyst and hilar structures even less distinct. Placement of a ureteral catheter with retrograde injection of indigo carmine–or methylene blue–stained saline is useful in identifying the course of the splayed collecting system and for identification of collecting system injuries. Precise identification of renal vascular braches can be aided by the use of laparoscopic ultrasound with Doppler if available. Unlike with simple peripheral renal cysts, excision of the entire anterior cyst wall may not be feasible with peripelvic cysts. Overzealous attempts at cyst wall excision as well as cauterization of the cyst lining can lead to vascular and/or collecting system injury.

Only partial cyst wall excision is advisable with spot cauterization of the cyst edge. Suture fixation of a tag of perirenal fat, omentum, or polytetrafluoroethylene (Gore-Tex®) wick into the residual cyst cavity can encourage drainage and prevent reaccumulation of cyst fluid (9).

Autosomal Dominant Polycystic Kidney Disease

In patients with autosomal dominant polycystic kidney disease, kidney size is often large and can at times occupy the majority of the abdominal cavity, displacing adjacent organs.

A mechanical bowel preparation is recommended prior to cyst ablation in patients with autosomal dominant polycystic kidney disease to help decompress the bowels and optimize the already limited working space secondary to the large kidneys.

The transperitoneal approach provides the most exposure to the numerous cysts encountered in patients with autosomal dominant polycystic kidney disease and allows for access to cysts located both anteriorly and posteriorly; however success with retroperitoneal access has also been reported (21). Dissection of Gerota's fascia and perirenal fat off the entire renal surface and complete mobilization of the kidney are required to expose and gain access to as many cysts as possible.

Side notes (margin):

Due to the close proximity of peripelvic cysts to the renal vasculature and collecting system, meticulous dissection must be carried out to avoid injury to these structures.

Only partial cyst wall excision is advisable with spot cauterization of the cyst edge. Suture fixation of a tag of perirenal fat, omentum, or polytetrafluoroethylene (Gore-Tex®) wick into the residual cyst cavity can encourage drainage and prevent reaccumulation of cyst fluid.

A mechanical bowel preparation is recommended prior to cyst ablation in patients with autosomal dominant polycystic kidney disease to help decompress the bowels and optimize the already limited working space secondary to the large kidneys.

> - Large-to-medium cysts are punctured and drained, the exposed cyst wall excised, and the edge of the cyst cauterized. Through the defects of these unroofed cysts, deeper cysts that are identified are similarly unroofed and drained. The lining of the cyst cavities are not routinely cauterized or packed, but rather marsupialized with the peritoneal cavity.
> - Small-to-tiny cysts can be merely incised, punctured, or cauterized.

Transcutaneous ultrasound has been described to aid in intraoperative localization of deep-seated renal cysts in patients with autosomal dominant polycystic kidney disease. However, the pneumoperitoneum can interfere with the accuracy of cyst localization and therefore must first be decompressed (22).

The use of a laparoscopic ultrasound probe has proven very effective in facilitating the identification and treatment of deep-seated renal cysts, with one report citing a total of 635 cysts ablated in a single session (23).

In addition, intraoperative reference to preoperatively obtained imaging studies may be helpful in identifying and ablating as many renal cysts as possible. Due to the large number of cysts located both peripherally and in proximity to the renal hilum, the risk of injury to the collecting system is increased.

All autosomal dominant polycystic kidney disease patients should undergo preoperative placement of a ureteral catheter with retrograde injection of dyed saline during and, at the conclusion of cyst ablation, to help identify any inadvertent entry into the collecting system.

Indeterminate Renal Cysts

With the use of contrast-enhanced cross-sectional imaging techniques, the vast majority of renal cystic lesions can be categorized radiographically as benign versus neoplastic. However, a small subset of lesions still remain indeterminate, making management difficult (24). As compared to the surgical management of most renal cysts, the management of indeterminate (i.e., Bosniak class II and III) lesions is more controversial with reports citing a 14% to 41% risk of malignancy (25,26).

Laparoscopic exploration offers a minimally invasive method of evaluating and treating these lesions. Patients must be aware of the possibility of requiring a partial or radical nephrectomy if malignancy is detected.

Fluid is aspirated from these indeterminate renal cysts during laparoscopic exploration and sent for cytologic analysis. Biopsies of suspicious regions (e.g., areas of discoloration, nodularity, or calcifications) along the base of the renal cyst are sent for frozen section histopathologic analysis. Partial or radical nephrectomy can be performed immediately if malignancy is detected on frozen section. A staged operative procedure may be required following receipt of final histopathologic analysis in cases where frozen section assessment is inconclusive. In the absence of malignancy, the cyst is managed similar to that of a simple cyst.

POSTOPERATIVE CARE

Patients are generally able to resume a clear liquid diet the evening of surgery and be advanced to a regular diet the following day. Antibiotic coverage can be maintained for a 24-hour period following surgery. Incisional pain may be controlled with intravenous narcotic medications and then switched to oral agents once a regular diet is started. Routine laboratory tests including a complete blood count and electrolytes may be drawn the first postoperative day with further blood test drawn only as needed on subsequent days. For uncomplicated cyst ablation cases, the urethral catheter is removed the day after surgery once the patient is fully ambulating and the patient discharged on postoperative day 2 or 3 once a regular diet is tolerated and pain is controlled with oral agents. In cases of a collecting system injury where placement of an internal ureteral stent and retroperitoneal drain were required at the time of surgery, the urethral catheter can be removed when the documented retroperitoneal drain output is minimal (usually by postoperative day 2 or 3), followed by removal of the retroperitoneal drain if its output does not subsequently increase. In the case of collecting system injury and repair, the ureteral stent is left in place for two to four weeks depending on the extent of injury and removed cystoscopically in the office.

In the rare case where the retroperitoneal drain output remains high, the urethral catheter should remain in place and the retroperitoneal drain taken off the bulb suction to discourage formation of a urinary fistula and to encourage antegrade drainage of urine with spontaneous closure of the collecting system. If stable, the patient may even be discharged home, and the drains subsequently managed in the office in one to two weeks.

Sidebar notes:

The use of a laparoscopic ultrasound probe has proven very effective in facilitating the identification and treatment of deep-seated renal cysts, with one report citing a total of 635 cysts ablated in a single session.

All autosomal dominant polycystic kidney disease patients should undergo preoperative placement of a ureteral catheter with retrograde injection of dyed saline during and at the conclusion of cyst ablation to help identify any inadvertent entry into the collecting system.

Laparoscopic exploration offers a minimally invasive method of evaluating and treating renal cystic lesions. Patients must be aware of the possibility of requiring a partial or radical nephrectomy if malignancy is detected.

In the case of collecting system injury and repair, the ureteral stent is left in place for two to four weeks depending on the extent of injury and removed cystoscopically in the office.

Repeat imaging studies (e.g., computed tomography) should be considered to confirm proper positioning of the ureteral stent within the collecting system in cases of persistent drainage despite the previously described maneuvers.

In the postoperative period, an urinoma and/or perinephric hematoma should be considered in the differential diagnosis in patients who exhibit persistent low-grade fevers (>38.5°C), ileus, nausea and vomiting, and leukocytosis.

Contrast-enhanced computed tomography can be used to confirm the diagnosis. In cases of an unsuspected hematoma, conservative management with blood transfusion as needed is usually sufficient. Rarely is renal arteriography with selective embolization or reoperation required. In cases of a postoperative urinoma, a urethral catheter is reinserted as well as either an internal ureteral stent or percutaneous nephrostomy tube. For an undrained collection, percutaneous placement of a retroperitoneal drain may be required if one was not placed at the time of the initial operation.

If histopathologic and cytologic analysis of the cyst wall and fluid confirms the presence of malignancy, a staged partial or radical nephrectomy should be discussed with the patient. This can be performed either laparoscopically or through an open approach ideally within one week of the initial surgery.

MEASURES TO AVOID COMPLICATIONS

Intraoperative Complications

Bleeding

Bleeding during laparoscopic renal cyst ablation can occur during many steps of the operation including (i) mobilization and dissection of the kidney, (ii) cyst wall excision and fulguration, and (iii) dissection around the renal hilum.

> Bleeding during laparoscopic renal cyst ablation can occur during many steps of the operation including (i) mobilization and dissection of the kidney, (ii) cyst wall excision and fulguration, and (iii) dissection around the renal hilum.

Dissection of Gerota's fascia and perinephric fat and mobilization of the kidney, especially along the hilum and adrenal gland, can lead to bleeding. In cases of simple, solitary renal cyst, only limited dissection of Gerota's and perirenal fat should be performed, providing just enough exposure of the entire renal cyst and adjacent renal parenchyma. Extensive dissection of these tissues is unnecessary and can lead to unwanted bleeding. Only in cases of autosomal dominant polycystic kidney disease is complete, exposure of the renal surface generally required.

> During cyst wall excision, only the exposed, extrarenal portion of the cyst wall should be excised, because attempts at complete enucleation often result in bleeding from the underlying renal parenchyma. Following cyst wall excision, only limited coagulation of the base should be performed because deep fulguration can initiate bleeding from larger parenchymal vessels.

During cyst wall excision, only the exposed, extrarenal portion of the cyst wall should be excised, because attempts at complete enucleation often result in bleeding from the underlying renal parenchyma. Following cyst wall excision, only limited coagulation of the base should be performed because deep fulguration can initiate bleeding from larger parenchymal vessels.

Dissection of the renal hilum is generally not required except in cases of a peripelvic cyst or autosomal dominant polycystic kidney disease. Electrocautery and sharp dissection should be minimized during dissection around the renal hilum to avoid iatrogenic injury to the renal vessels. If bleeding from the renal vein occurs, temporary pressure applied to the point of bleeding often results in cessation of hemorrhage, if the site of injury is small. In the case of a large venous or arterial injury, pressure can be applied with prompt consideration for open conversion or nephrectomy if laparoscopic means (i.e., clips and sutures) fail to control the source.

Collecting System Injury

Injury to the collecting system can occur during aggressive biopsy and fulguration of the base of the cyst wall or during attempts at cyst wall excision of a peripelvic or autosomal dominant polycystic kidney disease cysts.

> Injury to the collecting system can occur during aggressive biopsy and fulguration of the base of the cyst wall or during attempts at cyst wall excision of a peripelvic or autosomal dominant polycystic kidney disease cysts.

When biopsy of the cyst base is indicated, only superficial samples should be taken especially in the case of peripelvic cysts or cysts located close to the collecting system. Reference to preoperative radiologic films may be helpful in assessing the depth of the cyst and its proximity to the collecting system. Direct coagulation of the collecting system should be avoided. As mentioned previously, placement of an open-ended ureteral stent at the start of the operation especially in the treatment of peripelvic or autosomal dominant polycystic kidney disease cysts can help identify the precise location of a collecting system injury and facilitate its repair.

> The open-ended ureteral stent can be converted at the end of the case to an indwelling ureteral stent, which should be placed under fluoroscopic guidance to confirm proper positioning within the collecting system.

The open-ended ureteral stent can be converted at the end of the case to an indwelling ureteral stent, which should be placed under fluoroscopic guidance to confirm proper positioning within the collecting system.

As in any laparoscopic renal procedure, injury to surrounding structures such as the bowel, spleen, liver, pancreas, pleura, and adrenals can occur.

If recognized, a small bowel injury may be repaired laparoscopically in multiple layers with interrupted 3-0 silk sutures; however, a bowel resection may be required.

Complications such as ileus, fever, urinary tract infection, urinary retention, atelectasis, pneumonia, cellulitis, renal insufficiency, neuromuscular injury, incisional hernia, transfusion, recurrence of cyst, persistence of pain, deep venous thrombosis, and pulmonary embolism can occur following laparoscopic renal cyst ablation.

To avoid the occurrence of urinoma, every attempt should be made to avoid inadvertent entry into the collecting system when performing renal cyst ablation and to repair overt injuries if they occur.

Persistence of pain following ablation of a solitary renal cyst may indicate an incorrect diagnosis as to the initial cause of pain. It is therefore recommended that patients undergo an initial trial of cyst aspiration with laparoscopic ablation reserved only for those patients whose cyst and symptoms recur.

Success of laparoscopic renal cyst ablation as defined by relief of symptoms (i.e., symptomatic success) averaged 97% when comparing all series, with 92% of patients showing no evidence of cyst recurrence on follow-up imaging studies (i.e., radiographic success).

Adjacent Organ Injury

As in any laparoscopic renal procedure, injury to surrounding structures such as the bowel, spleen, liver, pancreas, pleura, and adrenals can occur.

Use of a preoperative bowel preparation especially in more challenging cases such as autosomal dominant polycystic kidney disease can decompress the bowel, improve visualization, and reduce the chance of iatrogenic injury from laparoscopic instrumentation. During mobilization of the colon and small bowel, the use of electrocautery should be minimized to avoid accidental cautery injury to the bowel and subsequent delayed bowel perforation. During a right-sided procedure, great care must be taken during the dissection of the duodenum. Use of electrocautery or careless sharp dissection around the duodenum can result in duodenal injury and catastrophic consequences.

If recognized, a small bowel injury may be repaired laparoscopically in multiple layers with interrupted 3-0 silk sutures; however, a bowel resection may be required.

A general surgery consultation can be obtained to help assess the degree of injury and assist in its repair. Gentle blunt retraction of the liver and spleen is the rule to avoid laceration and bleeding from these organs. If bleeding occurs, a combination of pressure, argon beam coagulation, and oxidized cellulose gauze can manage most abrasion and laceration injuries to the liver and spleen.

Postoperative Complications

Complications such as ileus, fever, urinary tract infection, urinary retention, atelectasis, pneumonia, cellulitis, renal insufficiency, neuromuscular injury, incisional hernia, transfusion, recurrence of cyst, persistence of pain, deep venous thrombosis, and pulmonary embolism can occur following laparoscopic renal cyst ablation.

Two postoperative complications that are worthy of special mention are perinephric hematoma and urinoma. To reduce the occurrence of postoperative bleeding and hematoma, meticulous hemostasis should be confirmed at the conclusion of renal cyst ablation. As high carbon dioxide insufflation pressures can mask ongoing bleeding, the intra-abdominal carbon dioxide pressures should be reduced to 8 to 10 mmHg when assessing for bleeding points.

To avoid the occurrence of urinoma, every attempt should be made to avoid inadvertent entry into the collecting system when performing renal cyst ablation and to repair overt injuries if they occur.

Recurrence of a renal cyst can occur due to incomplete resection of the cyst wall due to surrounding anatomy (e.g., peripelvic cysts and autosomal dominant polycystic kidney disease) or incomplete ablation of all renal cysts. As mentioned previously, the use of intraoperative laparoscopic ultrasound can improve the safety and thoroughness of renal cyst ablation, even of deep-seated cysts. In addition, suture fixation of perirenal fat or a wick of omentum can prevent cyst fluid reaccumulation.

Persistence of pain following ablation of a solitary renal cyst may indicate an incorrect diagnosis as to the initial cause of pain. It is therefore recommended that patients undergo an initial trial of cyst aspiration with laparoscopic ablation reserved only for those patients whose cyst and symptoms recur (Fig. 4).

RESULTS

Simple Renal Cysts

As listed in Table 4, numerous series of laparoscopic ablation of symptomatic simple renal cysts can be found in the literature performed via both the transperitoneal and the retroperitoneal route (9–16,22,27,28). Most series, however, are limited due to a small number of patients with short follow-up. In those series with 10 or more patients, the mean operative time was 111 minutes (range, 75–164 minutes) and mean length of hospital stay was 3 days (range, 1.9–5.4) (9,10,12,14–16). A complication rate of 0% to 20% and a 0% mortality rate in these series compares favorably with a historical series of open renal cyst ablation reporting a complication rate of 37% and mortality rate of 1.6% (4). In a multi-institutional review of 139 laparoscopic renal cyst ablation cases, Fahlenkamp et al. found a total complication rate of 3.5% (28). Postoperative pain following laparoscopic renal cyst ablation is low with Rubenstein et al. finding that 67% of patients required no parenteral narcotics and 89% took five or fewer tablets of oral narcotics postoperatively (9). Median return to normal activity for their patients was seven days.

> From the limited series of laparoscopic management of peripelvic cysts reported in the literature, symptomatic and radiographic success rates averaged 89% and 75%, respectively.

Success of laparoscopic renal cyst ablation as defined by relief of symptoms (i.e., symptomatic success) averaged 97% when comparing all series, with 92% of patients showing no evidence of cyst recurrence on follow-up imaging studies (i.e., radiographic success).

Interestingly, using strict criteria for symptomatic success by assessment with validated questionnaires and a visual analog pain scale, Yoder and Wolf found that only 78% of patients reported symptomatic relief of pain following laparoscopic renal cyst ablation (11).

Peripelvic Renal Cysts

The results of laparoscopic management of peripelvic cysts are somewhat lower than that reported with simple peripheral renal cysts (Table 5).

From the limited series of laparoscopic management of peripelvic cysts reported in the literature, symptomatic and radiographic success rates averaged 89% and 75%, respectively (10,11,29,30).

Roberts et al. reported on 11 patients with peripelvic cysts and found that operative time (233 minutes vs. 164 minutes, $p = 0.003$) and blood loss (182 mL vs. 98 mL, $p = 0.04$) were statistically greater than a concurrent group of 21 patients with peripheral renal cysts (10). There were no transfusions, open conversions, or radiographic recurrences in this series.

> Findings suggest that peripelvic cysts can be successfully treated by laparoscopic means; however, the longer operative time, greater blood loss, and lower symptomatic and radiographic success rates as compared to peripheral cysts, are likely due to the more challenging location of peripelvic cysts, lying in intimate association with the renal hilar structures.

Taken together, these findings suggest that peripelvic cysts can be successfully treated by laparoscopic means; however, the longer operative time, greater blood loss, and lower symptomatic and radiographic success rates as compared to that of peripheral cysts are likely due to the more challenging location of peripelvic cysts lying in intimate association with the renal hilar structures.

Cumulative results of laparoscopic ablation in patients with autosomal dominant polycystic kidney disease suggest an initial symptomatic success rate of 75% to 100% and 57% to 73% at two years follow-up.

Autosomal Dominant Polycystic Kidney Disease

In patients with autosomal dominant polycystic kidney disease, flank and/or abdominal pain are the most common presenting symptom and have been noted in 60% of autosomal dominant polycystic kidney disease patients (31). These symptoms have been attributed to massive enlargement of the kidneys due to growth of a multitude of renal cysts with stretching of the renal capsule, traction on the renal pedicle, and/or obstruction of the collecting system. These cysts have also been associated with the development of hypertension. In the largest series of autosomal dominant polycystic kidney disease cases to date, Dunn et al. reported on 15 patients who underwent a total of 21 laparoscopic ablation procedures (23). Advocating aggressive and thorough identification and treatment of as many cysts at the time of surgery, an average of 204 cysts were treated per procedure with a range of 11 to 635 cysts. Eighty-seven percent of patients reported symptomatic relief immediately following surgery and with a mean follow-up of 2.2 years; 73% reported, on average, a 62% improvement in preoperative pain.

As shown in Table 6, cumulative results of laparoscopic ablation in patients with autosomal dominant polycystic kidney disease suggest an initial symptomatic success rate of 75% to 100% and 57% to 73% at two years follow-up (21–23,27,32,33).

Hypertension remained unchanged or improved in 67% and renal function remained stable in 94% of patients in the series reported by Dunn et al. (23). The authors concluded that with extensive, bilateral laparoscopic renal cyst ablation in patients with autosomal dominant polycystic kidney disease, improvement in both pain and hypertension could be realized without compromising renal function. Furthermore, their early results favored bilateral versus unilateral cyst ablation. Extensive cyst ablation, however, is time consuming with an average operative time of 330 minutes.

SUMMARY

■ Laparoscopic renal cyst ablation is a minimally invasive technique that can be offered to patients who suffer from symptomatic simple renal cysts and who have failed previous conservative management and a trial of percutaneous drainage.

■ In patients with symptomatic peripelvic renal cysts, overzealous attempts at complete cyst wall excision should be avoided. Only a portion of the exposed cyst wall should be removed with meticulous dissection used to prevent injury to hilar structures. Fixation of perirenal fat or omentum within the cyst cavity can aid in preventing cyst fluid reaccumulation and recurrence.

■ Complete exposure and mobilization of kidneys in autosomal dominant polycystic kidney disease patients suffering from painful cysts are necessary to identify and ablate as many cysts as possible. Use of an intraoperative laparoscopic ultrasound probe can help identify and treat deep-seated cysts. Simultaneous bilateral renal cyst ablation should be performed when possible in patients presenting with bilateral symptoms.

■ Preoperative placement of a ureteral catheter with retrograde injection of dyed saline in complex renal cyst cases such as peripelvic cysts and autosomal dominant polycystic kidney disease can help identify the precise location of collecting system injuries and facilitate their repair.

■ Cytologic analysis of aspirated cyst fluid and histopathologic analysis of intraoperative biopsies of suspicious areas within the cyst cavity should be performed, especially in cases of indeterminate renal cystic lesions (e.g., Bosniak class II and III), to rule out malignancy.

LAPAROSCOPIC SURGERY FOR CALCULOUS DISEASE: TECHNIQUE AND RESULTS

Ashok K. Hemal

Department of Urology, All India Institute of Medical Sciences, New Delhi, India and Vattikuti Urology Institute, Henry Ford Health System, Detroit, Michigan, U.S.A.

INTRODUCTION/BACKGROUND

More than a million cases of urolithiasis occur each year in the United States. Renal stones are one of the most painful disorders that a human can experience, and indeed have been known for centuries. Stones have been found in 7000-year-old Egyptian mummies. The management of calculus disease has changed with the advent of extracorporeal shock wave lithotripsy, percutaneous nephrolithotripsy, ureteroscopy with use of different fragmentation devices, and, recently, laparoscopy in the armamentarium of urologist (1).

The natural corollary of technical development has been the steady decline of open surgery in the management of stone disease. However, despite ever-expanding indications, the new technologies have not been able to completely replace open surgery (2).

On the contrary, there still exist some situations where open surgery may be the treatment of choice. This is not to say that open surgery is the "only option" but probably the "most suitable option" and in order to avoid considering open surgery as a salvage procedure only, it is important to critically evaluate these cases of calculus disease for potential management with laparoscopic surgery (3).

Wickham et al. were the first to describe an attempted removal of a ureteral calculus using the laparoscope in the retroperitoneum (4). Since then several studies have been

> The natural corollary of technical development has been the steady decline of open surgery in the management of stone disease. However, despite ever-expanding indications, the new technologies have not been able to completely replace open surgery.

reported on laparoscopic management of calculus disease including ureterolithotomy (3,5–9), pyelolithotomy (10–14) nephrectomy and nephroureterectomy (12,15), and anatrophic nephrolithotomy (16). Successful laparoscopic management of calculus disease can be done for a variety of indications (Table 1). The indications have not been clearly defined and may vary from center to center depending on the available expertise.

Although laparoscopic removal of stones from kidney, ureter, and bladder can be performed by the transperitoneal or extraperitoneal approach, the latter approach may have certain advantages. The primary advantages of retroperitoneoscopy in calculus disease are rapid access to the diseased retroperitoneal organ and avoidance of urine spillage (which can vary from mild infection to frank pus) into the peritoneal cavity (12).

Laparoscopic simple nephrectomy for the removal of nonfunctioning kidneys due to stone disease is an established procedure (15). However, the role of laparoscopic ureterolithotomy and pyelolithotomy is still controversial. To date, few comparative studies between laparoscopic and open ureterolithotomy are reported with clear advantages for the laparoscopic approach (5,17). There is only one report in the literature, comparing laparoscopic pyelolithotomy and percutaneous nephrolithotripsy (14).

Recently, robotic assistance has also been reported for staghorn stones and in cases of pyelolithotomy with pyeloplasty in patients of uretero pelvic junction obstruction with secondary renal stones (18).

Initial procedural steps such as preoperative preparation, patient position, and approach (transperitoneal vs. retroperitoneal) are almost similar for laparoscopic ureterolithotomy, pyelolithotomy, pyelolithotomy with pyeloplasty, and nephrectomy or nephroureterectomy in calculous disease. Hence, these steps have been described in common rather than separately with each procedure.

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

The laparoscopic approach should be utilized in patients who have failed extracorporeal shock wave lithotripsy, percutaneous nephrolithotripsy, and ureteroscopy or in patients with unusual anatomy such as pelvic kidney, stones with uretero pelvic junction obstruction, and renal stone resistant to fragmentation.

The indications for laparoscopic ureterolithotomy, pyelolithotomy, pyelolithotomy with repair of uretero pelvic junction obstruction, nephrectomy, or nephroureterectomy for calculous disease are similar to that for open surgery.

However, complex staghorn stone with multiple secondary calculi, and patients requiring multistage percutaneous nephrolithotripsy or anatrophic nephrolithotomy may not be suitable for laparoscopic intervention at this point in time except in hands of highly skilled surgeons (16).

The indications for laparoscopic nephrectomy or nephroureterectomy in calculous disease are nonfunctioning kidneys due to renal stones, ureteric stones, megaureter with secondary stones, and uretero pelvic junction obstruction with stones.

> Although laparoscopic removal of stones from kidney, ureter, and bladder can be performed by the transperitoneal or extraperitoneal approach, the latter approach may have certain advantages. The primary advantages of retroperitoneoscopy in calculus disease are rapid access to the diseased retroperitoneal organ and avoidance of urine spillage (which can vary from mild infection to frank pus) into the peritoneal cavity.

TABLE 1 ■ Indications of Laparoscopic Surgery in Calculous Disease

		Kidney	Ureter	Bladder
Indications	Ablative	Nephrectomy, nephroureterectomy for nonfunctioning kidneys	Lower-ureteral calculi with nonfunctioning kidneys	
	Reconstructive	Pyelolithotomy—failure of endoscopic management	Ureterolithotomy for large/impacted upper, middle, or lower ureteral calculi; and stones in megaureter	Stone retrieval with diverticulectomy
		Partial nephrectomy—nonfunctioning pole requiring partial nephrectomy; duplex system with one nonfunctioning moiety		
Contraindications		Xanthogranulomatous pyelonephritis		

Nephrectomy is also suitable for patients with endstage renal disease due to urolithiasis necessitating pretransplant nephrectomy. Nonfunctioning kidneys due to calculous pyonephrosis, infected pyelonephritic kidneys due to stone disease, and failed shock wave lithotripsy therapy for renal stones are relative contraindications for laparoscopic nephrectomy, because of dense peri-renal adhesions, scarring and fibrosis as a consequence of inflammatory procedure. Occasionally, in such cases laparoscopic subcapsular nephrectomy should be contemplated. Although these are not suitable cases for the novice surgeon, a substantial number of these cases can be dealt with by experienced and skilled laparoscopic surgeons.

For most surgeons, the only absolute contraindication for laparoscopic nephrectomy is xanthogranulomatous pyelonephritis. Various indications for laparoscopic surgery for calculous disease are summarized in Table 1.

> For most surgeons, the only absolute contraindication for laparoscopic nephrectomy is xanthogranulomatous pyelonephritis.

PREOPERATIVE PREPARATION AND PATIENT POSITION

Anticoagulants, including aspirin, are discontinued five to seven days prior to surgery. Patients with mandatory indications for coumadin are hospitalized for intravenous heparin conversion prior to surgery. Antibiotic prophylaxis, typically with a first-generation cephalosporin is administered. Lower extremity sequential compression devices are placed just prior to the induction of general anesthesia. Bowel preparation is not necessary, however, a laxative is given the night before.

The patient is positioned in a flank position with the kidney-bridge elevated to flatten out the lumbar region, and is tilted varying from 45° to 60° for transperitoneal access. For the retroperitoneal approach, the patient is placed in standard lateral decubitus kidney position (90°). A slight anterior tilt helps the bowel to be displaced anteriorly by gravity.

TECHNIQUE

Transperitoneal Access
Initial steps are similar to any transperitoneal laparoscopic procedure performed on the kidney: (i) *Reflection of the colon*: The peritoneum is divided lateral to the ascending or descending colon in the line of Toldt using the monopolar scissors. (ii) *Dissection of the pelvis and the upper ureter*: Once the colon is reflected, the lower renal pole is visualized and minimal dissection is performed untill identification of the ureter laying parallel to the gonadal vessels. The ureter is dissected upward proximally toward the uretero pelvic junction, maintaining generous periureteral fat to maintain its blood supply. The renal pelvis is mobilized posteriorly for pyelolithotomy and circumferentially for pyeloplasty in conjunction with pyelolithotomy.

Retroperitoneal Access
Creation of Retroperitoneal Space
The success of the technique depends, to a large extent, on the safe and effective creation of the retroperitoneal space. The technique for accessing the retroperitoneum has been described in Chapter 10.

PYELOLITHOTOMY

The steps of pyelolithotomy are described in Table 2.

Approach
The choice to perform laparoscopic transperitoneal or retroperitoneal pyelolithotomy is often arbitrary and depends on the surgeon's preference, available expertise, and advanced laparoscopic skills for intracorporeal suturing.

> The choice to perform laparoscopic transperitoneal or retroperitoneal pyelolithotomy is often arbitrary and depends on the surgeon's preference, available expertise, and advanced laparoscopic skills for intracorporeal suturing.

Identification of the Upper Ureter
Identification of the upper ureter is the first step toward laparoscopic pyelolithotomy. Mostly, it can be seen as soon as the laparoscope is inserted, especially in a slender patient. The ureter is grasped in the endoBabcock and traced toward the renal pelvis with gentle dissection. Usually dissection is avascular and an attempt should be made to preserve ureteral vasculatures.

If the stone gets migrated proximally into a calyx or if there are preexisting stones in the calyces, a flexible nephroscope, cystoscope, or ureteroscope may be inserted through a laparoscopic trocar to remove these calculi under direct vision.

Dissection of the Renal Pelvis

Renal pelvis dissection is easy if there are no adhesions or inflammation, otherwise hook electrode or endoscissors are used to take down this fibrous tissue. Care should be taken to perform gentle handling of the renal pelvis to prevent dislodgement of the calculus in to the intrarenal calyces. Dissection close to renal pelvis helps in avoiding inadvertent injury to posterior segmental branch of renal artery or any aberrant vessel. Usually, the large stone can be felt (some degree of tactile sensation).

If the pelvis is intrarenal, further dissection of peripelvic fibrofatty and fascial tissue is required to expose the renal sinus with the help of grasping forceps and hook electrode. The right angle forceps or blunt spatula can be used to create the avascular space around the pelvis within the renal sinus.

Pyelotomy

In the setting of an intrarenal pelvis, an additional instrument is needed to retract the posterior lip of the sinus. The extrarenal pelvis, however, rarely requires any retraction for its exposure. The pyelotomy is made on the pelvis using a laparoscopic knife or scissors. Occasionally, a grating sensation of the underlying stone can be felt.

The incision can be either linear or curvilinear depending upon the stone size and configuration, and the shape, location (intra or extra), and exposure of the pelvis.

Retrieval of the Stone from the Renal Pelvis

- If the stone is not impacted and of a large size, which is the typical scenario, the stone is removed intact using a 10 mm right-angled or Babcock forceps.
- If the stone is impacted, a 5 mm right-angled dissector is employed to free the stone from the posterior wall of the renal pelvis. Then the anterior surface of the stone is freed from the renal pelvis after gently lifting it up at its lower end. The stone is then elevated and rotated to extract it from the pelvicalyceal system.

Sometimes, an intrarenal calyceal extension of the stone may prevent the stone removal. In this situation, the cautery J-hook can be used to drag the stone down and subsequently twist, rotate, and angulate it to disengage from the calyceal opening. If the stone still cannot be extracted, an infundibulotomy is created with the J-hook electrode to release the stone.

If the pelvis is of large size and the stone is not seen, or if the stone is located near the calyx, laparoscopic inspection after retraction of renal pelvis, exploration with right angle forceps, and flushing with saline may be of help.

If the stone gets migrated proximally into a calyx or if there are preexisting stones in the calyces, a flexible nephroscope, cystoscope, or ureteroscope may be inserted through a laparoscopic trocar to remove these calculi under direct vision.

It is not unusual to have excessive peripelvic inflammation, adhesions, and fibrosis leading to difficulty in dissecting the ureter or renal pelvis, especially in patients who have undergone multiple extracorporeal shock wave lithotripsy sessions. In such situations, fluoroscopy or intraoperative laparoscopic ultrasound may be helpful in locating the stone.

To Stent, Not to Stent, and How to Stent

J-stenting is not required in a routine case of pyelolithotomy. In patients where preoperatively J-stenting has been done, we do not change the stent and proceed with the status quo situation.

In patients without a J-stent wherein J-stenting is deemed necessary, this can be accomplished in an antegrade fashion. We have used the following different techniques for antegrade stenting during pyeloplasty, ureterolithotomy, or pyelolithotomy: (i) Alken's needle insertion through one of the ports: The needle is directed toward the site of pyelotomy and a straight guidewire is steered through it into the bladder and a 4.8 French stent is passed over this guidewire into the bladder; (ii) percutaneous placement of a 14 French intravenous cannula and insertion of a guide wire which is passed into the bladder followed by the double J-stent; (iii) direct passage of a guidewire through the port and its manipulation into the bladder (sometimes the placement of an extra port may be necessary); and (iv) insertion of a premounted stent over a guidewire and held with a 5 mm Hem-O-Lok clip, which is unlocked once the stent has reached into the bladder, allowing safe removal of the guidewire.

Closure of Pyelotomy

The stones are centrally placed in the retroperitoneum for later removal. The edges of the renal pelvis are cleaned of blood clot, stone dust, and freshened if irregular prior to suture repair. The pyelotomy incision is closed with interrupted 4.0 Vicryl. We do not advocate leaving the pyelotomy incision open, thus minimizing urine leak.

Removal of the Stone from the Body

The stone is retrieved at the end of the procedure from the primary port with 10-mm forceps and extracted through the port. If it is a larger stone, it is entrapped in a plastic bag and extracted through an enlarged port site. This step is monitored by the laparoscope inserted from other port.

Exit and Port Closure

The spilled fluid and urine are aspirated from the abdominal cavity, which is inspected for any bleeding, flushed-out stones, and clots. Copious irrigation with antibiotic solution is performed. Hemostasis is confirmed and a Jackson-Pratt drain is left and laparoscopic exit completed.

Postoperative Management

The patient is allowed to ambulate and take liquids orally the same evening. Oral analgesics are advised according to need. Antibiotics are continued until removal of the drain and catheter. Typically, the patient is discharged from the hospital the next day. However, if there is urine leakage, abdominal distension, pain, or discomfort, the hospital stay is extended as necessary.

PYELOLITHOTOMY WITH CONCOMITANT PYELOPLASTY

It is not uncommon to find coexisting secondary renal stones as a sequela of uretero pelvic junction obstruction. In such cases, the pyelotomy incision should be performed very carefully because it will eventually be incorporated in the flaps reconfigured for laparoscopic pyeloplasty (13,19). The line of incision in the pelvis can be marked and the pelvis incised with endoscissors. The pelvis is not disconnected from the ureter until all stones are cleared and the ureter is spatulated. Care should be taken if there is a priorly placed stent, so that the stent is not damaged or dislodged.

Occasionally, stone removal with rigid laparoscopic instruments becomes difficult and in such a situation, a flexible nephroscope, cystoscope, or ureteroscope can be used to retrieve caliceal stones.

> Occasionally, stone removal with rigid laparoscopic instruments becomes difficult. If such a situation, a flexible nephroscope, cystoscope, or ureteroscope can be used to retrieve caliceal stones.

ROBOT-ASSISTED PYELOLITHOTOMY AND PYELOPLASTY

Feasibility of robot-assisted pyelolithotomy and concomitant pyeloplasty was evaluated (18). After docking the robot, the ipsilateral colon is reflected off the kidney and uretero pelvic junction is dissected free all around. An appropriate pyelotomy is created for stone extraction and subsequent fashioning of the flaps for reconstruction. The pyelotomy is started by opening the entire length of the anterior wall of the pelvis, using the endoscissors, 3 cm away from the parenchymal edge of the renal sinus. The interior of the renal pelvis was explored to easily view the stone and remove it with the aid of long tip forceps. The removed stones are kept in a safe place in the abdominal cavity. At the end of the procedure, the stones are placed within the endocatch bag and removed through one of the port sites. The uretero pelvic junction is transected and the ureter spatulated laterally. The apex of the spatulated ureter is anastomosed to the most dependant part of the renal pelvis with interrupted intracorporeal suturing using 4-0 Vicryl suture 10 cm in length. Then the anterior half of the ureteropelvic anastomosis is performed using a running suture. The posterior wall is repaired using another 4-0 Vicryl suture 10 cm in length in the same manner. Lastly, the remaining part of the trimmed renal pelvis is closed by continuous suture. Some authors have also evaluated the feasibility of robotic extended pyelolithotomy for treatment of renal calculi as an effective treatment alternative to percutaneous nephrolithotomy.

ANATROPHIC NEPHROLITHOTOMY

A novel technique of anatrophic nephrolithotomy has been described in the porcine model by Kaouk et al. Synthetic stone formation and laparoscopic anatrophic

nephrolithotomy was successful in all ten animals including one that underwent staged bilateral anatrophic nephrolithotomy (16). These authors have since performed anatrophic nephrolithotomy clinically in three patients.

REMOVAL OF URACHOVESICAL CALCULUS

Urachal anomaly in an adult is rare, as the majority of urachal remnant obliterate shortly after birth. However, a rare case of urachal calculus may be encountered and the stone can be safely and effectively removed with laparoscopic excision of the urachus containing the stone (20).

URETEROLITHOTOMY

Indications and Contraindications

Indications of laparoscopic ureterolithotomy include large, impacted, upper/mid/lower ureteric stones leading to obstruction, where other minimally invasive treatments have failed.

These patients have typically required open ureterolithotomy in the past. Smaller calculi are managed by endourologic techniques. Classically, the ureter is identified by visualizing ureteric peristalsis. The stone location is identified by seeing the stone bulge. Small ureteric stones are difficult to locate as the stone bulge may not be visible and no tactile feedback is provided by the laparoscopic approach. In such situations, intraoperative fluoroscopy or laparoscopic ultrasound may be very useful for stone localization.

Technique

Laparoscopic ureterolithotomy can be performed either by transperitoneal or retroperitoneal approach. The steps of ureterolithotomy are described in Table 3.

Retroperitoneal Approach

After port placement, the ureter is dissected gently to prevent proximal migration of the stone. Usually, the calculus is large and can be easily dissected with blunt dissector or forceps in one port and an atraumatic clamp in the other. The ureter is held with a Babcock or atraumatic ring clamp above the stone and the periureteric tissue is cleared prior to incising. A longitudinal ureterotomy is performed using a laparoscopic knife or endoshears. Following stone retrieval, the ureterotomy is closed with interrupted, intracorporeal free hand suturing using 4/0-polyglactin suture. The stone is retrieved through one of the 10 mm ports.

In our modified technique, we use just one 10 mm port and two or three 5 or 3 mm ports instead of all 10 mm ports used in the classic procedure. The 10 mm port is used for the laparoscope and the 5 or 3 mm ports are used for dissection, suction, and retraction. The operative steps of the procedure are the same as in the standard procedure. However, we do not place the stent priorly. After stone removal and temporary stone placement in the retroperitoneum, the ureterotomy is closed as described above. A 5 mm laparoscope is then passed through one of the 5 mm ports to locate the stone and grasping forceps passed through the primary port (camera-10 mm port) and intact stone is removed by pulling the stone along with the port. A 14-French JP drain is placed in the retroperitoneal space through the 5 mm port site.

If the stone is in the lower ureter, an additional port is required medial to the anterior superior iliac spine for retraction. A 30° laparoscope is of great help in dissecting the lower end of ureter harboring the stone. Two secondary ports are enough for retroperitoneoscopic ureterolithotomy; however, a third port is needed in an obese patient for retracting the peritoneum and the retroperitoneal fat for intracorporeal suturing of ureterotomy site. We did not notice any increase in the duration of postoperative drainage in group of patients undergoing ureterolithotomy with modified technique without stenting.

Transperitoneal Approach

The patient is placed in the 45° to 60° flank position with the kidney-bridge elevated. The primary port is placed at the lateral edge of rectus muscle at the level of umbilicus. Two secondary ports are placed in the anterior axillary line below the costal margin, in the anterior axillary line in the iliac fossa and a fourth port is placed if required. The colon

> Indications of laparoscopic ureterolithotomy include large, impacted, upper/mid/lower ureteric stones leading to obstruction, where other minimally invasive treatments have failed.

  Closure of ureterotomy
  Removal of the stone
  Exit and closure of the ports
  Postoperative management

is reflected medially and the ureter is identified by visualizing the ureteric peristalsis and the stone bulge. A vertical incision is made over the stone bulge to remove the stone. The ureterotomy is then closed with interrupted, intracorporeal free hand suturing using 4/0 Vicryl suture.

Role of Stenting

Typically, a double J ureteric stent or open ended ureteric catheter is placed cystoscopically, then the patient position is changed for the laparoscopic ureterolithotomy. The preplaced stent also helps in identification of the ureter. Alternatively, the stent can also be placed intraoperatively under laparoscopic vision antegradely through one of the ports as described for pyelolithotomy.

Sometimes the stone is impacted and it is impossible to preplace a stent. In this circumstance, the J stent with a guide wire or open-ended ureteric catheter is retrogradely advanced up to and underneath the stone in the ureter. After stone retrieval, the ureteric stent is advanced into the renal pelvis under laparoscopic guidance. In some of these patients, we experienced difficult negotiation of the stent due to down slipping of the stent during position changing of the patient. Therefore, at the end of the procedure these patients were repositioned in lithotomy and the stent was inserted under fluoroscopic guidance. Because of this problem, in several subsequent cases we placed an end-hole ureteric catheter through which a guide wire was inserted up to the stone. After retrieval of the stone, the guide wire was advanced into the renal pelvis under laparoscopic vision, and a stent was advanced over the guide wire. The guide wire was introduced into the ureter through the ureteric catheter, even though it had slipped down a little during the change of patient position.

With increasing experience, we modified our technique again to make the procedure minimally invasive and cost effective. In patients where there is no history of stone impaction or any other absolute indication such as infected hydronephrosis, we do not place a J stent into the ureter at all. The ureterotomy is closed with 4/0-Vicryl by interrupted, intracorporeal suturing. The advantages are shorter operating time, avoidance of fluoroscopy, cost reduction, and reduced invasiveness since an additional procedure, e.g., initial cystoscopy for J stent placement and, later, for its removal is avoided. No increase in the duration of drainage or complication rate was noticed after this technical modification.

Laparoscopic Ureterolithotomy: Why?

The management of ureteric stones has evolved from open surgery to minimally invasive procedures such as ureteroscopy, extracorporeal shock wave lithotripsy, and percutaneous antegrade removal. The results of ureteroscopy are best for lower- and mid-ureteric stones. Park et al. reported a success rate for ureteroscopic stone removal of 75%, 94.6%, and 86.4% for proximal-, mid-, and lower-ureteric stones (21). Extracorporeal shock wave lithotripsy is suitable for managing ureteric stones of less than 1 cm (22); however, as the stone size increases, the chances of clearance decreases and the chances of multiple procedure increases. Koch et al. reported that up to 36% of patients require multiple sessions of extracorporeal shock wave lithotripsy and 46% require auxiliary procedures in order to get patients stone free besides the need for stent insertion and removal at a later date (23). Park et al. reported that the stone-free rate decreased from 84% to 42% when the stone was greater than 1 cm (20).

Percutaneous removal is indicated in patients with large stones in the upper ureter, but it is sometimes difficult to manage ureteric stones below the inferior border of the kidney. The results of mid- and lower-ureteric stones are even more dismal (24). In a series of percutaneous removal of ureteric stone, a complication rate of 43% was reported and 22% of patients required a supracostal puncture (25). Percutaneous removal is indicated only as a salvage procedure in those patients where extracorporeal shock wave lithotripsy or ureteroscopy have failed.

Laparoscopic ureterolithotomy is indicated for large impacted ureteric stones preferably in upper- and mid-ureter, as the results of extracorporeal shock wave lithotripsy and ureteroscopy are poor and require multiple sittings and auxiliary procedures. By contrast, laparoscopic ureterolithotomy achieves complete stone clearance in a single operative session in a minimally invasive manner.

Keeley et al. suggested that the ideal stone location for laparoscopic ureterolithotomy is the section of the ureter between the lower border of the kidney and the common iliac vessels, as more proximal stones are better managed percutaneously and stones below the iliac vessels by ureteroscopy (7). We did not find any difficulty in the

Laparoscopic ureterolithotomy is indicated for large impacted ureteric stones preferably in the upper- and mid-ureter, as the results of extracorporeal shock wave lithotripsy and ureteroscopy are poor and require multiple sittings and auxiliary procedures. By contrast, laparoscopic ureterolithotomy achieves complete stone clearance in a single operative session in a minimally invasive manner.

management of upper- and mid-ureteric stones, and also lower-ureteric stones have been managed successfully but require experience, skill, and patience.

RETROPERITONEAL VS. TRANSPERITONEAL NEPHRECTOMY FOR NONFUNCTIONING KIDNEYS DUE TO CALCULOUS DISEASE

The initial approach, retroperitoneal or transperitoneal, is the same as described for pyelolithotomy or ureterolithotomy. Subtle differences vary with the degree of perinephric inflammation encountered. In the absence of significant adhesions, we prefer to place the balloon inside Gerota's fascia because this allows rapid and easy dissection of the kidney. The hilum is then approached and the vessels clipped. Past history of pyelonephritis, evidence of renal scarring, perinephric adhesions, and pyonephrosis predominantly lead to dense perinephric adhesions which preclude safe and easy dissection, as the kidney is densely adherent to the posterior abdominal wall. Open conversions typically occur due to excessive bleeding and poor intraoperative progress. Because the adhesions are perinephric, the space external to Gerota's fascia is still relatively clear. The hilar vessels are approached first to minimize bleeding during the subsequent dissection of the kidney. It is important to avoid puncturing the kidney during mobilization lest infected material soil the operating space. Although the spillage is confined to retroperitoneum, thoroughly irrigation with antibiotics solution is important (12). Rarely, due to severe fibrotic adhesions, one may intentionally or unintentionally enter within the renal capsule, and resort to retroperitoneal subcapsular nephrectomy to complete the operation.

RETROPERITONEOSCOPIC NEPHRECTOMY FOR HYDRONEPHROTIC KIDNEY DUE TO URETEROPELVIC JUNCTION OBSTRUCTION WITH STONES

> Retroperitoneoscopic nephrectomy is the ideal procedure for patients with poorly functioning, hugely dilated, or giant hydronephrotic kidneys due to stone disease, irrespective of patient age and type of renal anomaly.

Retroperitoneoscopic nephrectomy is the ideal procedure for patients with poorly functioning, hugely dilated, or giant hydronephrotic kidneys due to stone disease, irrespective of patient age and type of renal anomaly (26).

In these cases, careful placement of the primary port is important so as to avoid puncturing the kidney. An initial 1.5 cm incision below and posterior to tip of the 12th rib is made and deepened down to the thoracolumbar fascia. Digital dissection or dissection with the help of Clutton's urethral dilator is done parallel to the dilated kidney to make space for placement of the balloon. The balloon itself may be placed within or outside Gerota's fascia as per the situation. The balloon should not be inflated over 400 to 500 mL. Retroperitoneal space can be created initially toward the upper pole, then toward the lower pole. Once the space is created, the kidney should be dissected first as the tense hydronephrotic sac helps in identification of the perirenal plane. With the distended renal sac keeping the renal parenchymal surface stretched, dissection can be performed with easy sweeping movements. After initial dissection, the kidney is deflated (often it gets punctured) and further dissection carried out after retracting the kidney anteriorly with a triflanged retractor. In these cases, usually renal vessels are attenuated and can be clipped with titanium clips or Hem-O-Lok plastic clips.

LAPAROSCOPIC NEPHRECTOMY FOR XANTHOGRANULOMATOUS KIDNEYS

Xanthogranulomatous pyelonephritic kidneys require the most difficult and cumbersome dissection, as they are almost plastered in the retroperitoneum. Dissection is time consuming and complicated. If such a condition is diagnosed preoperatively, it may be better to deal with conventional open surgery. In most instances, xanthogranulomatous kidneys constitute a contraindication to laparoscopic surgery (27).

LAPAROSCOPIC NEPHRECTOMY FOR PATIENTS WITH HISTORY OF PREVIOUS STONE SURGERY OR PERCUTANEOUS NEPHROSTOMY

These patients are difficult candidates for laparoscopic nephrectomy. After initial dissection, control of the renal vessels should be attempted first so as to prevent troublesome bleeding. However, gradual, slow, and careful dissection is the key to success in these cases. In patients who have an indwelling percutaneous nephrostomy, after initial dissection, the nephrostomy tract should be divided because this allows more room for further dissection (27). In a recent series (28), the authors presented their experience

with transperitoneal laparoscopic pyelolithotomy in pediatric patients in whom percutaneous renal access failed and the stone burden warranted open intervention. In this series, a transperitoneal laparoscopic approach was used for pyelolithotomy in eight patients, three months to ten years old (mean age four years). Percutaneous access failed secondary to a nondilated system and/or an occluding lower pole calculus. A posterior pelviotomy was made. Stones in the renal pelvis were removed with rigid graspers under direct laparoscopic vision. A flexible cystoscope was introduced through a port if caliceal stones were present. The renal pelvis was reconstructed. A watertight anastomosis was verified. Average operative time was 1.6 hours (range, 0.8–2.3). Mean hospital stay was 2.15 days (range, two to three days). A range of one to three stones (median of 1) were removed and the mean stone burden was 2.9 cm^2. No intraoperative complications were noted. Stone analysis revealed three patients with calcium oxalate stones, one with a calcium phosphate stone, and four with cysteine stones. Stones recurred in one patient at a mean follow-up of 12 months (range, 3–20 months). Overall long-term stone-free rate was 87.5%.

RETROPERITONEOSCOPIC NEPHROURETERECTOMY FOR NONFUNCTIONING KIDNEYS DUE TO CALCULOUS DISEASE

After the initial dissection, control of renal pedicle and mobilization of the kidney, the table is tilted posteriorly to make the patient partly supine and a fourth port inserted medial to the anterior superior iliac spine. The distal ureter is dissected downward till the ureterovesical junction or until obstructing stone is identified where it can be divided after applying a clip. This technique has been found to be superior to open approach (29).

PARTIAL NEPHRECTOMY

Partial nephrectomy in a kidney for nonfunctioning segment or pole due to stone disease is indicated because of recurrent infection, inability to remove the stones, hydronephrosis, and parenchymal atrophy. In these cases, the demarcation of the tissue to be removed is usually evident. The atrophic parenchyma lining the dilated system can be further delineated. After preserving a strip of renal capsule, the parenchyma is divided at the observed line of demarcation. There is usually minimal bleeding from the renal surface, and clamping of renal artery is not necessary. Then renal parenchyma is closed with interrupted sutures of 1-0 Vicryl over Surgicel; in addition fibrin glue may be used. Usually partial nephrectomy in these cases is easier in comparison to partial nephrectomy for tumor.

BLADDER DIVERTICULECTOMY WITH STONE REMOVAL

The presence of stone(s) in a bladder diverticulum can be a cause of recurrent urinary tract infection, or outflow of obstruction and may require diverticulectomy. In a large diverticulum, with history of infection or in a location close to ureter, bilateral ureteral catheterization or double J stenting is preferred. The dissection is started from the most prominent part of the diverticulum, proceeding toward the diverticulum neck. However, sometimes it is difficult to expose the diverticulum. Traction with a grasping forceps at the edge of the diverticulum mouth helps in subsequent dissection with the twist-and-roll technique. It should be kept in mind that course of the ureter is distorted, increasing chances of injury. Stones from inside the diverticular cavity are removed and diverticular wall is excised. The bladder is closed with interrupted intracorporeal 2-0 Vicryl sutures.

RESULTS

Results of Laparoscopic Surgery for Urolithiasis

During our initial experience (Table 4), laparoscopic retroperitoneal surgery was successful in 95 out of the 114 patients (12). Of the 40 patients undergoing retroperitoneoscopic ureterolithotomy, stones could be retrieved successfully in 30 patients with a mean operating time of 106.3 minutes (range, 40–275 minutes) and an estimated blood loss of 69.8 mL (range, 25–150 mL). There were 10 conversions to

TABLE 4 ■ Initial Experience of Laparoscopic Retroperitoneal Surgery in Calculous Disease

Procedure	No. of cases	Mean age (yr)	M:F	Previous procedures	Successful	Mean OR (min)	Mean estimated blood loss (mL)	Mean hospital stay (days)
Retroperitoneoscopic ureterolithotomy	40	48.5 (26–65)[a]	28:12	5 SWL; 9 URS	30 (75%)	106.3 (40–275)	69.8 (range 25–150)	3.76 (range 2–14)
Retroperitoneoscopic pyelolithotomy	7	37.5 (21–55)	5:2	–	5 (71.4%)	108.2 (45–150)	127.2 (range 60–200)	3.5 (range 3–8)
Retroperitoneoscopic nephrectomy	53	41.6 (19–68)	32:21	6 PCN	48 (90.5%)	99.7 (55–240)	135.6 (range 40–800)	2.86 (range 2–6)
Retroperitoneoscopic nephroureterectomy	14	44.4 (30–50)	7:7	1 PCN	12 (85.7%)	147 (70–210)	206.5 (range 70–400)	3.5 (range 2–6)

open surgery, most of them during our initial learning curve. Of the seven cases of retroperitoneoscopic pyelolithotomy, there were two conversions. The mean operating time was 108.2 minutes (range, 45–150 minutes) and the estimated blood loss was 127.2 mL (range, 60–200 mL).

There were five open conversions out of 53 cases of retroperitoneoscopic nephrectomies for calculous disease due to nonfunctioning kidneys because of the multiple stones and chronic infection. The mean operating time was 99.7 minutes (range, 55–240 minutes) and the average blood loss was 135.6 mL (range, 40–800 mL).

Of the 14 retroperitoneoscopic nephroureterectomies, we were successful in 12. Average operating time was 147.0 minutes (range, 70–210 minutes) and average blood loss was 206.5 mL (range, 70–400 mL). Average hospital stay ranged from three to four days for various procedures. There were two major complications. One patient with dense perinephric adhesions suffered a colonic injury during dissection with the J hook, which was detected intraoperatively and repaired primarily. Another patient sustained injury to the external iliac artery during ureterolithotomy, which was also managed to open surgically. Minor complications encountered were peritoneal rents in seven patients, postoperative fever in two patients, surgical emphysema in two patients, and wound infection in two patients.

Patients undergoing ureterolithotomy and pyelolithotomy were followed with an intravenous urogram at three months. This could be done in 30 of the 40 patients following ureterolithotomy and all seven patients following pyelolithotomy. There was no evidence of any obstruction or residual fragment in any of the cases.

Results of Laparoscopic Ureterolithotomy

A prospective study was carried out comparing retroperitoneoscopic and open ureterolithotomy (Table 5) (5). A total of 55 patients with large (mean size 2.1 cm) upper and mid-ureteric calculi with normal renal parameters were subjected to retroperitoneoscopic ureterolithotomy. In 22 patients, earlier attempts with shock wave lithotripsy and ureteroscopy had failed. These cases were compared with 26 cases (mean stone size, 2.4 cm) that underwent open ureterolithotomy during the same period. The two groups were similar to each other regarding patient age, sex, stone size, and stone location. Most stones were calcium based. Mean operating time and mean blood loss in the laparoscopic and open groups were 108.8 minutes versus 98.8 minutes, and 58.5 mL versus 50.5 mL, respectively (p = NS). Mean analgesic (pethidine) requirement and hospital stay were 41.1 mg versus 96.9 mg and 3.3 days versus 4.8 days, respectively ($p < 0.001$). Convalescence was quicker in the laparoscopic group: 1.8 weeks versus 3.1 weeks. The laparoscopic procedure has significant advantages over open surgery as regards analgesia, hospital stay, recuperation, and cosmesis. Retroperitoneal laparoscopy is a viable alternative for large upper and mid-ureteric calculus, and for those which have failed previous attempts at expert endourologic management.

Results of Laparoscopic Pyelolithotomy

We compared retroperitoneoscopic pyelolithotomy (n = 16) versus percutaneous nephrolithotripsy (n = 12) in the management of a solitary renal pelvic calculus more than 3 cm in size (Table 6). The two groups were similar regarding patient age and sex. Mean stone sizes were 3.6 cm versus 4.2 cm, respectively ($p < 0.006$). There were two conversions in the laparoscopic group for stone migration into the calyx and dense

TABLE 5 ■ Comparison of Retroperitoneoscopic and Open Ureterolithotomy

perirenal adhesions, making dissection difficult. Mean operating time was 142 minutes versus 72 minutes for percutaneous nephrolithotripsy ($p < 0.0001$). Blood loss was similar 173 cc versus 141 cc. Mean hospital stay was 3.8 days versus 3 days, although the duration of convalescence was somewhat shorter in the percutaneous nephrolithotripsy group. Laparoscopic pyelolithotomy is associated with longer operating time, longer recuperation, is more invasive, less cosmetic, and requires more skill as compared to percutaneous nephrolithotripsy. Advanced endourological facilities are required for removal of calyceal stones in the event of migration or for localization of stone such as laparoscopic ultrasound. Laparoscopy is not suitable in patients with dense peripelvic adhesions or history of previous retroperitoneal surgery.

Laparoscopic pyelolithotomy may be indicated for ectopically located, congenitally anomalous kidneys or in patients where concomitant laparoscopic procedure is indicated such as pyeloplasty (30–33).

Laparoscopic pyelolithotomy may be indicated for ectopically located, congenitally anomalous kidneys or in patients where concomitant laparoscopic procedure is indicated such as pyeloplasty.

COMPLICATIONS

Acceptance of any surgical procedure depends to a large extent on the demonstration of technical efficacy and an acceptably low complication rate. However, apart from the initial cases where open conversion was required, this has not been a problem in subsequent cases. Among the major intraoperative complications, rare vascular and visceral injuries have occurred, albeit managed successfully. Among 247 cases of retroperitoneoscopic surgery for calculous disease, comprised of ureterolithotomy ($n = 85$), pyelolithotomy ($n = 27$), nephrectomy ($n = 114$), and nephroureterectomy ($n = 31$), we had 10.9% minor complications, 1.6% major complications, and 6.8% conversion to open surgery (Table 7). Unforeseen hemorrhage can occur at any time during the procedure but this does not make it any different from open surgery for calculous disease. Possible problems and tips to manage these are described in Table 8.

TABLE 7 ■ Complications in Retroperitoneoscopic Surgery for Calculous Disease

	Complications	Nephrectomy (114)[a]; nephroureterectomy (21)	Ureterolithotomy (85)	Pyelolithotomy (27)	Total (247)

TABLE 8 ■ Technical Caveats and Tips

	Technical caveats	Tips
Ureterolithotomy	Stone migration	Hold ureter in Babcock forceps above the stone
		Use of flexible nephroscope to retrieve migrated stones
		Use of laparoscopic ultrasound or fluoroscopy
	Vascular injury	Careful dissection, and early conversion in cases of extensive adhesions
		If doubtful, ensure with ultrasound or fluoroscopy
	Inability to localize stone	Use of intraoperative fluoroscopy or ultrasound
	Peritoneal rent in retroperitoneoscopic approach	Place secondary ports under vision or digital guidance
		Retract the peritoneum with fan retractor
		Veress needle can be used for deflating abdomen
		Make rent bigger, so as to equalize pressure
Pyelolithotomy	Stone migration	Avoid excessive palpation of stone especially prior to pyelotomy
		Keep jaws of forceps open while attempting to grasp
		Use a flexible nephroscope to retrieve migrated stones
		Intraoperative fluoroscopy or ultrasound
	Excessive perirenal adhesions	Confirmation of stone and pelvis by USG and gentle dissection
	Adhesions, especially in post ESWL patients	
Nephrectomy	Excessive perirenal adhesions and pararenal adhesions	Renal dissection outside the Gerota's fascia
		Control hilar vessels first as for radical nephrectomy
Nephroureterectomy	Excessive perirenal adhesions	Renal dissection outside the Gerota's fascia
		Control hilar vessels first
	Inability to dissect the lower ureter due to adhesions	Place the patient in an oblique position rather than dead lateral and use lower port near anterior superior iliac spine

Abbreviations: USG, Ultrasonography, ESWL, extracorporeal shock wave lithotripsy.

SUMMARY

- In our current practice, in the properly selected patient, laparoscopic ureterolithotomy, pyelolithotomy with pyeloplasty, retroperitoneoscopic nephrectomy and nephroureterectomy for nonfunctioning kidneys due to calculous diseases of kidneys are now offered in lieu of open surgery.
- Open conversion may be occasionally necessary.
- Prior open surgery and history of peritonitis are not necessarily regarded as contraindications in expert's hands.
- Laparoscopic pyelolithotomy is performed only in selected cases. However, cases with perinephric adhesions such as xanthogranulomatous pyelonephritis are difficult for the laparoscopic approach.

COMMENTARY

D. Assimos
Department of Urology, Wake Forest University School of Medicine, Winston-Salem, North Carolina, U.S.A.

Laparoscopic stone removal currently has a limited role in the management of patients with nephrolithiasis. The indications should be similar to those for the pool of subjects who are candidates for open surgical stone removal. The latter comprises less than 1% of patients undergoing a stone-removing procedure, even at tertiary medical centers (1). Laparoscopic stone removal should not be undertaken in patients in whom shock wave lithotripsy or an endourological approach is anticipated to be successful. Failure of the aforementioned therapies may be a valid reason to consider laparoscopy. However, current endoscopic technology and the skills of contemporary urologists have made this rarely necessary (1).

Laparoscopic nephrectomy is appropriate in subjects with a nonfunctioning renal unit due to a stone-related problem. While some have reported successful laparoscopic removal of xanthogranulomatous pyelonephritic kidneys, I concur with the author that this is not advisable in most cases (2). Laparoscopic partial nephrectomy may be considered for patients with stones in a polar area having no or minimal function. Combined pyeloplasty and pyelolithotomy is indicated for those patients in whom endopyelotomy performed in conjunction with percutaneous nephrolithotomy is not likely to be successful. These include patients with severe hydronephrosis, diminished renal function, and crossing vessels (3,4). Patients with isolated stones in an anterior calyceal diverticulum not accessible or too large for a retrograde ureteroscopic management may benefit from a laparoscopic approach. The same holds true for those having stones located in a type II diverticulum—one that communicates directly with the renal pelvis or an infundibulum. These cavities typically have no overlying renal parenchyma. Laparoscopy can also allow safe percutaneous access for removing stones in pelvic and other types of ectopic kidney (5).

Laparoscopic ureterolithotomy is rarely indicated as retrograde and antegrade ureteroscopic approaches and shock wave lithotripsy are less invasive and highly effective. In most cases, it should only be employed as a salvage procedure. It has been undertaken in some countries where the aforementioned technology is not readily available. Percutaneous nephrolithotomy is the procedure of choice for the majority of patients harboring staghorn calculi (6). Anatrophic nephrolithotomy should be reserved for patients with extremely large staghorn calculi in kidneys with complex collecting system anatomy. While this has been done via laparoscopy in a porcine model and select patients with more favorable anatomy, it is not anticipated that this will supplant the open approach in the aforementioned setting.

Laparoscopy will continue to play an extremely small role in the management of patients with nephrolithiasis. In addition, future improvements in endoscopic technology are likely to further narrow its application.

LAPAROSCOPIC PYELOPLASTY: TECHNIQUE

George K. Chow
Department of Urology, Mayo Clinic, Rochester, Minnesota, U.S.A.

INTRODUCTION

Laparoscopic pyeloplasty offers a minimally invasive alternative for the management of ureteropelvic junction obstruction that duplicates the surgical principles of open pyeloplasty.

The laparoscopic pyeloplasty can be performed by either retroperitoneal or transperitoneal approach.

Laparoscopic pyeloplasty was first reported by Scheussler et al. in 1993. It offers a minimally invasive alternative for the management of ureteropelvic junction obstruction that duplicates the surgical principles of open pyeloplasty.

Numerous studies attest to the superior long-term efficacy of laparoscopic pyeloplasty over the various methods of antegrade and retrograde endopyelotomy.

Prior to the advent of laparoscopic prostatectomy and the need to perform a vesicourethral anastomosis, the most technically challenging reconstructive laparoscopic procedure was pyeloplasty. As such, the surgeon must be well versed in laparoscopic suturing techniques to perform pyeloplasty.

The laparoscopic pyeloplasty can be performed by either retroperitoneal or transperitoneal approach.

The retroperitoneal approach offers the advantage of less potential postoperative ileus, but has the disadvantage of a limited working space. Conversely, the transperitoneal approach offers familiar anatomic landmarks and more working space, but more bowel manipulation, and therefore higher likelihood of ileus. Choice of anatomic approach is dictated by surgeon experience and training.

Various techniques for pyeloplasty are described. These can be divided into dismembered and nondismembered techniques. The dismembered or Anderson–Hynes technique involves division of the ureteropelvic junction and excision of the narrowed segment, followed by reanastomosis of the ureter to the renal pelvis. The two common nondismembered techniques include Foley Y-V plasty and Fenger pyeloplasty. The Foley Y-V plasty consists of incising through the narrow segment and advancing the apex of the "Y" incision as a flap to bridge the previously narrowed segment. The advantage of this approach is its relative simplicity. The even simpler Fenger pyeloplasty involves horizontal incision through the narrowed segment closed vertically in a Heineke–Mikulucz fashion. Other techniques such as the Culp–DeWeerd pyeloplasty have also been reported, but are not among the commonly used techniques. The nondismembered techniques should not be used when crossing vessels are encountered or reduction of a redundant renal pelvis is anticipated.

The technique chosen depends on the task at hand. In general, when a crossing vessel, redundant renal pelvis, or coexisting renal calculi is present, the dismembered pyeloplasty is preferable.

Due to the inherent complexity of laparoscopic pyeloplasty, new technology has been introduced to facilitate the procedure. Hand-assisted laparoscopy has been described as a means to assist laparoscopic pyeloplasty. In this fashion, one-handed surgical tying can be performed intracorporeally. Furthermore, surgical robots can be employed to assist with suturing. Whether or not you use technological assistance, the technique remains essentially the same.

PATIENT SELECTION AND DIAGNOSIS

The indications for laparoscopic pyeloplasty include ureteropelvic junction obstruction associated with the following:

1. Flank pain
2. Deteriorating renal function
3. Renal calculus
4. Urinary tract infections
5. Associated hypertension

Diagnosis of ureteropelvic junction obstruction is based on radiography. Ultrasound, computed tomography, and intravenous pyelography are capable of identifying suspicious hydronephrotic kidneys. Often additional testing is necessary to confirm ureteropelvic junction obstruction. Retrograde pyelogram is often used to help identify the level of obstruction. A characteristic "jet" of contrast is seen at the area of narrowing during retrograde injection of contrast. Diuretic renography can often differentiate between the nonobstructed and obstructed ureteropelvic junction obstruction. Furthermore, if significant cortical loss is evident on radiography, nuclear renography can quantify renal differential function. If 20% or less of total renal function is present, a simple nephrectomy may be preferable to pyeloplasty.

Diuretic renogram can also document postoperative functional improvement, both with respect to renal function and the presence/absence of obstruction. Be aware that the results of diuretic renogram can be confounded by poor renal function and excessive renal pelvic redundancy.

Relative contraindications for laparoscopic pyeloplasty include:

1. Previous open renal surgery
2. Bleeding diathesis
3. Untreated active pyelonephritis

PREOPERATIVE PREPARATION

Prior to surgery, the patient should refrain from oral intake after midnight the day before surgery, and receive a mechanical bowel preparation. A bottle of magnesium citrate should suffice. An orogastric tube should be placed to deflate the stomach. This precaution should decrease the risk of injury to the stomach during trocar placement. Antibiotic prophylaxis such as a first-generation cephalosporin should be given. Pneumatic compression stockings should be placed to prevent deep venous thrombosis.

Patient positioning is dictated by the anatomic approach chosen. For the retroperitoneal approach, the patient is placed in full flank position, with the surgical table flexed and kidney rest deployed to maximize the space between the costal margin and iliac crest. If the transperitoneal approach is preferred, the patient is placed in a 60° lateral decubitus position. The patient should be carefully strapped to the surgical table. The patient should be sufficiently secured to permit maximal tilt of the table to either side. During the case, the tilt of the table can be adjusted to maximize gravity-assisted retraction of the bowels. Also, the patient should be well padded at all pressure points to avoid neurological injury.

Although not technically a preoperative measure, stent placement is an important step prior to laparoscopic pyeloplasty. Prepyeloplasty stent placement is much easier than intraoperative placement.

Selection of a stent at least 2 cm larger than the estimated required stent length is crucial. With division of the ureteropelvic junction, the natural elastic properties of the tissue result in retraction. If the stent is too short, it may not be easy to replace in the renal pelvis. The added length facilitates positioning of the proximal stent during anastomosis.

After stent placement, a Foley catheter should be placed in the bladder and left to gravity drainage.

SURGICAL TECHNIQUE

Access

Transperitoneal access is obtained by placement of the Veress needle. Aspiration and saline injection should be used to assure proper placement in the peritoneum. The

author's preference is to place the needle via the umbilicus where the abdominal wall is thinnest. Because the patient is in a 60° lateral decubitus position, the table is rotated until the patient is in a relatively supine position to facilitate access. Maintenance of low intra-abdominal pressure while insufflating the abdomen with carbon dioxide at a low flow rate confirms good intraperitoneal position. Once satisfied with the needle placement, the gas can be turned to high flow rate. The gas should be insufflated to a pressure of 10 to 15 mmHg. Initial placement of a 10 mm trocar can be performed under direct vision with an optical trocar such as the Optiview™[a] or Visiport™[b] devices. The first port can be placed at the umbilicus or in the lateral abdomen.

Retroperitoneal access is achieved by making a 12 mm incision anterior to the tip of the 12th rib. The incision is taken through the intercostal muscles and fasciae using the surgical cautery. The surgical plane between the Psoas fascia and Gerota's fascia is developed bluntly. A retroperitoneal dissecting balloon is placed and inflated to create a retroperitoneal workspace. The balloon is deflated and a balloon-tip trocar placed and secured. Carbon dioxide gas is insufflated to expand the retroperitoneal space.

Trocar Placement

For the transperitoneal approach, a 3-trocar configuration is used (Fig. 1). At least one 10 mm port is necessary to permit intracorporeal suturing. A 5 mm port is placed halfway between the umbilicus and xiphoid process in the midline. A 10 mm port is placed at the umbilicus. An additional lateral 10 mm trocar is placed lateral to the ipsilateral rectus muscle at the level of the umbilicus (Fig. 1B).

Surgical Tip

For right-sided pyeloplasty, liver retraction may be necessary. If so, a 2 mm or 5 mm port can be placed just inferior to the xiphoid process, and a locking grasping forceps used to tent up the liver edge and grasp a segment of the triangular ligament or portion of the peritoneum. This will function as a self-retaining liver retractor. This obviates the need for a surgical assistant to retract the liver. Therefore, your surgical assistant can concentrate on providing a good camera image.

For the retroperitoneal approach, three trocars are used as well. The initial port, a balloon-tip trocar, is placed at the initial incision. An additional 10 mm trocar is placed

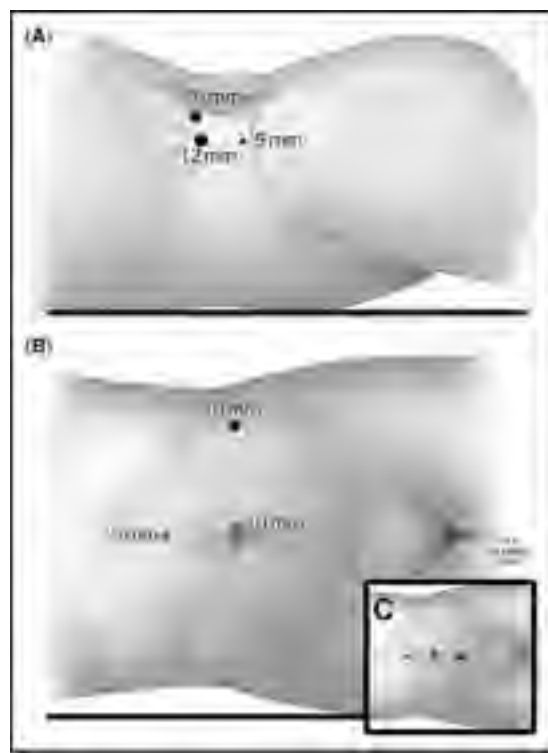
FIGURE 1 ■ (A) Trocar placement for retroperitoneal approach; (B) trocar placement for transperitoneal approach; (C) alternative trocar placement for transperitoneal approach.


FIGURE 2 ■ Endostitch™ (Autosuture Co., Norwalk, CT). The toggle from movement transfers the needle from jaw to faciliate suturing.

at the junction of the 12th rib and the paraspinal muscles. This can be done under tactile guidance (with a nonbladed trocar) or under direct vision. A 5 mm trocar is placed anteriorly, about two fingerbreadths above the iliac crest.

Dissection

Incision of the line of Toldt and mobilization of the colon is the first step during transperitoneal laparoscopic pyeloplasty. In right-sided cases, the Kocher maneuver may be necessary to mobilize the duodenum and expose the renal hilum. Next, the ureter is identified, and dissected free. Tenting up the ureter, the dissection is cephalad toward the ureteropelvic junction.

If a crossing vessel is identified, the ureter needs to be freed up completely from the vessel to facilitate eventual transposition. The renal pelvis needs to be freed up as much as possible to enable possible ureteral transposition and a tension-free anastomosis.

Retroperitoneal technique is usually facilitated by the fact that no extensive dissection is necessary. When dissecting in the proper anatomic space, the ureter and renal arterial anatomy should be rapidly identified. Dissection of these structures is necessary to ensure a tension-free anastomosis.

> If a crossing vessel is identified, the ureter needs to be freed up completely from the vessel to facilitate eventual transposition. The renal pelvis needs to be freed up as much as possible to enable possible ureteral transposition and a tension-free anastomosis.

Pyeloplasty Technique

Intracorporeal suturing is a necessary part of laparoscopic pyeloplasty. A 4-0 polyglycolic suture is used. Interrupted or running technique can be used. Freehand technique or mechanically assisted suturing can be used. An automatic laparoscopic suturing instrument such as the Endostitch (Fig. 2) can be used.

The author's preference is the interrupted technique for the following reasons:

1. Interrupted suture is potentially less ischemia producing.
2. Correction of unevenness in the anastomosis is easier.
3. A running anastomosis can be compromised by an air knot, and could require redoing the entire anastomosis.

Surgical Tip

> Clipping stay sutures to cut edges of the peritoneum can facilitate suturing the anastomosis. This frees up both of the surgeon's hands for suture placement and obviates the need for an assistant to assist with the anastomosis.

Anderson–Hynes Dismembered Pyeloplasty

Anderson–Hynes dismembered pyeloplasty is preferred when pelvic reduction may be necessary, a renal calculus is present, or a crossing vessel is encountered (Fig. 3).

A dismembered pyeloplasty may have superior efficacy compared with the other nondismembered techniques. In the largest head-to-head comparison of laparoscopic dismembered (*n* = 25) and nondismembered pyeloplasties (*n* = 15), Klingler et al. showed superior efficacy for dismembered (96%) versus nondismembered (73.3%) pyeloplasty.

Once the ureteropelvic junction is dissected free, the narrowed segment is excised (Fig. 3A). If there is excessive redundant pelvis, this can be excised. The defect can be closed. Next, the ureter is spatulated (Fig. 3B). The 6 o'clock and 12 o'clock positions of

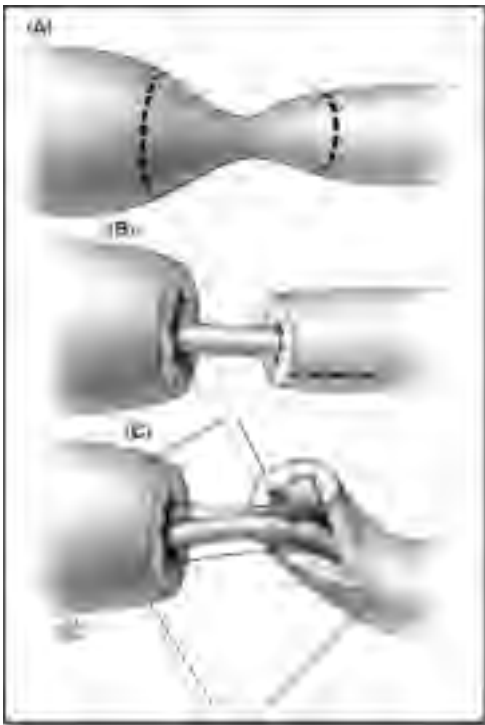
> Anderson–Hynes dismembered pyeloplasty is preferred when pelvic reduction may be necessary, a renal calculus is present, or a crossing vessel is encountered.


FIGURE 3 ■ Laparoscopic Anderson-Hynes disemembered pyeloplasty.
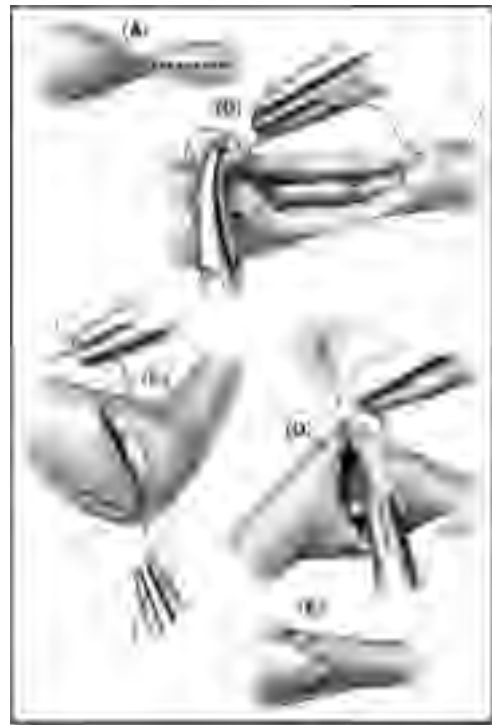

FIGURE 4 ■ Laparoscopic Foley Y-V plasty.

the ureter and pelvis are approximated (Fig. 3C). The intervening gaps on the front and back of the anastomosis can be closed with either running or interrupted suture.

Foley Y-V Plasty

Foley Y-V Plasty can be used with the following:

■ Small or modestly enlarged renal pelvis
■ Absence of crossing vessel
■ High ureteral insertion

A Y-shaped incision is made, which traverses the narrowed segment of the ureteropelvic junction (Fig. 4A). The apex of the Y limb is advanced to the distal end of the incision (Fig. 4B). Stay sutures are placed at each end of the incision (Fig. 4C), and the gaps in the anastomosis are filled in with interrupted sutures (Fig. 4D). The end result of the suturing should be a "V" shaped closure (Fig. 4E).

Fenger Pyeloplasty

The indications for Fenger pyeloplasty are the same as with the Y-V plasty. This relatively simple procedure uses a Heineke–Mikulucz type closure. The ureter is incised horizontally through the narrowed segment (Fig. 5A). The proximal end of the incision (Point 1) is then advanced and secured to the distal end (Point 2). The gaps on either side are then filled in with interrupted sutures (Fig. 5B).

POSTPYELOPLASTY PROCEDURE

After completion of the anastomosis, a Jackson-Pratt drain is left to bulb suction drainage via a lateral trocar site. Careful inspection of the surgical site is performed at low pressure to ensure good hemostasis. Cautery and hemostatic agents can be utilized to deal with nuisance bleeding. More significant bleeds may require suturing or clip application. In transperitoneal cases, some surgeons will reretroperitonealize the kidney by taking the colon back to the line of Toldt at the end of the case.

After the abdomen is desufflated and the gas expelled, the port sites can be closed under direct vision externally with a 2-0 polyglycolic suture if the patient is fairly thin

FIGURE 5 ■ Laparoscopic Fenger pyeloplasty.

and the fascia visible. With obese patients, a special port closure device such as the Carter-Thompson needle or CloseSure™ᶜ system can be used.

POSTOPERATIVE MANAGEMENT

After surgery, the patient remains in the hospital till a solid diet is tolerated. With retroperitoneal surgery, oral intake can be resumed more rapidly, and hospital stay is usually overnight. With transperitoneal surgery, oral intake can usually be resumed once flatus is passed the next day. Rapid resumption of bowel activity can be facilitated by the use of nonopiate analgesia such as ketorolac.

The drain can be removed if output is less than 100 cc/day. Usually, the drain can be removed the next day. With transperitoneal surgery, the output can be exaggerated by peritoneal fluid. In such cases, checking drain fluid creatinine can be used to biochemically identify if urine leak is the cause of excessive drain output. Management of persistent urinary leakage are addressed below.

The patient returns for stent removal at four to six weeks. One month after stent removal, a diuretic renogram or intravenous pyelogram can be obtained to verify a good surgical result.

POSTOPERATIVE COMPLICATIONS

The potential complications of laparoscopic pyeloplasty run the entire gamut of standard reported surgical complications. Two complications specific to the procedure are urine leak and stricture.

Urinary Leak

Leakage of urine can occur due to poor anastomosis, failure of suture material, distal ureteral obstruction, or unrecognized injury to the ureter distal to the anastomosis. Clinically, this can be identified by excessive and prolonged drain output or abdominal distension from urinary ascites. Confirmation can be achieved biochemically by testing the drain fluid for creatinine and comparing to serum creatinine. A drain fluid creatinine that is greater than the serum creatinine indicates the presence of urine.

> Management of urine leak is based on maximizing drainage, and urinary diversion. In the immediate postoperative period, placement or replacement of a Foley catheter can facilitate distal drainage.

Management of urine leak is based on maximizing drainage, and urinary diversion. In the immediate postoperative period, placement or replacement of a Foley catheter can facilitate distal drainage.

Sometimes, leakage can be exacerbated by physical contact of the drain with the anastomosis. The drain can be withdrawn a few centimeters to see if drainage subsides. If the leak is identified after stent removal, intravenous or retrograde pyelography can confirm the location of a leak and evaluate the ureteral anatomy. A stent should be replaced at that point. Prolonged catheter and stent drainage may be necessary to allow for proper healing. If the flank drain has been removed at the time of urine leak, a percutaneous drain or nephrostomy may need to be placed.

MEASURES TO REDUCE THE RISK OF URINE LEAK

1. Make sure that the anastomosis is tension free.
2. Check integrity of the anastomosis: place methylene blue in the bladder via urinary catheter or give intravenous methylene blue. There should be reflux up the stent. Identification of blue dye leakage can identify portions of the anastomosis that may need reinforcement.

> Stricture is synonymous with treatment failure.

> Endopyelotomy, either antegrade or retrograde, may be used to treat stricture of the ureteropelvic junction. Ultimately, open dismembered pyeloplasty may be necessary to treat recalcitrant secondary ureteropelvic junction obstruction.

Stricture

Stricture is synonymous with treatment failure. Clinical manifestations include flank pain, and/or continued obstruction on radiographic studies. Diuretic renography can confirm functional obstruction. Intravenous pyelogram may show delayed excretion of contrast.

Endopyelotomy, either antegrade or retrograde, may be used to treat stricture of the ureteropelvic junction. Ultimately, open dismembered pyeloplasty may be necessary to treat recalcitrant secondary ureteropelvic junction obstruction.

ᶜInlet Medical, Eden Prairie, MN.

Risk factors for stricture formation include previous irradiation, previous surgery on the ureteropelvic junction, and devascularization of the ureteral segment. Prevention relies on having a sound tension-free anastomosis at the time of surgery.

SUMMARY

- Laparoscopic pyeloplasty is rapidly becoming the treatment of choice for ureteropelvic junction obstruction.
- It offers success rate comparable to open surgery with all the benefits of minimally invasive surgery.
- Experience with intracorporeal suturing techniques is essential to ensure a good surgical result.

INTRODUCTION

The etiology of ureteropelvic junction obstruction may result from a number of factors, and can be classified as congenital or acquired in origin. Congenital ureteropelvic junction obstruction is typically characterized by an intrinsic luminal narrowing that is caused by an aperistaltic segment, in which the spiral musculature has been replaced by abnormal longitudinal muscle fibers and fibrous tissue (1–2). A less frequent cause of congenital ureteropelvic junction obstruction is a proximal ureteral stricture caused by abnormal ureteral muscle fiber and collagen deposition in this area (3). Additionally, intrinsic obstruction can be caused by infoldings of ureteral mucosa, a phenomenon that may result from exaggeration of congenital folds that are normally found in the ureter during fetal development (4). In some instances, ureteral adventitia may be present as external bands or adhesions that cause obstruction by producing angulation of the proximal ureter at the lower margin of the renal pelvis. High insertion of the ureter has also been reported as a primary obstructing lesion, and may coincide with other renal anomalies such as ectopia or abnormal fusion (5).

Acquired ureteropelvic junction obstruction may be the result of long-standing vesicoureteral reflux that leads to dilatation of the renal pelvis and upper ureter, with subsequent development of elongation, tortuosity, and kinking. Other causes of obstruction include fibroepi-thelial polyps, urothelial tumors, urolithiasis, and inflammation or scarring caused by prior surgery or ischemia.

The role of aberrant crossing vessels in the etiology of ureteropelvic junction obstruction remains controversial. Arteries or veins supplying the lower renal pole are noted if as many as 79% of patients with symptomatic ureteropelvic junction obstruction (6), and may arise from the main renal artery or vein, or directly from the great vessels. These vessels usually cross the ureteropelvic junction anteriorly; however in a minority of patients, these vessels cross posteriorly. As crossing vessels have been documented in patients with a normal ureteropelvic junction, it is possible that the associated vessel alone may not be solely responsible as the primary cause of the obstruction.

A combination of an intrinsic lesion at the ureteropelvic junction and subsequent dilatation and draping of the renal pelvis over the polar vessels may be more likely Nevertheless, the incidence of crossing vessels in the symptomatic population is higher and appears to have functional significance.

Open pyeloplasty has been the standard treatment for congenital or acquired ureteropelvic junction in adults and children, with overall success rates of 90% to 100% (7–9).

The desire to decrease surgical morbidity associated with open surgery has led to the evolution of less invasive procedures over the past two decades, including percutaneous antegrade and ureteroscopic retrograde endopyelotomy. Despite lower success rates of 61% to 89% and an increased risk for perioperative hemorrhage (10–15), the endoscopic approaches have gained favor over open pyeloplasty.

Technologic advances have played a significant role in the therapeutic management of ureteropelvic junction obstruction and have enabled the introduction of laparoscopic- and robotic-assisted laparoscopic pyeloplasty over the last several years.

Laparoscopic pyeloplasty was first described in 1993 by Schuessler et al. (16). This procedure maintained the benefits of endoscopic approaches, short length of hospitali-zation, and reduced postoperative recovery time, while demonstrating comparable success rates to the conventional open approach (17–20). However, the technical challenge of reconstruction limited this procedure to select medical centers with advanced laparoscopic surgeons.

The introduction of robotic-assisted laparoscopic surgery has widened the surgical dimensions for minimally invasive surgery. Specifically, the availability of the *da Vinci®* Robot[a] has facilitated complex reconstructive and laparoscopic procedures (21–23). The benefits imparted to the surgeon include enhanced three-dimensional visualization, improved dexterity, greater precision, increased range of motion, and reproducibility. The robot offers these potential advantages to even the smallest children. Despite reports of laparoscopic procedures being performed in various pediatric urologic procedures, only a handful of centers have embraced this technology.

This may be secondary to practice patterns but more likely reflects the inability of most practitioners to successfully implement and exploit laparoscopy for complex reconstructive procedures. With the advent of surgical robotics, the potential for a larger group of surgeons to employ minimal invasive methods for pediatric urologic operations is possible.

Over the last 10 years, laparoscopic pyeloplasties have been performed in adults and children but still remain a challenge for most surgeons. Robotic-assisted surgeries are beginning to find their place in urologic surgery. The surgical robot is ideally suited for the reconstruction of the ureteropelvic junction and is a good procedure for the novice robotic surgeon to attempt.

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

Indications for surgical intervention in patients with ureteropelvic junction obstruction include functionally significant obstruction, as defined by the presence of flank pain or other symptoms associated with the obstruction, impairment, or deterioration in renal function.

In addition, upper urinary tract infection or renal calculi formation secondary to inadequate urinary drainage can also prompt surgical intervention. Asymptomatic individuals, in whom the physiologic significance of obstruction is indeterminate based on radiologic imaging studies, may reasonably be observed and followed with routine monitoring.

The majority of patients with ureteropelvic junction obstruction will benefit from surgical intervention with the primary goal of relieving symptoms and preserving renal function. The gold standard for achieving unobstructed urinary flow has been open operative repair and reconstruction of the ureteropelvic junction in the form of pyeloplasty. Antegrade and retrograde endoscopic approaches have since become popular as initial procedures of choice due to their minimal invasive nature and patient preference. However, success rates with these alternative techniques have not proved comparable with those of open pyeloplasty, especially in cases of

Margin notes:

Open pyeloplasty has been the standard treatment for congenital or acquired ureteropelvic junction in adults and children, with overall success rates of 90% to 100%.

Technologic advances have played a significant role in the therapeutic management of ureteropelvic junction obstruction and have enabled the introduction of laparoscopic- and robotic-assisted laparoscopic pyeloplasty over the last several years.

The robot offers the potential advantages of enhanced three-dimensional visualization, improved dexterity, greater precision, increased range of motion, and reproducibility to even the smallest children. Despite reports of laparoscopic procedures being performed in various pediatric urologic procedures, only a handful of centers have embraced this technology.

The surgical robot is ideally suited for the reconstruction of the ureteropelvic junction and is a good procedure for the novice robotic surgeon to attempt.

Indications for surgical intervention in patients with ureteropelvic junction obstruction include functionally significant obstruction, as defined by the presence of flank pain or other symptoms associated with the obstruction, impairment, or deterioration in renal function.

long strictures, crossing vessels, or a large redundant renal pelvis. The indications for open and endoscopic management of ureteropelvic junction obstruction are still evolving, and careful patient selection for each approach may yield improved success rates (24).

The principal contraindication to any minimally invasive approach is a long segment of obstruction, precluding the performance of a tension-free anastomosis between normal ureter and the renal pelvis. Age, body mass, prior operations, and/or side of involvement are other possible exclusion criteria.

The presence of a large struvite stone may present a relative contraindication to robotic-assisted pyeloplasty repair. However, several series of laparoscopic- and robotic-assisted pyeloplasty repairs with concomitant pyelolithotomy have been performed without difficulty. Smaller stones were simply grasped and removed under direct vision or entrapped using a flexible cystoscope. Larger stones were taken out with an EndoCatch® bag[b] (19,20,25–29). However, in the setting of struvite renal calculi that cannot be easily accessed via a laparoscopic procedure, an alternative approach may be more appropriate.

The presence of a crossing vessel is not a contraindication for laparoscopic- or robotic-assisted repair. In such instance, a dismembered Anderson–Hynes type repair is recommended. Indeed, some authors do not obtain preoperative studies to detect crossing vessels, believing that intraoperative recognition is readily apparent and addressed at the time of surgery (19).

Nephrectomy is often the preferred option for kidneys with no function or poor function and minimal potential for salvage. When repeated attempts at repair have failed and further intervention would be complicated with a low yield for success, nephrectomy may be considered as well. Additionally in patients with significant medical comorbidities, advanced age, or limited life expectancy, nephrectomy may be a suitable option. In any situation warranting surgical removal of the kidney over a reconstructive procedure, it is of extreme importance to verify the presence of an essentially normal contralateral kidney on the basis of radiographic or radionuclide studies.

PREOPERATIVE PREPARATION

Patients undergoing a robotic-assisted pyeloplasty should be subjected to preoperative evaluation and preparation as if they were undergoing an open operative intervention. This includes a search for any comorbidity that may increase the risk of anesthesia. Any urinary infection should be treated, and sterile urine should be ensured at the time of definitive intervention. If upper tract infection cannot be cleared because of obstruction, an internal stent or percutaneous nephrostomy drainage should be placed.

The patient should be counseled as to the risks and benefits of the procedure, including the fact that the success rate of any robotic-assisted approach may be less than that of a standard open operative intervention.

In addition, for any minimally invasive approach, there is always a risk that an open conversion may be possible. Patients should also be apprised of the fact that bleeding requiring transfusion is a risk of the procedure, and a "type and screen" should be part of the protocol.

A bowel preparation is usually recommended especially when robotic surgery is performed by the novice practitioner. Any standard bowel preparation will suffice. In the unlikely event of a bowel injury, this step may ensure a less complicated postoperative course for the patient.

All patients in both the adult and pediatric populations should have radiographic evidence of ureteropelvic junction. This may include ureteropelvic junction on diuresis renography or hydronephrosis with delayed function on excretory urography (IVP). Computed tomography, magnetic resonance imaging, or ultrasound may be helpful for anatomic mapping of the ureteropelvic junction with or without a crossing vessel, but will not always definitively indicate a ureteropelvic junction obstruction.

Finally, a renal split function may be helpful in cases where renal deterioration is suspected. This provides a baseline study to compare with in the future and will also predict the likelihood of a successful repair. The lower the renal function in the obstructed renal unit, the lower the chances of a successful repair.

Margin notes

The principal contraindication to any minimally invasive approach is a long segment of obstruction, precluding the performance of a tension-free anastomosis between normal ureter and the renal pelvis. Age, body mass, prior operations, and/or side of involvement are other possible exclusion criteria.

The presence of a crossing vessel is not a contraindication for laparoscopic- or robotic-assisted repair.

The patient should be counseled as to the risks and benefits of the procedure, including the fact that the success rate of any robotic-assisted approach may be less than that of a standard open operative intervention.

A bowel preparation is usually recommended especially when robotic surgery is performed by the novice practitioner.

ROBOTIC-ASSISTED TECHNIQUE

Adult Technique

After the induction of general anesthesia, a retrograde pyelogram is often performed to confirm the diagnosis and define the anatomy. If desired, an internal ureteral stent may be placed at that time, and an indwelling Foley catheter is placed to gravity drainage.

Our Anderson–Hynes dismembered pyeloplasty technique is similar to other previously described methods (25–29). The *da Vinci* Surgical System consists of two interactive robotic arms, a camera arm, a three-dimensional imaging system, and a virtual control chamber.

Newer robot surgical systems have incorporated a fourth arm that can be used as either a second right or a left arm. However, the robotic-assisted pyeloplasty does not warrant a fourth robotic arm, and the protocol is described using a three-arm robot with an assistant.

The patient is placed in a lateral or semilateral decubitus position and three laparoscopic ports, including two 8 mm ports and one 12 mm disposable port, are placed in a "c" configuration (Fig. 1). The beginning portion of the operation is performed as a standard transperitoneal laparoscopic approach by gaining access with a Veress needle or Hasson technique. Some institutions have performed this beginning portion entirely with the robot.

For the novice, it is recommended that the first 20 cases be performed with laparoscopic assistance until a comfort level is reached with the *da Vinci* robot.

Noteworthily, there are reports in the adult literature describing a retroperitoneal approach to the laparoscopic pyeloplasty but not as a robotic-assisted pyeloplasty (30–32).

On the left side, the descending colon is displaced medially in order to gain access to the ureteropelvic junction. On the right side, the peritoneum is incised from the liver attachments down to the iliac vessels and parallel to the ascending colon, allowing identification of the ureteropelvic junction between the lower pole of the kidney and the inferior vena cava. The ureter and renal pelvis are also completely mobilized. Extensive dissection of the proximal ureter is avoided to maintain the vascular supply to the ureter and ureteropelvic junction.

Once the diseased ureteropelvic junction and/or crossing vessel are identified, the *da Vinci* robot is docked into place.

Depending on surgeon preference, the camera consisting of a 0° or 30° lens is placed through the disposable 12-mm port at the umbilicus. The robot arms are each placed through the two reusable 8-mm ports. At this time, a fourth port is placed in the lower infraumbilical area in a position contralateral to the operative side. Some surgeons prefer to place this fourth port at the time of the initial port placements. A 12-mm disposable port allows the assisting surgeon to introduce and retrieve sutures, aid in retraction, and perform suctioning. Robotic instruments employed include needle drivers, forceps, and scissors.

Margin notes:

Newer robot surgical systems have incorporated a fourth arm that can be used as either a second right or a left arm. However, the robotic-assisted pyeloplasty does not warrant a fourth robotic arm, and the protocol is described using a three-arm robot with an assistant.

For the novice, it is recommended that the first 20 cases be performed with laparoscopic assistance until a comfort level is reached with the da Vinci robot.

Once the diseased UPJ and/or crossing vessel are identified, the da Vinci robot is docked into place.

FIGURE 1 ■ Trocar positioning for left robotic-assisted laparoscopic Anderson–Hynes-dismembered pyeloplasty in an adult patient. Four laparoscopic ports (two 8 mm ports and two 12 mm disposable ports) are placed in a "c" configuration with one contralateral port. The mirror image is done for a right-sided procedure.

In performing Anderson–Hynes dismembered pyeloplasty, the renal pelvis is circumferentially transected above the ureteropelvic junction (Fig. 2A and B), and the proximal ureter is spatu-lated laterally. Some earlier cases were performed using laparoscopic endoshears. At this time, the current preference is to spatulate the ureter using potts scissors. In the case of crossing vessels, the ureter and renal pelvis are transposed to the anterior side of the vessel prior to initiation of the anastomosis (Fig. 2C). If the renal pelvis is redundant, excess tissue is excised. An absorbable 4-0 suture is placed through the apex of the spatulated ureter and at the most dependent portion of the renal pelvis. The posterior anastomosis is then performed with an interrupted or running suture. If redundant pelvis tissue was excised, the remaining pyelotomy incision is closed using additional sutures.

If an indwelling stent was not placed at the beginning of the procedure, it is placed into the ureter over a guidewire and under direct vision at this time. The wire can be passed through the abdominal wall using a 14-gauge angiocatheter or the assistant may pass it through the 12-mm accessory port. The distal coil is positioned within the bladder, and the proximal coil is positioned within the renal pelvis. With experience, the distal portion of the stent is easily manipulated into the bladder, but methylene blue dye can be placed in the bladder to confirm positioning of the stent. Alternatively, fluoroscopy may be used to visualize the distal portion of the curled stent in the bladder.

The anterior anastomosis is then completed (Fig. 2D). Following a watertight anastomosis, a drain is placed and then exits the patient via one of the laparoscopic 8-mm ports.

In some of our earlier cases, the indwelling stent was placed prior to surgery but we believe that this made the transection and repair of the ureteropelvic junction more difficult.

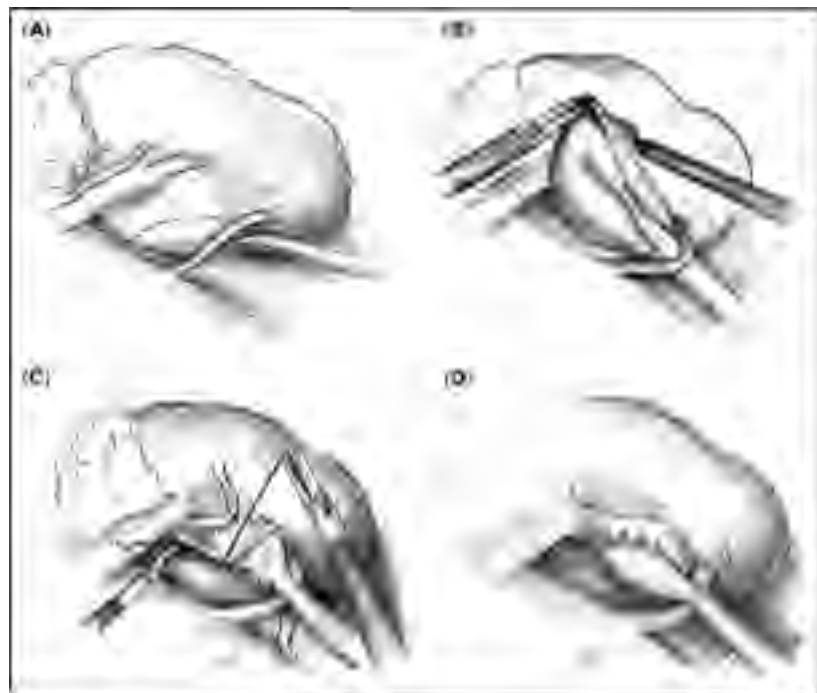
Patients are scheduled for follow-up at four to six weeks for stent removal. A diuretic renal scan is performed at three months and annually thereafter. Clinical follow-up is scheduled annually. Success is defined as improvement of symptoms related to the previous renal obstruction and improved function on diuretic renal scan.

Nondismembered pyeloplasty may be performed for appropriately selected patients using robotic assistance.

Different methods of nondismembered repairs have been described in the laparoscopic pyeloplasty literature such as Culp-DeWeerd spiral flap (33), Fenger plasty (34), Y-V plasty (Fig. 3) (18), Heineke-Mikulicz repair (19), and Davis-intubated ureterotomy (19). The ureteropelvic junction incision and suturing in these repairs are performed in a similar manner as in the open operative intervention.

In some of our earlier cases, the indwelling stent was placed prior to surgery but we believe that this made the transection and repair of the ureteropelvic junction more difficult.

Nondismembered pyeloplasty may be performed for appropriately selected patients using robotic assistance.

FIGURE 2 ■ Anderson–Hynes dismembered pyeloplasty is the procedure of choice for robotic-assisted cases. (A) Dissection of the proximal ureter and ureteropelvic junction reveals a crossing vessel. (B) Incision of the renal pelvis and transposition of the crossing vessel. (C) After spatulation of the ureter laterally, a posterior anastomosis is performed with running or interrupted sutures. (D) A tension-free, water-tight repair is achieved with an internal stent previously placed (not shown).


Pediatric Technique

The transperitoneal Anderson–Hynes dismembered pyeloplasty approach to the pediatric patient is similar to the adult patient (35–38). A retroperitoneal approach to the robotic-assisted pyeloplasty has been described in the pediatric literature, but is less commonly performed (39).

After performing a cystoscopic, retrograde pyelogram to demonstrate the ureteropelvic junction obstruction and placement of a ureteral stent (this may be placed at completion of the repair as an options), the patient is placed in the modified flank position at about 45° to permit transmesenteric access to the pelvis and/or to mobilize the colon medially.

In children with extensive mesenteric fat, mobilization of the colon may be a safer approach. Some authors have suggested performing the initial mobilization of the ureteropelvic junction using the robot, but until a surgeon is completely comfortable with the robot, we suggest starting with a standard laparoscopic approach to mobilize the ureteropelvic junction.

A Hasson approach is used to place a 12-mm supraumbilical trocar for the camera. Two 8-mm robotic trocars are placed in the left anterior axillary line under direct vision (5-mm ports and instruments are likely to be available in the near future). A fourth 5-mm is placed in the left flank just anterior to the colon.

After the renal pelvis is exposed, it is incised leaving a handle of the pelvis and ureteropelvic junction on the ureter for manipulation. Generally a stay suture is also placed at the medial portion of the ureter to aid in retraction. The ureter is spatulated laterally, and any diseased ureteropelvic junction is excised and sent to pathology for evaluation. The previously placed ureteral stent aids in identification of the ureter. The posterior wall anastomosis is started with running or interrupted absorbable suture, usually a 5.0 or 6.0 monocryl.

The water-tight anastomosis is finished after the closure of the anterior wall. A JP drain is placed and brought out through the 5-mm port. The transmesenteric incision is closed with a running 4-0 chromic to retroperitonealize the ureter and pelvis. All other ports are closed with fascial stitches that are generally placed at the time of port positioning. A bladder catheter is left in place overnight and then removed in the morning. The JP drain is removed prior to discharge usually the next afternoon.

Surgical Steps

The steps involved in a robotic-assisted pyeloplasty can be simplified into a 12-step method.

1. Trocar placement.
2. Transperitoneal exposure of the retroperitoneum using standard laparoscopy.
3. Dissection of the pelvis, ureter, and possible crossing vessel.
4. Docking of the *da Vinci* Surgical System.
5. Transection of the ureteropelvic junction and excision of diseased segment.
6. Spatulation of the ureter laterally.
7. Apical and posterior wall suture placement.
8. Guide wire and stent placement (if not placed at the beginning of operation).

FIGURE 3 ■ Y-V plasty.

9. Anterior wall suture placement.
10. Renal pelvis reconstruction.
11. Reretroperitonealization of the kidney.
12. Placement of JP drain and exiting of the abdomen.

Various Modifications Published in the Literature

Several experiences with robot-assisted laparoscopic pyeloplasty have demonstrated the feasibility of this technique in providing improved surgical dexterity and decreasing operative times (21–23,25–29,35–39).

Gettman et al. compared the *da Vinci* Robotic System to the standard laparoscopic pyeloplasty (23). The investigators noted that the Anderson–Hynes pyeloplasty is feasible with either technique. Procedures performed with the *da Vinci* robot resulted in overall decreased operative times when compared to standard laparoscopy. Gettman et al. also reviewed nine patients who underwent laparoscopic Anderson–Hynes pyeloplasty using the *da Vinci* system (25). The total mean operative time was 138.8 minutes (range 80–215), of which the mean suturing time was 62.4 minutes (range 40–115). Estimated blood loss was less than 50 mL in all cases, and the length of hospitalization averaged 4.7 days (range 4–11). Although there were no intraoperative complications, one patient (11.1%) required postoperative open exploration to repair a persistent renal pelvis defect. At short-term follow-up of 4.1 months (range less than 1–8 months), all procedures were successful on the basis of the subjective and radiographic data. In this series, robot-assisted laparoscopic pyeloplasty resulted in favorable overall operative times, suturing times, and short-term success rates. Peschel et al. presented their clinical experience of 19 patients in whom Anderson–Hynes pyeloplasty and nondismembered pyeloplasty were performed (28). The operative time and hospital stay in both groups were in the range of 90 to 180 and 75 to 130 minutes and 4.7 and 4.5 days, respectively. An overall objective success of 100% was achieved. Another group from France also published an 18 case series of robotic-assisted pyeloplasty with a mean operative time and suturing time of 147 minutes and 42 minutes. The average hospital stay was approximately 6.5 days (29).

In our combined institutional series, all surgeons were able to reduce their operative times (skin to skin) from an average of 283.3 minutes for the first five cases to 192 minutes for the most recent five cases (p < 0.001). As even more experience is gained with this procedure, it is likely that this operating time can be reduced even further. In addition, most surgeons preferred to start the case with standard laparoscopic techniques. Reasons for this include that the mobilization of the colon, duodenum, liver, spleen, or pancreas is more easily performed with laparoscopic instruments. Also, during the time of laparoscopy, the surgical staff may set up the da Vinci robot. Being performed at a teaching institution, the laparoscopic portion allows all members of the surgical team to be involved with the surgery. Finally, the amount of time required to dock the da Vinci system is only 10 to 15 minutes. With more experience, all surgeons will likely start the procedure using only the robot (40).

We exclusively performed the Anderson–Hynes pyeloplasty repair using the *da Vinci* robot. This repair is the gold standard for open pyeloplasty repairs and the robot allowed us to duplicate this procedure in the most complicated cases. Intrinsic problems were easily excised and repaired. Exposure and repair of extrinsic problems such as crossing vessels were readily addressed.

Patients with concomitant stones were successfully addressed at the time of surgery. The larger stones were grasped and extracted under direct vision using a flexible cystoscope. The smaller stones were easily washed out with suction and irrigation. Other authors have similar experiences.

Laparoscopic surgeons continue to show a preference for transperitoneal laparo-scopy; however, the feasibility of retroperitoneoscopic pyeloplasty has assisted in elucidating advantages and disadvantages of both approaches.

During pyeloplasty, the transperitoneal approach offers ease in identifying, dissecting, and mobilizing intra-abdominal structures, whereas the potential disadvantages include prolonged ileus, adhesion formation, and injury to adjacent viscera.

The major advantage of the retroperitoneoscopic approach is that it provides a direct route to the ureteropelvic junction and allows access without interference from intra-abdominal structures. However, the working space is more restricted and the absence of anatomic landmarks may make dissection more cumbersome for the inexperienced surgeon.

Several experiences with robot-assisted laparoscopic pyeloplasty have demonstrated the feasibility of this technique in providing improved surgical dexterity and decreasing operative times.

This repair is the gold standard for open pyeloplasty repairs and the robot allowed us to duplicate this procedure in the most complicated cases. Intrinsic problems were easily excised and repaired. Exposure and repair of extrinsic problems such as crossing vessels were readily addressed.

During pyeloplasty, the transperitoneal approach offers ease in identifying, dissecting, and mobilizing intra-abdominal structures, whereas the potential disadvantages include prolonged ileus, adhesion formation, and injury to adjacent viscera.

The major advantage of the retro-peritoneoscopic approach is that it provides a direct route to the UPJ and allows access without interference from intra-abdominal structures. However, the working space is more restricted and the absence of anatomic landmarks may make dissection more cumbersome for the inexperienced surgeon.

Olsen et al. describe their experience using the robot surgical system in 13 children to perform robotic-assisted retroperitoneoscopic pyeloplasties (36). They concluded that the technically difficult procedure was easily performed; however, the surgeons without laparoscopic training will encounter problems because the same rules as in laparoscopy apply. These include correct port placement, maintenance of appropriate carbon dioxide pressure, and the basic principle of laparoscopic dissection. In addition, orientation in the retroperitoneal space can be difficult because the surgeon in a remote placement from the patient has no sense of up and down.

Pros and Cons

It is likely the inexperienced laparoscopic surgeon may gain the most from the *da Vinci* Surgical System.

Besides the experience required for performing complex reconstructive procedures, standard laparoscopic surgery is also handicapped by the reduction in the range of motion due to a fixed trocar position determining the angle of the working field. The robotic instruments are designed with seven degrees of motion that mimic the dexterity of the human hand and wrist. Each instrument has a specific surgical mission such as clamping, suturing, and tissue manipulation. In addition, three-dimensional vision is afforded to the surgeon rather than a two-dimensional view in standard laparoscopy. Other advantages include potential loss of tremor, decreased trauma to the patient in comparison to open procedures, and comfort for the surgeon.

Disadvantages include the lack of tactile sensation and thus visualization of anatomic landmarks is the key to successfully completing the operation. The surgeon is away from the operating table and therefore must depend on an experienced assistant. Active communication between the primary surgeon, first assistant, and staff is imperative.

Although the learning curve for the surgeon may be short (in our experience less than 10 cases), there is a substantial learning curve for the ancillary staff. Many hours of in-servicing may be required and consistency in the assignment of staff to *da Vinci* robot cases allows for a smooth transition between cases.

Finally, the cost of the *da Vinci* robot is always a consideration. An initial investment of over $1,000,000 and subsequent running costs may not make this procedure feasible at many centers. However, as the robotic prostatectomy becomes more popular, the *da Vinci* robot system may become more readily available at many institutions.

TECHNICAL CAVEATS/TIPS

The technical advantages afforded to the surgeon by the robotic surgical system are readily apparent. It is especially intriguing to experience the ease of intracorporeal suturing by the translation of the surgeon's hand movements via a remote console to the robotically manipulated instruments. With any new technology, trial and error pave the way to a successful operation.

It is always important to have performed a cystoscopy and retrograde pyelogram prior to every procedure. This will help to facilitate your understanding of the ureteropelvic junction anatomy and clearly define the obstruction. In the pediatric population, it may be easier to place the internal stent prior to the docking of the robot system. But in both children and adults, the indwelling stent should never be in the patient for weeks prior to the surgery. The stent leads to ureteral edema, making every anastomotic repair all the more difficult. If a ureteral stent is in place, we recommend removing the stent at least one week prior to pyeloplasty repair.

When placing a ureteral stent prior to completion of the water-tight anastomosis, it is important to make sure that the guide wire is pushed into the bladder.

The addition of methylene blue into a full bladder with a clamped Foley may aid in the successful placement of the ureteral stent. Fluoroscopy or direct vision of the distal end of the stent in the bladder with a flexible cystoscope may also ensure proper placement of the ureteral stent.

A "hitch stitch" placed at the medial side of the ureter may aid in retraction. This stitch can either be held by the operating surgeon or the assistant, or can be tacked up to the peritoneal wall if necessary. Alternatively leaving some diseased ureter and/or periureteral tissue attached will create a handle for retraction.

The novice robotic surgeon will find the robotic-assisted pyeloplasty to be a wonderful introduction to the robotic surgical system.

The first several cases may be time consuming, but for the surgeon, the greatest advantage is the comfortable working position. Also, the three-dimensional view with

easy handling of the instruments will lead to shorter operative times as experience is gained.

SPECIFIC MEASURES TO AVOID COMPLICATIONS

There are several disadvantages to the robotic surgical system that may lead to complications if not taken into account. Firstly, the robot surgical system is expensive and requires a large initial and ongoing investment for the hospital. Surgeons and operating room personnel must both be trained to use the system safely and efficiently. This also includes care and storage of the robot device.

If personnel are not appropriately trained and careful when setting up and taking down the device, complications could theoretically occur secondary to mechanical failures.

There have been no system malfunctions to date that could not be attributed to human error. Most common are instrument malfunction due to incorrect insertion or vision system problems due to incorrect calibration. External collisions of robotic arms are usually due to judgment errors in trocar placement or cart positioning.

The operating surgeon must become accustomed to the absence of haptic feedback. Complications may ensue owing to the lack of tactile sensation. Tissue damage may occur secondarily to excessive pressure or tension.

Until extensive experience is gained with the robotic surgical system, it is recommended that the novice robotic surgeon start the robotic-assisted pyeloplasty with a standard laparoscopic technique.

This will ensure familiarity of the anatomy and help to avoid any complications. Also, preoperative installation of the robot surgical system may require 30 to 60 minutes depending on personnel experience. This must always be taken into consideration when operating room times are assessed. Therefore, beginning the case as a standard laparoscopic procedure may give the operating room staff time to complete the robot surgical system setup.

> **Sidebar 1:** If personnel are not appropriately trained and careful when setting up and taking down the device, complications could theoretically occur secondary to mechanical failures.

> **Sidebar 2:** Until extensive experience is gained with the robotic surgical system, it is recommended that the novice robotic surgeon start the robotic-assisted pyeloplasty with a standard laparoscopic technique.

SUMMARY

- Technologic advances have played a significant role in the therapeutic management of ureteropelvic junction obstruction and have enabled the introduction of laparoscopic- and robotic-assisted laparoscopic pyeloplasty over the last several years.
- The surgical robot is well suited for the reconstruction of the ureteropelvic junction and is a good procedure for the novice robotic surgeon to attempt.
- The presence of a crossing vessel is not a contraindication for laparoscopic- or robotic-assisted pyeloplasty.
- Several experiences with robot-assisted laparoscopic pyeloplasty have demonstrated the feasibility of this technique in providing improved surgical dexterity.
- Although the learning curve for the surgeon may be short (in our experience less than 10 cases), there is a substantial learning curve for the ancillary staff. Many hours of in-servicing may be required, and consistency in the assignment of staff to da Vinci robot cases allows for a smooth transition between cases.
- The novice robotic surgeon is likely to find the robotic-assisted pyeloplasty to be a good introduction to the robotic surgical system.

LAPAROSCOPIC PYELOPLASTY: CURRENT STATUS

Ioannis M. Varkarakis and Thomas W. Jarrett

The James Buchanan Brady Urological Institute, Johns Hopkins Medical Institutions, Baltimore, Maryland, U.S.A.

INTRODUCTION

Ureteropelvic junction obstruction leads to progressive dilatation of the renal collecting system and can result in progressive deterioration of renal function. Most cases are congenital; however, symptoms are not clinically apparent until later in life. Most frequent presenting symptoms are flank pain, urinary tract infection, and hematuria after minor trauma. It is the most common site of obstruction in the upper urinary tract, and surgical management is necessary when obstruction is confirmed with functional radiographic studies.

The gold standard therapy for repair of ureteropelvic junction obstruction has been open pyeloplasty with long-term success rates consistently exceeding 90% (1,2).

In an attempt to reduce the morbidity of the flank incision, new minimally invasive procedures, endoscopic or fluoroscopic retrograde, and endoscopic percutaneous antegrade pyelotomy were developed (3–6). All achieved the goals of short hospital stay and rapid recovery, but had lower success rates.

In an effort to achieve both minimal morbidity and results equivalent to or better than those of open surgery, laparoscopic dismembered pyeloplasty was introduced in 1993 (7,8). Initial promising results were confirmed by larger series (9–12). Despite the existing long learning curve, laparoscopic pyeloplasty is now an established procedure at select centers worldwide, applicable to both pediatric (13,14) and adult patient populations.

Dismembered and nondismembered pyeloplasties [Foley Y-V (15), Fenger (16)] may be performed using transperitoneal and retroperitoneal laparoscopic approaches.

CURRENT MANAGEMENT OF URETEROPELVIC JUNCTION OBSTRUCTION AND INDICATIONS FOR LAPAROSCOPIC PYELOPLASTY

The treatment of adult ureteropelvic junction obstruction has undergone significant changes during the past two decades, with the advent of laparoscopic pyeloplasty being one of them. Despite its advantages, this procedure requires both laparoscopic experience and considerable skill with laparoscopic suturing. Laparoscopic approaches are performed in selected centers and only recently have been integrated into almost all residency programs. As a consequence, laparoscopic pyeloplasty is still not widely performed. The familiarity of most urologists with endoscopic techniques makes endopyelotomy feasible without the need for any further training after residency. As a

---

The gold standard therapy for repair of ureteropelvic junction obstruction has been open pyeloplasty. Long-term success rates consistently exceed 90%.

In an effort to achieve both minimal morbidity and results equivalent to or better than those of open surgery, laparoscopic dismembered pyeloplasty was introduced in 1993.

Dismembered and nondismembered pyeloplasties may be performed using transperitoneal and retroperitoneal laparoscopic approaches.

consequence, endopyelotomy still continues to be more commonly performed, even in tertiary referral centers (17). However, endopyelotomy frequently fails in the presence of a crossing vessel or a very dilated renal pelvis. Current imaging with three-dimensional helical computing tomography or contrast-enhanced color Doppler can identify accurately abnormal renal vessels. Therefore preoperative knowledge of the existence of a crossing vessel or a huge pelvis allows urologists to avoid endoscopic management.

> In the presence of a crossing vessel or a huge pelvis, laparoscopic dismembered pyeloplasty is preferred due to its low morbidity and the capability of transposing the crossing vessel or reducing the renal pelvis similar to open pyeloplasty.

In the presence of a crossing vessel or a huge pelvis, laparoscopic dismembered pyeloplasty is preferred due to its low morbidity and the capability of transposing the crossing vessel or reducing the renal pelvis similar to open pyeloplasty.

Patients with anatomic variations such as a horseshoe or pelvic kidney are also good candidates for laparoscopic surgery. Failed prior procedures do not preclude laparoscopy (18,19). The presence of ipsilateral renal calculi is not a contraindication for the procedure (20). However, laparoscopic pyeloplasty for small intrarenal pelvis would be technically challenging, similar to open surgery.

RESULTS: TRANSPERITONEAL LAPAROSCOPIC PYELOPLASTY

> The transperitoneal approach, which provides more anatomic landmarks than the retroperitoneal approach, has been used in most pyeloplasty series and is considered easier for the beginner.

The transperitoneal approach, which provides more anatomic landmarks than the retroperitoneal approach, has been used in most pyeloplasty series and is considered easier for the beginner.

Although more space for intracorporeal suturing is provided, proficiency in suturing and tying techniques are important in completing a watertight anastomosis. Laparoscopic suturing is tedious and often responsible for the long operating times seen in most laparoscopic pyeloplasty series. Unfortunately, operation time is still the highest among therapeutic modalities for ureteropelvic junction obstruction. Nevertheless with increasing experience and improved instrumentation, operating times have decreased as confirmed in studies with larger number of patients (Table 1) (9,13,21–23). Conversion rates range from 1.4% to 20% (16,22), and are usually dependent on the ability to complete a free tension anastomosis (Table 1).

> Morbidity of transperitoneal laparoscopic pyeloplasty has been shown to be considerably less than that of open pyeloplasty. Complications have decreased with experience and range between 11% and 20% in latest series.

Morbidity of transperitoneal laparoscopic pyeloplasty has been shown to be considerably less than that of open pyeloplasty (22). Complications have decreased with experience and range between 11% and 20% in latest series (Table 1) (24,25).

A variety of complications general to laparoscopy and specific to the procedure itself have been reported (Table 2). Minor complications predominate with the most common being urine leak and persistent drainage, which are usually treated conservatively. With experience, improving methods of creating the anastomosis and securing drains can minimize complications.

> In all studies comparing laparoscopic versus open pyeloplasty, the laparoscopic approach provides less postoperative pain, shorter hospital stay, and faster recovery. Success rates in most recent series are above 90% and similar to those obtained with the open approach.

In all studies comparing laparoscopic versus open pyeloplasty, the laparoscopic approach provides less post-operative pain, shorter hospital stay, and faster recovery (27,28). Success rates in most recent series are above 90% and similar to those obtained with the open approach (12,26).

TABLE 2 ■ Complications Reported During Transabdominal Laparoscopic Pyeloplasty

Serosal tear	Transient ureteral edema	Myocardial infarction
Abdominal wall hematoma	Stent migration	Congestive heart failure
Clipped colonic diverticulum	Transient ileus	Pneumonia
Urinoma formation	Pyelonephritis	Thrombophlebitis
Postoperative bleeding	Stone recurrence	

This is attributed to the fact that laparoscopy allows direct evaluation of the ureteropelvic junction and therefore appropriate management of crossing vessels and dilated renal pelvis in a similar way to the open procedure. This may be why laparoscopy presents with better overall results than endoscopic management. When the anatomic conditions that predispose to failure of endoscopic management are absent, antegrade endopyelotomy and laparoscopic pyeloplasty present with equally good results (29).

When compared to retrograde endopyelotomy, the laparoscopic approach presents with more postoperative pain, longer hospital stay, and slower recovery. On the contrary, when compared to percutaneous endopyelotomy, these differences are not so prominent and all the above parameters are almost similar (30).

Good pyeloplasty results rely on selecting the appropriate technique. This depends from the anatomy of the obstruction encountered in each patient. For example, Fenger plasty is less extensive repair than dismembered pyeloplasty and should be used for short strictures with a not very dilatated renal pelvis. With the laparoscopic approach, the technique chosen, dismembered or nondismembered, can be selected intraoperatively, while taking into consideration the anatomy of the ureteropelvic junction obstruction. This obviates the necessity for detailed preoperative imaging of the ureteropelvic junction anatomy and renal vasculature.

Lack of standardization of pre- and postoperative investigations may confound interpretation of data when evaluating rates of success among various methods of treating ureteropelvic junction obstruction. As such, the definition of final success should comprise subjective improvement of pain analog scores along with objectively improved drainage. Intravenous pyelogram or nuclear renal scan with diuretic is the best way to evaluate for persistent obstruction. Retrograde pyelography is helpful with equivocal cases.

RESULTS: RETROPERITONEAL LAPAROSCOPIC PYELOPLASTY

With the retroperitoneal technique the abdomen is not entered and therefore this approach may be preferable when multiple adhesions from previous intrabdominal operations are expected. Some authors suggest that using the retroperitoneal access, the ureteropelvic junction may be visualized after a relatively limited dissection, and crossing vessels causing the obstruction better appreciated. On the contrary, the transperitoneal access approaches the ureteropelvic junction from the wrong (vessel) side of the renal hilum mandating more dissection with the potential for more distortion before the ureteropelvic junction can be visualized.

Extraperitoneal laparoscopy is difficult for the inexperienced. Orientation is harder because anatomic landmarks are not as evident as in transperitoneal laparoscopy. In addition, less working space is available, making intracorporeal suturing more challenging. Any previous retroperitoneal surgery makes subsequent retroperitoneal laparoscopic pyeloplasty very difficult and therefore unsuitable for secondary ureteropelvic junction.

With increasing experience similar operating times to open pyeloplasty have been achieved with retroperitoneal pyeloplasty (31). Some authors even reported shorter operating times than the transabdominal approach. Open conversion is infrequent and occurs due to problems to create a watertight anastomosis without tension.

Short hospital stay (32), low analgesic requirements, and fast recovery confirm the advantages of laparoscopy also with the retroperitoneal approach. Low morbidity with similar complication rates is seen as well (10).

Success rates of retroperitoneal laparoscopic pyeloplasty are comparable to its transabdominal counterpart (11,33). However long-term outcomes must be assessed for further validation of this approach. In fact, in the only direct comparison of the retroperitoneal approach to the open procedure by Soulie et al. (31) the only advantage reported was a more rapid return to normal activity, particularly in young patients (Table 3).

Sidebar quotes:

When compared to retrograde endopyelotomy, the laparoscopic approach presents with more postoperative pain, longer hospital stay, and slower recovery. On the contrary, when compared to percutaneous endopyelotomy, these differences are not so prominent and all the above parameters are almost similar.

LAPAROSCOPIC PYELOPLASTY IN CHILDREN

> The small caliber of a child's ureter makes pyeloplasty a difficult procedure.

The small caliber of a child's ureter makes pyeloplasty a difficult procedure. For this reason, dismembered pyeloplasty is not ideal in children younger than six months and should be avoided. However, this technique remains the preferred method for treating ureteropelvic junction obstruction in older children and the open dismembered pyeloplasty is the gold standard.

Children's body habitus requires smaller instrumentation and fine 6.0 sutures for the ureteropelvic junction reconstruction. The first laparoscopic dismembered pyeloplasty in a pediatric patient was performed by Peters et al. (34) when 3 mm laparoscopic ports and instruments became available.

> Available series of laparoscopic dismembered pyeloplasty showed excellent results, thus confirming the feasibility and safety of this procedure in this patient population.

Available series of laparoscopic dismembered pyeloplasty showed excellent results, thus confirming the feasibility and safety of this procedure in this patient population (Table 4) (13,14,35).

Both transperitoneal and retroperitoneal routes, and lower insufflation pressures (12 mmHg) were employed. Recently robot-assisted pyeloplasty was performed using the *da Vinci* Surgical System[a] with equally good results in a series of 13 children older than 3.5 years (36). However, longer follow-up and further evaluation of the metabolic effects of CO_2 insufflation in children undergoing laparoscopic surgery are awaited before establishing laparoscopic pyeloplasty the standard of care in this population.

ROBOT-ASSISTED LAPAROSCOPIC PYELOPLASTY

Laparoscopic pyeloplasty requires expertise and ability with intracorporeal suturing. Despite improvements in surgical instrumentation, laparoscopic pyeloplasty remains a demanding procedure that requires a long learning curve.

The recent introduction of robotics in the field of minimally invasive surgery may facilitate this procedure and allow for more widespread implementation by surgeons of varying skill levels. The goal of advance robotic systems is to improve operative technique and simplify suturing during reconstructive procedures.

Initially, two robotic systems were available: the Zeus™ [b] and the *da Vinci*™. Animal studies comparing the two systems demonstrated a shorter learning curve and operative

times with the *da Vinci* system, which is now the only commercially available robotic system (37). These systems may enable the surgeon inexperienced with laparoscopic suturing to perform reconstructive procedures with greater ease. Experimental data showing that intracorporeal suturing and dexterity tasks are learned quicker using robot-assisted than manual laparoscopy indicated the robot as an ideal choice during reconstructive surgery (38).

Gettman et al. (39) confirmed the feasibility and safety of robot-assisted dismembered pyeloplasty in a small number of patients. Mean suturing time was 62.4 minutes and overall operating time 138.8 minutes, shorter than those reported in conventional laparoscopic pyeloplasty series. A comparison of conventional versus robot-assisted laparoscopic pyeloplasty, both dismembered and nondismembered, performed in the same institution confirmed shorter operating times in the robotic group (40). Although the robotic system was favorable for suturing; some aspects of the procedure that require gross rather than precise movements, e.g., the reflection of the bowel or the counter traction during dissection, were more difficult with the robotic arms.

Although suturing for the inexperienced is easier with the robot, laparoscopic knowledge is still required and the use of the robot involves a steep learning curve as well.

Proper trocar placement is necessary to prevent mechanical interference between the robotic arms. Due to the lack of tactile feedback, the surgeon must develop an intuition about suture tension to prevent suture breakage and tissue strangulation during knot-tightening. As a result, laparoscopic surgeons experienced with intracorporeal suturing may not find the robot helpful. Finally investment and running costs are factors that must be considered.

A larger number of patients with longer follow-up must be evaluated to determine whether pyeloplasty performed with robotic assistance have equally good functional results as those obtained with conventional laparoscopic pyeloplasty.

LAPAROSCOPIC PYELOPLASTY FOR SECONDARY URETEROPELVIC JUNCTION OBSTRUCTION

Endourological treatment of ureteropelvic junction obstruction has been established as a minimally invasive alternative to open pyeloplasty. It is frequently preferred due to its good results and the familiarity urologists have with endoscopy. Nevertheless, endopyelotomy in the presence of crossing vessels, high-grade hydronephrosis, or poor renal function associates with high failure rates. Although recommended as salvage procedure in such cases, open pyeloplasty associated with incisional morbidity, prolonged recovery, and difficult intraoperative dissection.

Laparoscopic pyeloplasty has been used in the presence of crossing vessels, high-grade hydronephrosis, and poor renal function as another minimally invasive alternative. The laparoscopic ability to directly identify crossing vessels and reduce a large renal pelvis recapitulates the advantages of the open approach.

A transperitoneal access may be preferable. Postoperative fibrosis and adhesions are always present in the region of the previously operated ureteropelvic junction. This makes secondary procedures, both open and laparoscopic more challenging. In the largest series (*N*= 36) of secondary laparoscopic pyeloplasties by Sundaram et al. (19), initial long operating time (6.2 hours) decreased with experience and open conversion was necessary only in one instance. Although the advantages of less analgesic requirements, shorter hospital stay, and faster recovery were confirmed, success rates of 83% to 88% are poorer than the results of open pyeloplasty (95%) for secondary ureteropelvic junction obstruction due to failed endopyelotomy (12,18,19,41). However, differences in subjective and objective criteria determining success may be responsible for this difference.

LAPAROSCOPIC PYELOPLASTY WITH CONCOMITANT PYELOLITHOTOMY

Ureteropelvic junction obstruction can be complicated by the presence of renal stones. Correction of the ureteropelvic junction, necessary to prevent stone recurrence, and stone removal consisting of open pyeloplasty and pyelolithotomy or percutaneous pyelolithotomy followed by endopyelotomy performed at the same setting have been the gold standard (42). The open approach has a success rate of 90% but is associated with more postoperative pain and prolonged recovery. On the other hand, the minimally invasive percutaneous approach is associated with lesser morbidity, faster recovery, but also lower success rates (64–85%) (3,43,44).

In an effort to achieve better results and less morbidity, concomitant pyelolithotomy and pyeloplasty were attempted using a laparoscopic approach. Both retroperitoneal and transperitoneal access have been reported (45,46). In the largest series of

laparoscopic pyeloplasty and concomitant pyelolithotomy reported by Ramakumar et al., spoon forceps, basket graspers, and holmium laser were used for stone removal or fragmentation (20). A flexible cystoscope was introduced through one of the working ports to detect and remove calculi located in calyces, especially those in the lower pole.

CAVEATS

- Incomplete transection of the ureter before performing a dismembered pyeloplasty prevents retraction of the renal pelvis and the problematic introduction of any further instrument for stone removal.
- Initial pyelotomy through which the stones are removed should be kept as small as possible to prevent avulsion of the ureteropelvic junction during manipulations.

> Laparoscopic pyelolithotomy is feasible when combined with pyeloplasty. Although technically demanding, the results obtained are comparable to those of stone removal during open pyeloplasty or percutaneous endopyelotomy. The advantages of open surgery appear to be maintained in this minimally invasive approach.

Both dismembered and nondismembered techniques have been used. Despite long operating times (mean 4.6 hours), no complication occurred and hospital stay was short (3.4 days). Stone free and pyeloplasty success rates were both 90%.

Laparoscopic pyelolithotomy is feasible when combined with pyeloplasty. Although technically demanding, the results obtained are comparable to those of stone removal during open pyeloplasty or percutaneous endopyelotomy. The advantages of open surgery appear to be maintained in this minimally invasive approach.

LAPAROSCOPIC PYELOPLASTY IN THE PRESENCE OF UPPER URINARY TRACT ABNORMALITIES

Ureteropelvic junction obstruction can be associated with renal anomalies and occurs in 25% to 33% of horseshoe kidneys (47), and 22% to 37% of ectopic kidneys (48). Due to the rarity of these renal anomalies, few reports address the treatment of ureteropelvic junction obstruction in adults with congenital urinary tract malformations. Open pyeloplasty is the preferred management and has been reported to be successful in 55% to 80% of patients with a horseshoe kidney (49,50). Despite a success rate of 78% (51), retrograde endopyelotomy in horseshoe or ectopic kidneys is more risky because such kidneys usually have anomalous vascular supply. In addition, the abnormal anatomic site of these kidneys makes percutaneous access quite challenging. In fact, the access to the above mentioned study was obtained with laparoscopic assistance.

> Laparoscopic pyeloplasty in the setting of an ectopic or horseshoe kidney has been performed successfully. Trocar positioning can be different for abnormally located kidneys and should be individualized. The overall success rate in the only series presented by Bove et al. is 91% and is higher than those reported for either open repair (55–80%) or endoscopic management (78%) of ureteropelvic junction obstruction in such kidneys.

Laparoscopic pyeloplasty in the setting of an ectopic or horseshoe kidney has been performed successfully. Trocar positioning can be different for abnormally located kidneys and should be individualized. The overall success rate in the only series presented by Bove et al. is 91% and is higher than those reported for either open repair (55–80%) or endoscopic management (78%) of ureteropelvic junction obstruction in such kidneys (52).

The results compare favorably to the outcome of transperitoneal laparoscopic pyeloplasty in otherwise normal kidneys, which associates with success rates greater than 90%. Risk factors for surgical failure are similar and include a history of multiple prior operations and poor preoperative renal function. The laparoscopic approach provides excellent surgical exposure of these kidneys and operative time similar to laparoscopic pyeloplasty in otherwise normal kidneys. Scant data on extraperitoneal laparoscopic pyeloplasty in a horseshoe kidney are available to date (53).

MANAGEMENT OF FAILED PRIMARY LAPAROSCOPIC PYELOPLASTY

All primary ureteropelvic junction repairs can potentially fail, and in such a case a second operation is usually needed. Failure rate after laparoscopic pyeloplasty is approximately 5%. However, little is known about the best management after failure of laparoscopic pyeloplasty for primary ureteropelvic junction obstruction.

Endourologic Management of Failed Primary Laparoscopic Pyeloplasty:

- Comprises balloon dilatation, laser, cold knife, and cutting balloon endopyelotomy.
- Is used in the majority of patients who failed primary laparoscopic repair.
- Has an overall success of 77.7% after a follow-up period of 25.5 months.
- Is performed to treat short (<1 cm) recurrences amenable to incision or dilation performed at the same setting of the retrograde pyelography that confirmed the presence of recurrent obstruction.
- Requires short hospitalization.
- Has a low complication rate (crossing vessels, if existent, were already displaced during the primary laparoscopic procedure and therefore could not account for failures or postoperative bleeding).

SUMMARY

- Laparoscopic dismembered pyeloplasty was introduced in 1993.
- Both dismembered and nondismembered pyeloplasties (Foley Y-V, Fenger) may be performed using transperitoneal and retroperitoneal approaches.
- The transperitoneal approach has been used in most pyeloplasty series.
- Morbidity of transperitoneal laparoscopic pyeloplasty is considerably less than that of open pyeloplasty. Complications occur in approximately 11% to 20% of patients.
- Success rates in most recent series of transperitoneal laparoscopic pyeloplasty are above 90% and similar to those obtained with the open approach.
- Laparoscopic dismembered pyeloplasty is feasible and safe in children.
- The learning curve of robot-assisted laparoscopic pyeloplasty is steep.
- The ability of laparoscopic pyeloplasty to directly identify crossing vessels and reduce a large renal pelvis recapitulates the advantages of the open approach.
- Laparoscopic pyelolithotomy with concomitant pyeloplasty is feasible.
- Laparoscopic pyeloplasty in the setting of an ectopic or horseshoe kidney has been performed successfully.

COMMENTARY

Michael C. Ost and Arthur Smith
Department of Urology, North Shore–Long Island Jewish Medical Center, New Hyde Park, New York, U.S.A.

Minimally invasive therapies for the management of ureteropelvic junction obstruction currently challenge the standard open surgical approach to this entity with an ever-changing armamentarium of laparoscopic skill and technology. An endopyelotomy, laparoscopic pyeloplasty, or even a combination of the two techniques (1) may be employed with the confidence that outcomes will be highly successful and repairs will be durable. Presently we

most often choose between an endopyelotomy or laparoscopic pyeloplasty for definitive treatment of ureteropelvic junction obstruction rather than even consider an open approach primarily.

Laparoscopy, in particular, is playing an increasing role in ureteropelvic junction management and has proven to be a viable alternative for patients with ureteropelvic junction obstruction. As in the open technique, a tension-free mucosa-to-mucosa watertight anastomosis will dictate operative success. In turn, such success is contingent on proficiency with laparoscopic suturing, a skill that has become easier to acquire with the aid of robotics (2), hand-assisted laparoscopy (3), and newly described laparoscopic instrumentation and techniques (4,5).

In the last decade, approximately 16 series have reported on laparoscopic pyeloplasty for the treatment of primary ureteropelvic junction obstruction. Anderson-Hynes dismembered pyeloplasty, Y-V plasty, and Fengerplasty, which have all been described utilizing either a transperitoneal or retroperitoneal approach. Most impressive are the overwhelming success rates (>95%) in the large majority of these patients with operative times ranging from two to four hours. Few series, however, have compared data on the open versus laparoscopic approach at their respective institutions. Bauer et al. (6), for example, represent the minority to do so demonstrating comparable outcomes between open and laparoscopic groups with regard to relief of obstruction, relief of symptoms, and improved activity. Future efforts in follow-up studies must focus on defining "success rates" prospectively in a stratified and uniform manner. Outcomes, for example, in terms of pre and postoperative renal function (i.e, $T_{1/2}$ emptying time) and objective pain scales will give us the agency to truly compare minimally invasive techniques and determine which method is arguably most successful.

Comparisons between minimally invasive treatments for ureteropelvic junction obstruction have been made. In a multivariate analysis, Gill et al. (7) demonstrated that laparoscopic pyeloplasty was more successful (95.5%) than percutaneous endopyelotomy (86%), ureteroscopic endopyelotomy (85%), or electrocautery balloon endopyelotomy (76.7%). Why was laparoscopy superior? Were the preoperative parameters capable of foretelling such success? Massive hydronephrosis, poor renal function, stenotic segments greater than 1 cm, and a large renal pelvis draped over a renal vessel, for example, may be predictors of such success if a laparoscopic approach is used. It is important to note that it is still debatable as to whether or not "crossing vessel(s)" are truly significant in the etiology of ureteropelvic junction obstruction (8). Until the significance of this anatomic entity is better elucidated, treatment should not necessarily be dictated based on its presence.

Conversely, absence of the aforementioned anatomical variants suggests that there is more of an indication to utilize an endopyelotomy as the primary treatment modality. To this end, Pardalidis et al. (9) reported a success rate of 95% when patients were well selected for either endopyelotomy or laparoscopy based on such anatomical differences. Currently, this appears to be the general practice trend among academic endourologists in North America (10). It is evident that success in approaching a ureteropelvic junction obstruction may not necessarily rely on which minimally invasive technique is used but rather which procedure is utilized on an individual basis.

The pediatric population may be the most important group to focus on when analyzing the benefits of new technology for the treatment of ureteropelvic junction obstruction. Similar to adult cohorts, laparoscopic pyeloplasties in three pediatric series have demonstrated success rates from 87% to 100%. The dismembered pyeloplasty has been deemed the ultimate challenge in pediatric urological laparoscopy, as fine suturing with small instrumentation is required (11). Robotics may aid the pediatric urologist in this demanding operation, serving as a model for the adult urologist wishing to acquire better laparoscopic suturing skills. Future prospective and well-stratified studies in the pediatric population will especially give us a clearer view of the effect of laparoscopy on renal development and functionality over time. Results with pediatric endopyelotomy have yielded poor results that have been attributed to

the difficulties encountered with ureteral stenting. Further development in pediatric endopyelotomy is needed. There is no doubt, however, that laparoscopic approaches to ureteropelvic junction obstruction in the pediatric population will soon challenge the open technique as the standard of care.

A secondary ureteropelvic junction repair poses a challenge for the laparoscopist. Adhesions and fibrosis may limit exposure and prolong operative times. Despite this, minimally invasive salvage procedures yield a greater than 80% success rate. Salvage procedures for failed primary laparoscopic pyeloplasties are best served with an endopyelotomy. Conversely, failed primary endopyelotomies are best served with a laparoscopic pyeloplasty.

Laparoscopic pyeloplasty with concomitant pyelolithotomy has also emerged as a primary mode of treatment for instances of nephrolithiasis with a ureteropelvic junction obstruction. Although series reporting on this approach are few and demonstrate prolonged operative times, the feasibility of this technique has been demonstrated. It is our practice to evaluate the extent of edema at the ureteropelvic junction if repair is anticipated at the time of percutaneous nephrolithotomy. If there is no edema, endopyelotomy is performed. Conversely, the presence of edema calls for re-evaluation of the ureteropelvic junction with a functional study once all stones have been cleared and the edema has subsided. A ureteropelvic junction "obstruction" in the presence of nephrolithiasis may be a function of inflammation, precluding repair. Immediate laparoscopic pyeloplasty with concomitant pyelolithotomy may run the risk of unnecessary ureteropelvic junction "repair." Perhaps better technology fusing endoscopic technique during laparoscopy will further facilitate the employment of this procedure. Along the same line, laparoscopic pyeloplasties performed for ureteropelvic junction obstructions in the presence of upper tract anomalies in horseshoe kidneys or ectopic kidneys have yielded equivalent results to the open approach. Although comparable success rates have been reported, such anomalies may present technical challenges (i.e., anomalous blood supply) requiring cases to be individualized only in highly skilled hands.

A minimally invasive approach for the treatment of primary ureteropelvic junction obstruction has certainly emerged as perhaps a "new gold standard." Laparoscopic pyeloplasty, in particular, is more widely utilized and has proven to be efficacious. It is specifically geared toward cases in which known anatomical variables preclude the likelihood of endoscopic success. In the very near future, it will be exciting to see how accelerations in endoscopic and laparoscopic refinements, "raise the bar" even higher for what we will consider or demand as standard of care in both the adult and pediatric populations with ureteropelvic junction obstructions. Operator experience coupled with ultimate advancements in laparoscopic suturing techniques and instrumentation will certainly decrease operative times, former minimize morbidity, and assure that patients undergoing laparoscopic pyeloplasties will be in near perfect stead. On the horizon, urinary markers such as tumor growth factor (12) and nuclear factor-kappa B (13) hold great promise as predictive markers for what might translate into a ureteropelvic junction obstruction repair success or failure, further aiding in our minimally invasive treatment decisions.

LAPAROSCOPY FOR THE CALYCEAL DIVERTICULUM: TECHNIQUE AND RESULTS

Christopher S. Ng

Minimally Invasive Urology Institute, Cedars-Sinai Medical Center, Los Angeles, California, U.S.A.

BACKGROUND

> A calyceal diverticulum is an anomalous intrarenal cavity lined by nonsecretory transitional cell epithelium that communicates with the normal collecting system via a narrow diverticular neck.

A calyceal diverticulum is an anomalous intrarenal cavity lined by nonsecretory transitional cell epithelium that communicates with the normal collecting system via a narrow diverticular neck.

Although not directly associated with a draining renal papilla, calyceal diverticula fill passively with urine from the adjacent collecting system. Calyceal diverticula are usually less than 10 mm in size, and found incidentally during evaluation for other conditions. Incidence, from 2.1 to 4.5 per 1000 intravenous pyelograms, is similar in adults and children, which suggests an embryologic origin (1). It has been proposed that failure of degeneration of third- and fourth-order divisions of the developing ureteral bud results in a blind-ending outpouching of the collecting system. Others have implicated childhood vesicoureteral reflux, intrarenal rupture of a cyst or abscess, and fibrosing infundibular stenosis (2,3).

Types of Calyceal Diverticula Based on Their Location:

- Type I: diverticula communicate with minor calyces in the upper and lower polar regions
- Type II: diverticula communicate with the renal pelvis or major calyces and are located in the interpolar region.

> It is important to differentiate a calyceal diverticulum from a hydro calyx, which is a true calyx with its own renal papilla that has become severely dilated due to congenital or acquired infundibular obstruction.

Currently, this classification remains purely descriptive and bears no implication regarding patient selection for urologic intervention. It is important to differentiate a calyceal diverticulum from a hydrocalyx, which is a true calyx with its own renal papilla that has become severely dilated due to congenital or acquired infundibular obstruction (4). The appearance of the calyceal distribution and configuration on intravenous pyelograms may be helpful in this regard.

INDICATIONS FOR UROLOGIC INTERVENTION

The diagnosis of a calyceal diverticulum in itself is not an indication for surgery, because most lesions are found incidentally. However, urologic intervention is warranted if a patient becomes symptomatic as a result of the calyceal diverticulum.

Passive filling and poor drainage of urine from the diverticulum lead to focal urinary stasis, which may result in urinary tract infection and calculus formation, and therefore intermittent or persistent flank pain and gross hematuria. Recurrent infections or hematuria should be localized to the side of the lesion, prior to definitive intervention. Rarely, large calyceal diverticula may cause ischemic or obstructive renal damage, and nephrectomy may be required (2).

Because it is lined with urothelium, a calyceal diverticulum may potentially harbor urothelial carcinoma, although this is exceedingly rare (5,6).

IMAGING

Most calyceal diverticula are found by the intravenous pyelograms. With the aid of tomograms and oblique films, intravenous pyelograms can demonstrate the anterior–posterior orientation of the diverticulum; however, it may not clearly demonstrate the communicating neck or the renal parenchyma. Cystoscopy with ureteral catheterization and retrograde pyelography may be necessary not only to localize symptoms but also to better identify the width, length, and location of the diverticular neck. This is particularly useful when an endourologic approach is considered.

Computed tomography scan enables precise localization of the lesion as well as demonstrates its relation to surrounding structures. Most importantly, it allows for characterization of the renal parenchyma overlying the calyceal diverticulum, which is paramount in selecting patients for a laparoscopic approach.

Recently, a novel computed tomography protocol has been described in which noncontrast computed tomography is performed prone during inspiratory and expiratory phases (7). Three-dimensionally rendered images clearly demonstrate the anatomic relationship between the diverticulum, the parietal pleura, and retroperitoneal organs, and may identify patients in whom a percutaneous approach may not be safe or feasible, warranting a laparoscopic approach.

UROLOGIC TREATMENT MODALITIES

Prior to the advent of endourologic and laparoscopic techniques, the mainstays of surgical management for symptomatic calyceal diverticula with or without stones included open calyceal diverticulectomy or open partial nephrectomy. Calyceal diverticulectomy involved unroofing the thinned area of overlying renal parenchyma, removal of stones, figure-of-eight suture closure of the communicating neck when possible, fulguration of the diverticular surface, marsupialization of the cut diverticular edge, and obliteration of the cavity with perinephric fat. Partial nephrectomy was reserved for deeper lesions that were not amenable to diverticulectomy.

Over the last two decades, increasing experience with minimally invasive techniques has significantly changed the management of symptomatic stone-bearing calyceal diverticula. Nearly all contemporary, minimally invasive approaches have been applied to calyceal diverticula, including extracorporeal shock-wave lithotripsy, retrograde intrarenal surgery, percutaneous endoscopy, and laparoscopy.

Each minimally invasive modality has its own inherent technical limitations, such that "definitive management" of the congenital anomaly itself in the traditional sense, namely complete obliteration of the lesion, may not be possible for certain approaches. Therefore, it is apparent from the reported literature that proper patient selection is paramount to successful outcomes.

Shock-wave lithotripsy has been applied to stone-bearing calyceal diverticula with the primary goal of symptomatic relief of pain, with the understanding that the underlying anomaly remains unchanged. It has been shown that patients with a stone burden of less than 15 mm and a patent diverticular neck on X-ray can achieve symptomatic relief (86%) and stone-free status (58%) with shock-wave lithotripsy alone (8). However, recurrent symptoms and stone formation requiring secondary interventions may be more the rule (9).

The retrograde intrarenal approach allows for balloon dilation or laser incision of the narrow diverticular neck with intracorporeal lithotripsy and stone extraction in the same setting. Generally, no attempt is made to fulgurate the diverticular epithelium. This approach is technically feasible in 70% to 95% of cases, with the majority of failures due to a

Percutaneous management of calyceal diverticula is the most widely used endourologic modality, providing definitive obliteration of the congenital anomaly.

Successful diverticular eradication via the percutaneous approach appears to be related to the ability to obtain direct diverticular access, performing incision of the infundibular neck, fulguration of the epithelial lining, and placement of a nephrostomy tube. With this in mind, performing a "neoinfundibulotomy" when the true diverticular neck cannot be identified may provide improved outcomes.

lower pole location. When complete stone fragmentation is achieved, with or without the aid of concurrent shock-wave lithotripsy, symptom-free and stone-free rates are more than 90% (10,11). This technique may provide improved drainage of the diverticulum; however, the adynamic cavity remains in situ as a potential source for recurrent symptoms and stones.

Percutaneous management of calyceal diverticula is the most widely used endourologic modality, providing definitive obliteration of the congenital anomaly. This technique involves accessing the diverticulum via a percutaneous tract, which can be dilated up to 30 French. Percutaneous nephrolithotomy is performed in standard fashion. The draining infundibulum, if identified, can be fulgurated, incised, or dilated with a balloon and traversed by a nephrostomy tube. Symptom-free, stone-free, and "diverticular-free" success rates of 75% to 100% have been reported (9,12–14).

Successful diverticular eradication via the percutaneous approach appears to be related to the ability to obtain direct diverticular access, performing incision of the infundibular neck, fulguration of the epithelial lining, and placement of a nephrostomy tube (12,15). With this in mind, performing a "neoinfundibulotomy" when the true diverticular neck cannot be identified may provide improved outcomes (16,17).

This technique involves creating a new direct tract from the diverticulum into the renal pelvis, which can then be dilated for placement of a nephrostomy tube. The angle of approach for the percutaneous access still remains critically important to successful outcomes. As such, a percutaneous approach may not be ideally suited for some anterior or medial diverticula.

Laparoscopic Management of Calyceal Diverticula

- It is the most invasive of the closed surgical approaches.
- Nevertheless, like the percutaneous approach, it definitively removes the underlying congenital anomaly.
- Unlike the other minimally invasive modalities, it most closely recapitulates the standard open surgical principles, therefore providing the best chance of long-term success.
- It includes laparoscopic calyceal diverticulectomy and laparoscopic partial nephrectomy, both of which duplicate all open surgical steps.
- It allows for complete renal exploration and subsequent simple nephrectomy, in cases where the diverticulum causes irreversible renal functional loss.

PATIENT AND TREATMENT SELECTION

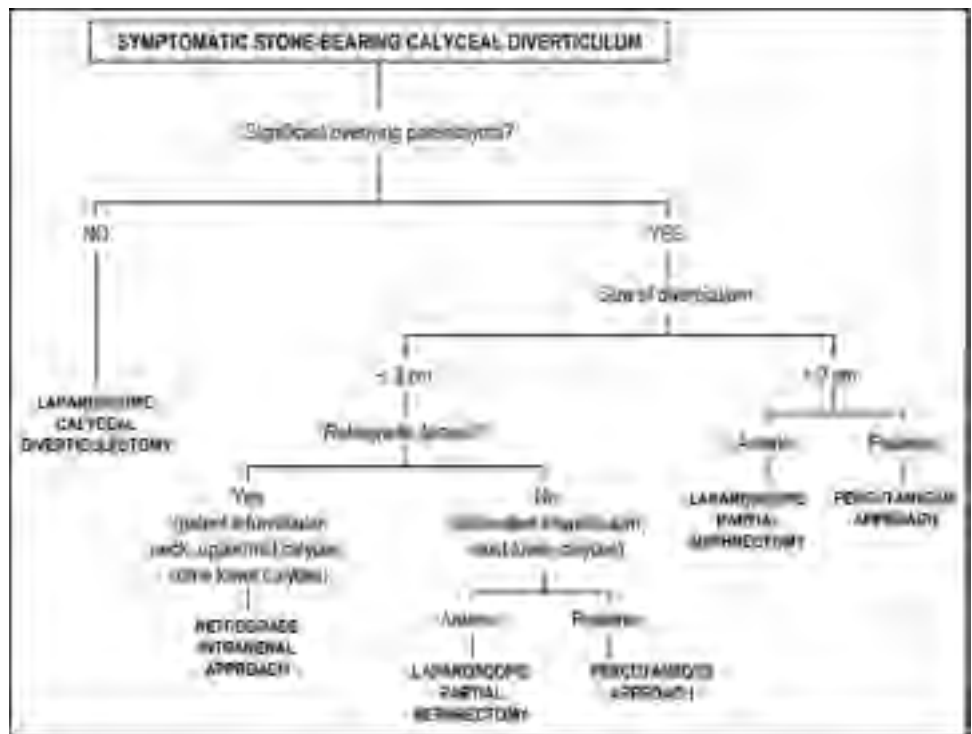
Due to inherent limitations of various minimally invasive modalities of treatment for symptomatic calyceal diverticula, proper patient and treatment selection are crucial to successful outcomes. Miller et al. proposed a detailed patient-selection algorithm for retrograde intrarenal, percutaneous, and laparoscopic approaches derived from a purely technical standpoint (Fig. 1) (18). Several key factors determine the ultimate urologic intervention, including degree of overlying renal parenchyma, diverticular size and location, and presence of retrograde access.

- Any lesion with thinned overlying renal parenchyma is amenable to laparoscopic calyceal diverticulectomy.
- Conversely, those lesions with thicker overlying parenchyma that are not endoscopically accessible may require formal laparoscopic partial nephrectomy.
- Lastly, repeated endoscopic treatment failures may be best managed with a definitive laparoscopic approach.

In the era of minimally invasive surgery, one must emphasize the role of well-informed patient preference in selecting treatment modalities—patients often opt for the least invasive or least morbid procedure, while accepting the fact that a secondary procedure may be necessary. For example, when the indication for intervention is recurrent infections, hematuria, or pain without stones, definitive management of the congenital anomaly is desired, and therefore a percutaneous or laparoscopic approach is preferable. However, if technically feasible, an initial attempt with an outpatient retrograde intrarenal balloon dilation or laser incision of the diverticular neck may provide temporary or even long-standing symptomatic relief, and may be preferred in the setting of a functionally solitary kidney.

Transperitoneal vs. Retroperitoneal Laparoscopic Access

When considering laparoscopic calyceal diverticulectomy, the selection of the method of laparoscopic renal access, whether transperitoneal or retroperitoneal, depends on

FIGURE 1 ■ Patient-selection algorithm for symptomatic stone-bearing calyceal diverticula.


several factors including size and location of the diverticulum, likelihood of requiring a partial nephrectomy, and patient-related factors (prior surgery and body habitus).

■ Most lesions with thin overlying parenchyma are amenable to laparoscopic calyceal diverticulectomy.
■ Larger lesions (greater than 2 cm) can be adequately accessed from either the transperitoneal or retroperitoneal approaches. In these cases, the risk of bleeding is low because there is minimal renal tissue excised.

Furthermore, with complete renal mobilization, adequate suturing angles to the diverticular infundibulum can be created from either approach. However, for smaller lesions, the angle toward the diverticular infundibulum becomes more restricted, and therefore anterior lesions should be approached transperitoneally, whereas posterior lesions should be approached retroperitoneoscopically.

When there is significant renal parenchyma overlying the diverticulum, a formal laparoscopic partial nephrectomy offers the best chance for definitive management of the calyceal diverticulum, as well as for a watertight and hemostatic end result.

The technique of laparoscopic partial nephrectomy in this setting is identical to that for renal masses. Several caveats regarding selection of method of laparoscopic access have arisen from a large comparative study between transperitoneal and retroperitoneal laparoscopic partial nephrectomy at the Cleveland Clinic (19). A transperitoneal approach to laparoscopic partial nephrectomy provides increased working space and improved suturing angles for renal reconstruction, and should be the approach of choice for substantive or deep resections, and for all anterior, lateral, or apical lesions. The retroperitoneal approach to laparoscopic partial nephrectomy should be reserved for smaller, more superficial lesions that are directly posterior or posteromedial. This is a rare situation in the setting of calyceal diverticula, because the majority of such lesions can be managed successfully with a percutaneous approach.

When there is significant renal parenchyma overlying the diverticulum, a formal laparoscopic partial nephrectomy offers the best chance for definitive management of the calyceal diverticulum, as well as for a watertight and hemostatic end result.

PREOPERATIVE PREPARATION

Patients undergoing laparoscopic management of symptomatic calyceal diverticulum should receive the same preoperative regimen as any laparoscopic renal surgery patient.

Patients undergoing laparoscopic management of symptomatic calyceal diverticulum should receive the same preoperative regimen as any laparoscopic renal surgery patient. Bowel preparation consists of a clear liquid diet and one to two bottles of magnesium citrate the day before surgery. In addition, culture-specific antibiotics should be started

at least 48 hours prior to surgery. This may require outpatient intravenous dosing or admission to the hospital. In the absence of documented urinary tract infection, a prophylactic intravenous dose of cefazolin is given one hour prior to surgery. All candidates for laparoscopic management of symptomatic calyceal diverticulum should have undergone computed tomography scan to delineate the three-dimensional location and the overlying renal parenchyma of the lesion.

TECHNIQUE: LAPAROSCOPIC CALYCEAL DIVERTICULECTOMY

Step 1: Cystoscopic Placement of Ureteral Catheter
An open-ended ureteral catheter is advanced into the ipsilateral renal pelvis so that diluted methylene blue can be later administered to assist in the identification of the calyceal diverticulum itself (Step 4) and identification of the infundibular connection to the normal collecting system (Step 7).

The patient is placed in the dorsal lithotomy position. Under cystoscopic guidance, a 0.035-inch. or 0.038-inch. guidewire is passed into the ipsilateral renal pelvis, followed coaxially by a 6 French open-ended ureteral catheter. The wire is removed, and the ureteral catheter is secured with 2–0 silk ties to a Foley urethral catheter. A luer-lock adapter is used to connect the ureteral catheter to extension tubing (such as intravenous catheter line tubing), whose end is capped. The cystoscopy table and wires are maintained for placement of a double-pigtail ureteral stent at the end of the procedure (Step 11).

> **CAVEAT**
>
> ■ The utility of the setup for retrograde injection of methylene blue is enhanced if the surgical team has access to the syringe rather than having the circulating staff inject from "under the drapes."

Therefore, on the sterile field, one ampule of methylene blue is diluted in 300 to 400 cc of sterile water or glycine—saline is avoided if one anticipates the use of monopolar electrocautery for fulguration of the diverticular epithelium (Step 8). A 60-cc syringe with the prepared methylene blue is filled and connected to additional sterile extension tubing to be kept on the field. Once the patient has been repositioned, prepped, and draped for laparoscopy, the two free ends of tubing off the field are connected by the circulating staff.

Step 2: Laparoscopic Access
For the "transperitoneal approach," the patient is repositioned into 60-degree flank, with the iliac crest just below the break of the operating table. The patient is supported with a back roll and axillary rolls, and all pressure points are adequately padded. The table is slightly flexed to expand the working space. The patient is secured on to the table with a 3-inch. cloth tape across the greater trochanter of the ipsilateral femur and across the upper chest at the nipple line. Veress needle access is obtained along the parasagittal plane at the midpoint between the umbilicus and the anterior superior iliac spine, at or just above the level of the umbilicus. A 12-mm trocar is placed at this location. Under laparoscopic visualization, a 5-mm trocar is placed along the same parasagittal line, just under the costal margin. Lastly, a second 12-mm trocar is placed between the working ports in the midline or along the ipsilateral pararectal line. On the right side, an additional 5-mm trocar may be necessary to retract the liver.

> **CAVEAT**
>
> ■ In select cases with thin overlying parenchyma and known milk of calcium or small stone burden, only 5-mm trocars may be utilized if a 5-mm laparoscope is available.

For the "retroperitoneal approach," the patient is placed in the 90° flank position, with the iliac crest just below the break of the operating table. The patient is supported with

an axillary roll, and all pressure points adequately padded. The table is maximally flexed to expand the retroperitoneal working space. The patient is secured to the table with a 3-inch. cloth tape across the greater trochanter of the ipsilateral femur and across the upper chest at the nipple line. Landmarks include the tips of the 11th and 12th ribs, iliac crest, and the angle between the body of the 12th rib and the paraspinous musculature. A 15-mm incision is made along the mid–axillary line between the tips of the 11th and 12th ribs and carried through the lumbodorsal fascia. The plane between Gerota's fascia and the psoas fascia is created bluntly with index finger dissection. The retroperitoneal space is created with balloon dilation of 800 cc. A cuffed balloon port is placed at this entry site. Under laparoscopic visualization, a 12-mm trocar is placed anteriorly. Additional blunt mobilization of the peritoneum medially using the tip of the laparoscope may be necessary in order for this trocar to be placed extraperitoneally. Lastly, a 5-mm trocar is placed at the posterior angle.

Step 3: Operative Exposure
For the transperitoneal approach, the ipsilateral colon is reflected medially to expose Gerota's fascia. The remainder of the procedure is identical for the transperitoneal and retroperitoneal approaches. Gerota's fascia is entered to expose the cortical surface of the kidney in the suspected area of the diverticulum. Limited exposure over the diverticulum is sufficient if there is a direct angle of approach. However, when suboptimal angles exist, completely mobilize and rotate the kidney.

CAVEATS

- Whenever possible, an adequate vascularized flap of perinephric fat for subsequent obliteration of the diverticular cavity should be maintained (Step 9).
- If a more substantial excision of renal parenchyma is needed or partial nephrectomy anticipated, vascular clamping of the renal hilum may be necessary.

When utilizing a laparoscopic Satinsky-type instrument, en bloc hilar clamping may be performed. This requires mobilization of the periureteral package off the psoas fascia, continuing the dissection up to the caudal border of the hilum. On the left side, care must be taken to identify and preserve lower pole renal vessels and lumbar veins. The anterior and posterior aspects of the renal hilum must be freed completely. Lastly, a window above the hilum between the adrenal gland and upper medial aspect of the kidney is created. An additional trocar is placed in the ipsilateral lower quadrant for entry of the vascular clamp. Alternatively, selective arterial clamping using either Bulldog-type or Satinsky-type clamps requires complete exposure of the main artery and all accessory arteries.

Step 4: Identification of Calyceal Diverticulum
Large diverticula are readily identifiable as a cystic mass. However, smaller diverticula may only appear as a dimpled scar along an otherwise normal-appearing cortical surface.

CAVEAT

- Retrograde injection of methylene blue via the ureteral catheter may demonstrate bluish discoloration of the diverticulum.

The laparoscopic cyst-aspiration needle can be useful to probe the suspected area of the diverticulum. Intraoperative laparoscopic ultrasound allows for precise three-dimensional localization of the diverticulum (Fig. 2). If this is not available, fluoroscopy via C-arm device may be necessary, albeit cumbersome, because the kidney is positioned at the break or post of the operating table. Cross-table lateral and oblique views will be necessary. In the absence of a radiopaque calculus, retrograde injection of diluted contrast material may be necessary as well.

Step 5: Excision of Overlying Renal Parenchyma
With the location of the diverticulum precisely demarcated, the nephrotomy incision is begun at the thinnest portion of the diverticulum, typically at the tip of the exophytic

FIGURE 2 ■ Transperitoneal laparoscopic view of the left kidney with large anteromedial calyceal diverticulum. Intraoperative laparoscopic ultrasound is useful in localizing the diverticulum.

FIGURE 3 ■ Wide excision of the thinned parenchyma overlying the large stone-bearing calyceal diverticulum.

dome. The overlying renal parenchymal tissue is circumferentially excised to expose the base of the diverticulum using monopolar electrocautery hook electrode or scissors, or harmonic/ultrasonic scalpel or shears (Fig. 3).

CAVEAT

■ Hemostatic adjuncts should always be readily available, because more substantive renal parenchymal excision may be required.

Applying pressure with oxidized cellulose (Surgicel™[a]), or collagen–thrombin matrix products (FloSeal™[b]), provides excellent hemostasis for mild parenchymal bleeding. Argon beam coagulation may also be sufficient for mild oozing (the intra-abdominal argon gas rapidly generated when activating the argon beam has to be simultaneously released). For brisk bleeding, simple parenchymal figure-of-eight or horizontal mattress sutures of 2–0 or No.0 polyglactin on a computed tomography-2 or computed tomography-1 needle may be necessary. Lastly, if a wedge-type excision of the lesion is necessary, formal parenchymal sutures of No.0 polyglactin on a computed tomography-1 needle over Surgicel bolsters may be required for hemostasis. Hilar clamping may be required to control major bleeding, in preparation for formal laparoscopic partial nephrectomy.

Step 6: Nephrolithotomy

Once the diverticulum is unroofed and hemostasis is obtained, the stone burden can be readily removed. Milk of calcium can simply be aspirated using the suction irrigator. Multiple small stones may be individually removed through the trocar or initially placed in a specimen retrieval bag (Fig. 4).

CAVEAT

■ For stones larger than the port site, mechanical lithotripsy with a heavy grasper can be performed intracorporeally inside the specimen retrieval bag. Alternatively, the stone can be removed in toto at the end of the procedure by extending one port site.

Step 7: Identification and Management of Calyceal Diverticular Infundibulum

With the stone burden removed, the base of the diverticulum has to be examined for the communicating infundibulum, and methylene blue injected through the retrograde

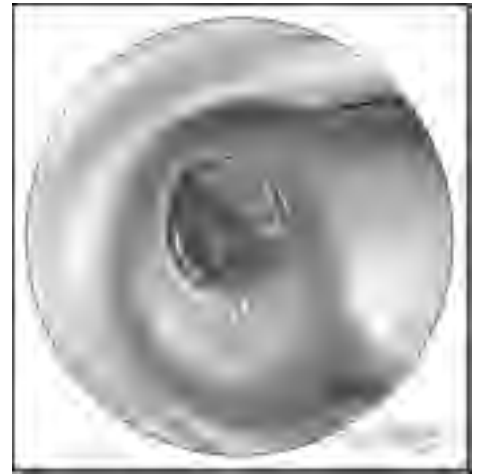
FIGURE 4 ■ Removal of the diverticular stone burden with grasping forceps. The diverticular infundibulum may be readily identifiable.


FIGURE 5 ■ Retrograde injection of diluted methylene blue solution through the ureteral catheter can assist in identifying the infundibular connection to the normal collecting system.

ureteral catheter (Fig. 5). One or two figure-of-eight sutures are placed across the infundibulum using 2–0 or 3–0 polyglactin on an RB-1 or computed tomography-2 needle (Fig. 6). Repeat retrograde injections of methylene blue are performed to recheck the integrity of the closure. Additional sutures may be added as needed.

If the connection to the main collecting system is not identified, or if suture placement is not feasible, the base can be carefully fulgurated with monopolar electrocautery or argon beam coagulation.

CAVEAT

■ Tiny persistent communications with the collecting system may be effectively closed by using commercially available tissue sealant products (Step 9).

Discussion: Is Suture Repair Necessary?
Of 14 reported cases, only two utilized suture ligation of the infundibular neck, albeit successful in both (18). Of the other 12 cases in which the communication was fulgurated, only one had a prolonged self-limited fluid leak from the primary retroperitoneal port site (20).

Is suture repair necessary? Perhaps the question should be "why not?". Intracorporeal suturing is becoming part of the basic laparoscopic skill set. In the interest of adhering to open surgical principles, suture closure of the infundibular connection should be performed whenever possible.

Step 8: Management of Calyceal Diverticular Epithelium
The remainder of the calyceal diverticular epithelium should be carefully fulgurated with monopolar electrocautery or argon beam. If sutures were placed, fulguration near or on the sutured area should be avoided (Fig. 7).

> Is suture repair necessary? Perhaps the question should be "why not?". Intracorporeal suturing is becoming part of the basic laparoscopic skill set. In the interest of adhering to open surgical principles, suture closure of the infundibular connection should be performed whenever possible.

CAVEAT

■ Beware of thin areas of the diverticular wall adjacent to the normal collecting system. This may appear as a cystic bulge or translucent membrane. Aggressive fulguration in this area may lead to urine leak and urinoma formation. Argon beam coagulation may be superior to monopolar electrocautery in this regard. Repeat retrograde instillation of methylene blue to identify any leak that may need suture closure.

FIGURE 6 ■ Suture repair of the diverticular infundibulum with a figure-of-eight stitch using 2–0 or 3–0 polyglactin on a computed tomography or 2 RB-1 needle. Repeat retrograde injection of methylene blue may check the integrity of the closure.

FIGURE 7 ■ Fulguration of the diverticular epithelium with argon beam coagulation. Avoid fulguration in the area of the suture line.

FIGURE 8 ■ Commercially available tissue sealant products or fibrin glue may be used to reinforce the suture repair and is particularly useful when sutures cannot be placed.

FIGURE 9 ■ The remainder of the diverticular cavity should be completely obliterated with a surrounding pedicle of fat from the perinephric tissue or omentum.

TABLE 1 ■ Operative Steps for Laparoscopic Calyceal Diverticulectomy for Symptomatic Calyceal Diverticula With or Without Stones

Step 1	Cystoscopic placement of ureteral catheter
Step 2	Laparoscopic access
Step 3	Operative exposure
Step 4	Identification of calyceal diverticulum
Step 5	Excision of overlying renal parenchyma
Step 6	Nephrolithotomy
Step 7	Identification and management of calyceal diverticular infundibulum
Step 8	Management of calyceal diverticular epithelium
Step 9	Obliteration of diverticular cavity
Step 10	Drain placement and exit
Step 11	Ureteral stent placement

Step 9: Obliteration of Diverticular Cavity

Cover the base of the diverticular cavity with any commercially available tissue sealant products such as Tisseel™ᶜ or CoSeal™ᶜ or other form of fibrin glue (Fig. 8). Hoznek et al. utilized gelatin resorcinol formaldehyde glue on a piece of surgical mesh to provide adjunctive hemostasis and sealing as well as obliteration of the cavity (21).

The remainder of the cavity should be filled with a fat pedicle (Fig. 9), such as perinephric fat or omentum (if transperitoneal), to eliminate any "dead space." This may be pexed to the renal capsule with 3–0 polyglactin as needed.

CAVEAT

■ Formal marsupialization of the cut cortical edge is generally not necessary to preclude recurrent diverticular formation as long as the cavity is adequately filled and obliterated.

Operative Equipment Checklist	
Instrument	Standard laparoscopic renal instrument tray
	Laparoscopic cyst aspiration needle
	Laparoscopic needle drivers
	Laparoscopic vascular clamps
	Cystoscopy table, ureteral catheter, guidewire
Materials	Methylene blue ampule in 200 cc sterile water
	Radiopaque contrast material, diluted 50%
	Tissue sealants (fibrin glue, Tisseel™ [a])
	Hemostatic agents (Surgicel™ [a], Floseal™ [b])
	3-0 or 2-0 polyglactin, RB-1 or CT-2 needle
	#0 polyglactin, CT-1 needle
Devices	Intraoperative ultrasound probe
	C-arm fluoroscopy
	Argon beam coagulator

[a]Ethicon, Inc., Somerville, NJ.

Nevertheless, for the purpose of hemostasis, several interrupted figure-of-eight or horizontal mattress sutures of 3–0 or 2–0 polyglactin on a computed tomography-2 or computed tomography-1 needle may be placed. Alternatively, a running circumferential stitch may be placed.

Step 10: Drain Placement and Exit

Through the lateral most port site, a 19-French closed suction drain is placed and secured to the skin with 3–0 nylon suture. The working space is completely desufflated for several minutes and the operative field is reinspected under an intra-abdominal pressure of less than 10 mmHg. Hemostasis is obtained as needed. For the transperitoneal approach, any port sites of more than 8 mm is closed with No. 0 or No. 1 polyglactin ties using a fascial closure device, such as a Carter-Thomason system, under direct laparoscopic visualization.

If the specimen retrieval bag has not yet been extracted, the string of the cinch knot is brought through the anticipated exit site. All remaining trocars are removed under direct laparoscopic visualization. The extraction site is extended as needed for specimen removal, and closed with No. 0 polyglactin suture.

Step 11: Ureteral Stent Placement

The patient is repositioned in the dorsal lithotomy position, the guidewire placed into the renal pelvis through the ureteral catheter, and the ureteral catheter removed with the Foley urethral catheter. Under cystoscopic guidance, a double-pigtail indwelling ureteral stent is placed. Alternatively, the stent is placed using fluoroscopic guidance. The Foley catheter is replaced (Tables 1 and 2).

Discussion

Descriptions of the open operative technique do not routinely include ureteral stenting. In six of 14 reported cases, neither a ureteral stent nor a ureteral catheter was left in place—only one patient had prolonged but self-limited fluid leak; however, this was not specified as urine. Therefore, with the meticulous surgical technique described herein, including infundibular suturing, tissue sealant application, and obliteration of the cavity, it seems reasonable to omit routine postoperative ureteral J-stenting (Table 3).

CAVEAT

- Alternatively, the ureteral catheter and Foley catheter are left to gravity until the day of discharge. This provides an extended period of drainage without the need for a double-pigtail indwelling stent.

TABLE 3 ■ Specific Technical Alternatives Described in the Literature, Including Type of Laparoscopic Approach, Use of Ureteral Stenting, and Method of Management of the Diverticular Epithelium, Infundibular Neck, and Cavity

[a]Gelatin resorcinol formaldehyde glue on surgical mesh.
[b]Ureteral catheter for five to eight days with retrograde pyelogram confirming no leak prior to removal.
Abbreviation: N/A, not available.

POSTOPERATIVE MANAGEMENT

Standard postoperative care of the laparoscopic renal surgery patient should ensue. The Foley catheter should be kept in place until the day of discharge to maximize drainage. The closed-suction drain may be removed when output remains less than 60 cc per day. The ureteral stent, if placed, may be removed two weeks after drain removal.

Follow-up intravenous pyelograms or computed tomography urogram is obtained at six weeks after stent removal, then at six months, 12 months, and as needed for symptoms. Subsequent yearly follow-up with ultrasound is sufficient.

> Follow-up intravenous pyelograms or computed tomography urogram is obtained at six weeks after stent removal, then at six months, 12 months, and as needed for symptoms. Subsequent yearly follow-up with ultrasound is sufficient.

RESULTS

For open calyceal diverticulectomy, success is the rule (2). Laparoscopic calyceal diverticulectomy replicates the techniques and principles of the open surgical approach. As such, symptom-free, stone-free, and "diverticulum-free" rates in reported series are 100%, 100%, and 93%, respectively, albeit with very short follow-up (Table 4) (18–24).

In one patient, a residual diverticulum was noted on follow-up intravenous pyelograms, measuring only 10% of the original lesion (20). The authors noted that the diverticular cavity was fulgurated but not filled with fat tissue in this case; all subsequent cases involved obliterating the diverticulum with fat tissue, and no recurrences were noted.

Overall morbidity is low with laparoscopic calyceal diverticulectomy. Operative time is about three hours, and hospital stay is generally two to three days. Complications were minor, including subcutaneous emphysema, self-limited fluid leak, and a three-unit blood transfusion, occurring in one patient each (Table 4).

> Laparoscopic calyceal diverticulectomy replicates the techniques and principles of the open surgical approach. As such, symptom-free, stone-free, and "diverticulum-free" rates in reported series are 100%, 100%, and 93%, respectively, albeit with very short follow-up.

[a]Residual diverticulum measuring 10% of original size, cavity not filled.
Abbreviations: N/A, not available; IVP, intravenous pyelogram; CT, computed tomography.

SUMMARY

- Laparoscopic calyceal diverticulectomy presented herein strictly adheres to open surgical principles.
- The procedure includes:
  - clear identification of the diverticular cavity,
  - wide unroofing of the diverticular dome,
  - suture closure of the infundibular neck,
  - fulguration of the diverticular epithelium, and
  - obliteration of the diverticular cavity.
- Patients with large diverticula with thin overlying renal parenchyma are ideal candidates for laparoscopic calyceal diverticulectomy.
- High success rates and low morbidity can be achieved with laparoscopic calyceal diverticulectomy.

LAPAROSCOPIC LIVE DONOR NEPHRECTOMY: TECHNIQUE

Joseph J. Del Pizzo

Department of Urology, James Buchanan Brady Foundation, The New York Presbyterian Hospital–Weill Cornell Medical Center, New York, New York, U.S.A.

INTRODUCTION

Renal transplantation is the ideal solution to end-stage renal disease. It has had a major impact on the survival and quality of life of those suffering from kidney failure, affording these patients an independent lifestyle free from dialysis and its significant morbidity. Unfortunately, the annual supply of renal allografts has continued to fall short of the increasing number of patients seeking renal transplantation.

Live donor nephrectomy has long been viewed as an underused alternative in renal replacement therapy. Live donor kidney transplantation offers substantially superior graft function and survival compared to cadaveric renal transplantation (1,2). Other advantages over cadaveric renal allografts include shorter time waiting for transplantation, the ability to schedule it as an elective procedure and therefore optimize the medical status of the recipient, and overall reduced immunosuppression requirements (3). The large discrepancy between the supply and demand for renal allografts, coupled with the advantages of live versus cadaveric renal transplantation, has prompted efforts to increase the pool of live renal donors.

Prior to 1995, the standard method of kidney procurement was open donor nephrectomy performed through a flank or subcostal incision. Although this procedure can be performed safely and produces an allograft of excellent quality with minimal warm ischemia, it is associated with considerable perioperative morbidity for the renal donor. Postoperative pain, prolonged hospitalization and convalescence, lost wages, and poor cosmesis have been identified as significant disincentives for organ donation (4). As a result, the number of live renal transplants that were performed accounted for only a small fraction of the total number of transplants performed.

The first series of laparoscopic live donor nephrectomies were performed in 1995, specifically intended to decrease the morbidity of renal donation for the healthy donor and thus reduce disincentives and expand the pool of live donor candidates (3,4). Since its inception, technical modifications that have come with surgeon experience have led to a substantial reduction in total donor complications, as well as a progressive decline in the rate of recipient complications including delayed graft function or loss, ureteral stricture and necrosis, and vascular thrombotic events (5–9).

Laparoscopic live donor nephrectomy is now the standard technique at many transplant centers, resulting in less postoperative pain and convalescence for the living donor while maintaining equivalent allograft function and recipient outcomes as compared with results from traditional open donor nephrectomy. Despite technical modifications, improved instrumentation, and increased surgeon experience, laparoscopic live donor nephrectomy remains a technically challenging operation with a steep learning curve.

Laparoscopic live donor nephrectomy is now the standard technique at many transplant centers, resulting in less postoperative pain and convalescence for the living donor while maintaining equivalent allograft function and recipient outcomes as compared with results from traditional open donor nephrectomy (5,10–13). Despite technical modifications, improved instrumentation, and increased surgeon experience, laparoscopic live donor nephrectomy remains a technically challenging operation with a steep learning curve.

With no margin for error, it requires an advanced level of laparoscopic skill and meticulous technique, as well as a detailed knowledge of renal vascular anatomy. It must replicate the standards set by traditional open donor nephrectomy—optimize the safety of the donor and procure a healthy functioning allograft for transplantation.

PATIENT SELECTION

Initial Screening

All potential donor candidates must undergo an extensive medical and psychological evaluation in accordance with guidelines published by the American Society of Transplant Physicians (14–16).

Psychologic evaluation includes a complete evaluation of the donor's emotional stability and determination if an altruistic motivation for donation exists.

Psychological evaluation includes a complete evaluation of the donor's emotional stability and determination if an altruistic motivation for donation exists.

A thorough laboratory evaluation is performed for histocompatibility testing and to ensure that the healthy donor will be left with normal renal function after nephrectomy. Standard blood testing includes ABO histocompatibility, HLA crossmatching, complete blood count, serum chemistries including liver function tests, and a coagulation profile.

The potential donor is also screened for viral exposure, including hepatitis profile and exposure to human immunodeficiency virus, cytomegalovirus, varicella, and Epstein–Barr virus. Urine testing includes urinalysis, urine culture, and a 24-hour urine collection analysis to evaluate urine protein levels and creatinine clearance. Female patients over age 40 must have a recent negative Papanicolaou cervical smear and negative screening mammogram.

Radiographic Evaluation

Radiologic imaging is a crucial component of the preoperative assessment of potential live renal donors. Precise preoperative mapping of the number and location of the main renal vessels, and the presence of accessory vessels is crucial for obtaining safe hilar dissection and minimizing vascular complications.

Radiologic imaging is a crucial component of the preoperative assessment of potential live renal donors. Precise preoperative mapping of the number and location of the main renal vessels, and the presence of accessory vessels is crucial for obtaining safe hilar dissection and minimizing vascular complications.

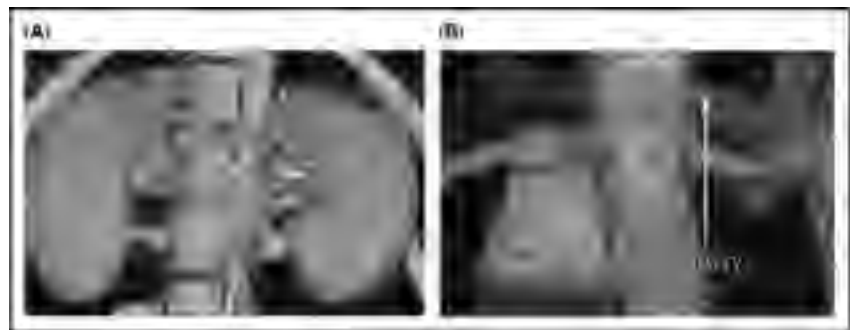
Assessment of the kidneys and renal vasculature will identify some unsuitable donors and dictate which renal unit should be chosen for transplantation in others.

The traditional role of excretory urography, intravenous pyelography, and renal arteriography in the evaluation of potential kidney donors has been challenged by helical computed tomography with three-dimensional arteriography. Helical computed tomography arteriography can be employed as a single imaging modality to evaluate the entire region of the kidney and obtain relatively noninvasive arteriogram-like images of the renal vasculature. In addition, these images can be reformatted to provide the surgeon with a three-dimensional display of the data and allow improved vascular imaging.

Computed tomography angiography is highly accurate and specific for the delineation of renal vascular anatomy in these patients, including detection of multiple renal vessels.

Computed tomography angiography is highly accurate and specific for the delineation of renal vascular anatomy in these patients, including detection of multiple renal vessels (Fig. 1) (17).

The presence of multiple vessels is not a contraindication to laparoscopic live donor nephrectomies, but preoperative identification will optimize patient safety and

FIGURE 1 ■ Helical computed tomography with three-dimensional arteriographic images demonstrating (A) left renal artery outlined cephalad to the left renal vein and (B) accessory renal artery (*arrow*) off the aorta and supplying the left upper renal pole.


possibly recipient outcome. The entire surgical transplant team should review the films together, because a clear picture of renal vascular anatomy is mandatory in helping to plan both the donor and recipient procedures.

PREOPERATIVE PREPARATION

The donor and recipient surgeon(s) decide which renal unit will be used for transplantation.

- When the kidneys are equal in size and function and have favorable vascular anatomies, the left kidney is selected to take surgical advantage of the longer left renal vein for recipient surgical implantation (4).
- Selection of the right kidney is based on traditional criteria independent of the laparoscopic approach.
- When deemed a good candidate for donation, the patient is left with the "better" kidney if a discrepancy exists.

RIGHT-SIDED DONOR NEPHRECTOMY

Absolute Indications
- Larger left kidney with presumed greater glomerular filtration rate
- The presence of cysts in the right kidney
- Mild fibromuscular dysplasia of only the right renal artery

Relative Indications
- Complex or aberrant left renal vasculature
- Duplicated left collecting system
- Ptosis of the right kidney

Additional considerations include the donor's body mass index and prior abdominal surgical procedures. Laparoscopic donor nephrectomy has been performed safely in obese patients. Donor and recipient outcomes have been similar to those seen in nonobese donors (18). Therefore, obesity is not a contraindication for laparoscopic donor nephrectomy. Patients who have undergone extensive prior intra-abdominal surgery, especially in close proximity to the proposed operative field, are still considered candidates for renal donation but may benefit more from a retroperitoneal approach, either laparoscopic or open.

Informed consent should be obtained from the donor surgeon. All potential complications are discussed, with ample opportunity for the donor patient to ask and receive answers to questions. The potential for open conversion is discussed. It is made clear to the patient that the primary responsibility of the surgical team is to ensure patient safety and procure a healthy allograft suitable for transplantation. If either of these objectives is compromised during the laparoscopic approach, conversion to traditional open surgery may be necessary. The donor patient is also educated about living with a solitary kidney. Although there is no need for major dietary or other lifestyle modifications, these patients should avoid contact sports and have serum creatinine and blood pressure monitoring in the perioperative period and then yearly.

Patients are advised to maintain a clear liquid diet the day prior to surgery. No preoperative bowel preparation is necessary.

OPERATIVE PREPARATION

Patient Preparation

Surgery is performed with the donor under general endotracheal anesthesia. Sequential compression stockings are placed on the lower extremities. After induction of anesthesia, an oral gastric tube is placed to decompress the stomach, and a Foley catheter is placed to decompress the bladder. One dose of intravenous antibiotics is administered. The urine collection bag is placed near the anesthesiologist to closely monitor intraoperative urine output.

> Pneumoperitoneum decreases renal blood flow; so vigorous intravenous hydration is necessary to maintain urine output.

Pneumoperitoneum decreases renal blood flow; so vigorous intravenous hydration is necessary to maintain urine output (19). Patients should receive 1 to 2 L of intravenous fluid prior to insufflation of the abdomen, and typically receive 5 to 6 L of

> The anesthesiologist should be instructed to maintain a urine output of 100 cc/hr. This will keep the potential allograft well hydrated and keep the renal vein appearing full and make it easier to identify during the dissection.

> The extraction incision site should be marked prior to positioning and rotating the patient to ensure symmetry and a good cosmetic result.

crystalloid during a routine procedure. The first dose of intravenous mannitol (12.5 g) is given after the second liter of fluid is infused.

The anesthesiologist should be instructed to maintain a urine output of 100 cc/hr. This will keep the potential allograft well hydrated and will keep the renal vein appearing full and make it easier to identify during the dissection.

Patient Positioning

Prior to patient positioning, a 5 to 6 cm Pfannenstiel incision is drawn with a marking pen two fingerbreadths above the symphysis pubis. This will serve as the extraction site. The extraction incision site should be marked prior to positioning and rotating the patient to ensure symmetry and a good cosmetic result.

The patient is placed in a modified flank position at a 45° angle with the operating table, with the ipsilateral flank facing upwards. Two 10 lbl. sandbags are placed behind the patient to maintain the modified flank position. The downside leg is flexed at the knee and separated from the extended upside leg with a pillow. All pressure points on the downside ankle, hip, and knee are well padded. The downside arm is padded and an axillary roll is carefully positioned. The upside arm is placed on a well-padded arm-board, or, alternatively, pillows may be used (Fig. 2). The upper extremities must be positioned such that there is no tension on the brachial plexus. Once the patient is adequately positioned, the table is gently flexed to extend the flank. The patient is secured to the operating table at the level of the shoulders and thighs with 3-inch cloth tape. A surgical blue towel or additional foam pads are placed over these areas to prevent skin irritation or compression injuries from the secured tape. Once the patient is secured to the operating table, the table can be rotated to facilitate exposure during the procedure.

Operating Room Setup

When performing either left or right transperitoneal laparoscopic live donor nephrectomies, both the operating surgeon and assistant stand on the abdominal side of the patient. The equipment table is positioned at the foot of the operating table, and the scrub nurse stands opposite the surgeon. This allows the scrub nurse to hand instruments directly to the operating surgeon. The main video monitor should be placed at eye level, near the head of the table, opposite the surgeon. The secondary monitor is placed in a similar position on the other side of the table, allowing the scrub nurse to also monitor the surgical procedure. A standard monopolar electrocautery unit and/or a harmonic scalpel generator are placed either in front of or behind the operating surgeon. A typical operating room configuration for a left laparoscopic donor nephrectomy is shown in Figure 3.

Some surgeons use the AESOP™ [a] robotic arm to control the laparoscope during laparoscopic live donor nephrectomies. In these cases, the robotic arm should be attached to the operating table on the surgeon side at the level of the patient's shoulders. Its position must be monitored throughout the procedure to ensure that no pressure is being placed on the patient's hands, arms, or shoulder as the robotic arm is maneuvered.

Instrumentation and Medication

Instrumentation for performing laparoscopic live donor nephrectomies varies according to surgeon comfort and experience.

LAPAROSCOPIC DONOR NEPHRECTOMY: BASIC INSTRUMENTATION
■ Standard laparoscopic tower, complete with a carbon dioxide insufflator, light source, camera, monitor, and suction–irrigation device
■ A laparoscope with a 30° lens, because the angled lens facilitates direct videoscopic visualization during challenging portions of the procedure, such as splenic mobilization and hilar dissection.
■ A 5-mm curved tip Harmonic® scalpel[b] for the majority of the blunt and coarse pararenal dissection, including periarterial dissection. It allows for expeditious, safe dissection with excellent hemostasis.
■ Suction–irrigation device. Its tip can also be used as a blunt tip dissector for nonvascular tissue.

Control of the major branches of the renal vein is achieved with titanium clips. The renal artery, renal vein and ureter are controlled with the Endo-GIA® linear stapler with a vascular load. Occasionally, the Endo-TA[c] linear stapler is used to achieve extra length on the renal hilar vessels. A 15-mm Endocatch[c] bag is used to entrap and deliver the renal allograft through the Pfannenstiel extraction incision.

In addition to standard preoperative antibiotics, several medications are necessary to perform laparoscopic live donor nephrectomies and optimize immediate graft function. Each application will be discussed in detail during the comprehensive description of the operative technique. Mannitol is given on two occasions to help optimize renal perfusion. Anticoagulation is achieved with intravenous heparin prior to dividing the renal artery and then reversed with intravenous protamine prior to division of the renal vein. Topical papaverine is used to reduce arterial vasospasm during hilar dissection and allograft manipulation.

Table 1 lists necessary and optional laparoscopic equipment for performing laparoscopic live donor nephrectomies. A list of intraoperative medications is also supplied.

OPERATIVE TECHNIQUE

Laparoscopic Left-Sided Live Donor Nephrectomy

Insufflation and Trocar Placement

The peritoneal cavity is insufflated through a Veress needle to establish a pneumoperitoneum of 15 mmHg. A 5-mm incision is made just lateral to the umbilicus to accommodate the Veress needle. The needle is inserted directly perpendicular to the skin surface, with the distal tip stabilized by the surgeon's hand to prevent past-pointing during placement. The position of the needle tip is confirmed by the saline drop test. If the saline passes through the needle without resistance, the insufflation

TABLE 1 ■ Laparoscopic Instrumentation and Intraoperative Medications

Instruments

- Veress needle
- Two 5-mm laparoscopic trocars
- One 12-mm laparoscopic trocar
- One 15-mm laparoscopic trocar
- 30° laparoscope (5 or 10 mm)
- Harmonic scalpel[a]
- Antifog lens solution
- Debakey forceps/Maryland dissector
- Suction–irrigation device

- Endoscopic shears
- 10-mm right-angled dissector
- 10-mm Titanium clip applier
- 15-mm Endocatch device[b]
- Endo-GIA[b] vascular stapler with two reload cartridges
- Carter-Thomason[c] fascial closure device
- Sterile ice slush
- Standard open nephrectomy tray, retractors, and instrumentation

Optional equipment

- 12-mm Endo Paddle Retract[b]
- Electrocautery hook
- Bipolar electrocautery forceps

- Hemo-lok clips[d]
- Hand-access device

Medications

- Mannitol (12.5 g intravenous × 2 doses)
- Papaverine (30 mg/mL solution, 20 mL total)
- Heparin (5000 U intravenous)
- Protamine (30 mg intravenous)
- Cephazolin (1 g intravenous)

tubing is connected and the flow of carbon dioxide is initiated. An initial intra-abdominal pressure of less than 10 mmHg confirms achieved access to the peritoneal cavity.

In patients who have had extensive intra-abdominal surgery, a direct cut down to the peritoneal space (Hasson technique) is recommended.

Three transperitoneal trocars are used to perform left laparoscopic live donor nephrectomies (Fig. 4). The initial 5-mm trocar is placed at the site of the Veress needle. The abdominal contents are inspected using a 30° laparoscope to ensure that no injury occurred during placement of the Veress needle or the first trocar.

Alternative to a 30° laparoscope, an optical trocar may be used, which allows the surgeon to visualize the layers of the abdominal wall and confirm safe placement of the initial trocar.

Next, another 5-mm trocar is placed under direct vision, approximately three fingerbreadths below the xiphoid process just lateral to the abdominal midline. This will be used for operating the laparoscope during the procedure. The surgeon may choose a 10-mm trocar if he/she wishes to use a 10 mm, 30° laparoscope to perform the operation. A 12-mm trocar is placed on the mid-clavicular line, halfway between the umbilicus and the anterior superior iliac spine. The position of this trocar is important to avoid injury to the epigastric vessels. A 12-mm trocar must be used here to accommodate a standard endovascular stapling device, which is used to control the renal hilum. Some surgeons describe making the Pfannenstiel extraction incision, at the beginning of the procedure, and inserting a 12-mm trocar, through which an instrument can be placed to assist with retraction of the colon, pancreas, or mesentery (12,14). This trocar site is then extended during extraction of the renal allograft at the conclusion of the procurement. In most cases, if these intra-abdominal structures are fully mobilized during the initial steps of the procedure, further retraction is not necessary.

Step 1: Reflecting the Descending Colon/Splenic Mobilization

The white line of Toldt is incised at the pelvic inlet using either laparoscopic electrocautery endoshears or the active blade of the harmonic scalpel. The colon must be protected from electrocautery to prevent burn injury. Dissection is made in a cephalad

---

Sidebar notes:

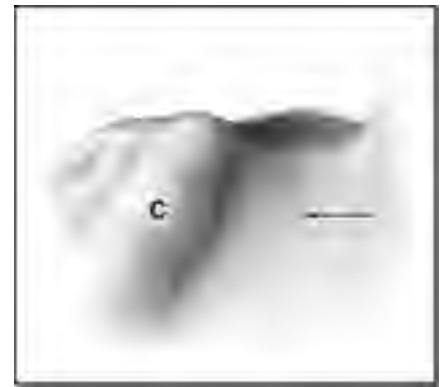

FIGURE 5 ■ The line of Toldt (*arrow*) is incised to begin mobilization of the descending colon (C).

direction over the anterior surface of the kidney toward the spleen (Fig. 5). There are often adhesions from the descending colon at the level of the splenic flexure to the anterior abdominal wall; these attachments need to be divided to carry the incision of the line of Toldt along the spleen toward the diaphragm. This includes releasing any splenophrenic attachment, thereby mobilizing the spleen from the abdominal sidewall.

> It is crucial to release only the peritoneal attachments between the colon and the lateral sidewall; deeper dissection can result in the kidney dropping medially and obscuring the renal hilum, precluding safe hilar dissection. This also prevents inadvertent torsion of the kidney on its vascular pedicle during manipulation.

It is crucial to release only the peritoneal attachments between the colon and the lateral sidewall; deeper dissection can result in the kidney dropping medially and obscuring the renal hilum, precluding safe hilar dissection. This also prevents inadvertent torsion of the kidney on its vascular pedicle during manipulation.

Once the peritoneal attachments have been divided, the avascular plane between Gerota's fascia and the mesentery of the colon is identified and developed. The bright yellow fat of the colonic mesentery is separated from the glistening white fibers of Gerota's fascia. The mesentery is bluntly dissected and mobilized medially. Tethering attachments are divided with the harmonic scalpel. Identification of this plane is critical.

> Dissection too close to the mesentery may result in injury to mesenteric vessels and bleeding, which may obscure the plane of dissection or cause a mesenteric defect. In addition, premature violation of Gerota's fascia may also cause excessive bleeding and limit identification of the renal hilum.

Dissection too close to the mesentery may result in injury to mesenteric vessels and bleeding, which may obscure the plane of dissection or cause a mesenteric defect. In addition, premature violation of Gerota's fascia may also cause excessive bleeding and limit identification of the renal hilum.

Dissection is taken in a cephalad direction and continued by dividing the splenocolic ligament, which allows further medial mobilization of the descending colon. The surgeon's left-handed instrument (Maryland dissector) gently retracts the spleen medially, allowing incision of the splenorenal ligament, which further releases the spleen and precludes inadvertent tearing of the splenic capsule. Bleeding from the splenic capsule should be managed with gentle pressure and application of a hemostatic agent, such as Surgicel®. In addition, the argon beam coagulation device is often successful in achieving hemostasis in minor splenic tears. Major splenic injuries often require open conversion for splenorrhaphy. The dissection then follows the plane between the spleen and pancreas, and the upper border of Gerota's fascia. Attachments are divided using the harmonic scalpel, and the surgeon will feel the spleen releasing medially (Fig. 6).

> The tip of the dissection instruments should be maintained in direct view because past-pointing may lead to diaphragmatic injury and pneumothorax.

The tip of the dissection instruments should be maintained in direct view because past-pointing may lead to diaphragmatic injury and pneumothorax *(20)*.

The operating table can be rotated medially to facilitate the dissection. The goal is to release all the lateral attachments of the spleen so that it does not have to be retracted during the procedure, thereby minimizing the chance of injury. In addition, this will allow safe dissection of the upper pole of the kidney with minimal risk of splenic injury.

> Visualization of the fundus of the stomach is the landmark used to signal that complete mobilization has been achieved.

Visualization of the fundus of the stomach is the landmark used to signal that complete mobilization has been achieved.

Additional attachments between the pancreas and Gerota's fascia will also be seen and can be bluntly dissected. Minimal traction should be placed on the pancreas during its mobilization.

Step 2: Identification of the Renal Hilum
Once the descending colon, pancreas, and spleen have been mobilized and reflected medially en bloc, the surgeon should not have the need for retraction and should be able to identify the renal hilum with both instruments.

FIGURE 6 ■ The colonic mesentery is mobilized off of the anterior surface of Gerota's fascia en bloc with the pancreas and spleen. The splenophrenic ligament is divided to allow complete mobilization of the spleen away from the upper pole of the left kidney.

FIGURE 7 ■ The adrenal (AV) and gonadal veins (GV) are divided to attain maximum length on the renal vein (RV).

Once the descending colon, pancreas, and spleen have been mobilized and reflected medially en bloc, the surgeon should not have the need for retraction and should be able to identify the renal hilum with both instruments.

Clips on the specimen side should not be placed too close to the renal vein in anticipation of using the vascular stapling device later in the procedure. Retained clips may become entrapped within the Endo-GIA® stapler and cause misfiring of the device at the time of transection of the renal vessels.

If the renal vein is not easily identified, the left gonadal vein is an important structure because it reliably leads the surgeon to the renal vein.

Great care must be taken not to past-point the clips on the lumbar vein, because they may inadvertently catch the renal artery, which classically is located behind the lumbar branch of the renal vein.

Excessive traction on the renal hilum must be avoided to prevent arterial vasospasm.

Bleeding occurring during laparoscopic donor nephrectomy is most commonly encountered during hilar dissection.

The renal vein can often be visualized through Gerota's fascia, especially if adequate intravenous hydration has been maintained. The investing tissues overlying the renal vein are grasped and divided. The anterior surface of the renal vein is meticulously skeletonized, primarily by blunt dissection with the suction–irrigation device. Sharp dissection should be used sparingly around the renal hilum to minimize the chance of iatrogenic injury to the main renal vessels. Dissection is taken medially to ensure adequate length of the vein for transplantation. The take-off of the adrenal and gonadal veins is identified, and each vessel is isolated using blunt dissection. The harmonic scalpel is an excellent device to control several small branches that are often seen coming off the gonadal vein. Both the adrenal vein and gonadal vein are divided between hemoclips (Fig. 7).

Clips on the specimen side should not be placed too close to the renal vein in anticipation of using the vascular stapling device later in the procedure. Retained clips may become entrapped within the Endo-GIA stapler and cause misfiring of the device at the time of transection of the renal vessels (21).

The second dose of intravenous mannitol (12.5 g) is given at this point of the operation.

If the renal vein is not easily identified, the left gonadal vein is an important structure because it reliably leads the surgeon to the renal vein.

The gonadal vein is most easily identified inferiorly; it can then be traced in a cephalad direction to the level of the renal hilum. Once the gonadal vein has been safely transected, the surgeon gently grasps the proximal cut end of the gonadal vein and rotates it medially, exposing the lumbar vein. Hemostatic clips are applied to the lumbar vein prior to transection.

Great care must be taken not to past-point the clips on the lumbar vein, because they may inadvertently catch the renal artery, which classically is located behind the lumbar branch of the renal vein.

The renal artery is usually easily identified once the lumbar vein is transected. The renal artery should be dissected down to its origin from the aorta to achieve maximum renal vascular length.

Excessive traction on the renal hilum must be avoided to prevent arterial vasospasm. To minimize vasospasm, topical papaverine (30 mg/mL) may be applied to the renal artery periodically. The renal artery should be skeletonized toward the origin of its surrounding perivascular and lymphatic tissues. Further skeletonization of the artery toward the renal sinus is not necessary. Aggressive dissection may cause vasospasm and will risk injury to branches of the artery if it bifurcates proximally.

Bleeding occurring during laparoscopic donor nephrectomy is most commonly encountered during hilar dissection. Bleeding emanating from small venous branches can often be controlled with direct pressure, placement of Surgicel or Gelfoam, or by temporarily elevating the insufflation pressure. Minor arterial sources of bleeding usually require hemoclips.

Large venous or arterial injuries, including damage to the main renal artery or vein often require open conversion to obtain hemostasis and ensure the safety of the living donor and the health of the allograft.

Large venous or arterial injuries, including damage to the main renal artery or vein often require open conversion to obtain hemostasis and ensure the safety of the living donor and the health of the allograft.

Surgeons with advanced laparoscopic skills may attempt to manage certain vascular injuries laparoscopically or with conversion to a hand-assisted approach. However, the importance of maintaining a low threshold for open conversion with this procedure cannot be overstated.

When the decision for open conversion is made, the surgeon should hold pressure with a laparoscopic instrument until the necessary equipment for open conversion is available. The surgeon quickly decides which incision (flank, subcostal, or midline) will give the best exposure to the renal hilum.

Step 3: Dissection of the Ureter

Successful dissection of the ureter during laparoscopic donor nephrectomy centers upon performing a wide dissection to ensure preservation of the periureteral tissue and blood supply, as well as obtaining satisfactory ureteral length for transplantation.

Successful dissection of the ureter during laparoscopic donor nephrectomy centers upon performing a wide dissection to ensure preservation of the periureteral tissue and blood supply, as well as obtaining satisfactory ureteral length for transplantation.

Early published series of laparoscopic live donor nephrectomies cited aggressive dissection of periureteral tissues to expose and identify the ureter as the main factor in a high incidence of ureteral complications, including ureteral stricture and necrosis (6,9). To avoid this, dissection is carried out medial to the distal gonadal vein stump, bluntly sweeping this structure and the periureteral tissues in a lateral direction. The medial attachments of the gonadal vein can be controlled with the harmonic scalpel, because small tributaries may cause minor bleeding. However, thermal energy should be used carefully to prevent thermal injury to the ureter or its blood supply.

In our current technique, one instrument is placed under the ureteral packet (including the gonadal vein) and elevated anteriorly (Fig. 8). The other instrument bluntly dissects the posterior attachments back to the fascia overlying the psoas muscle. Dissection is carried to the lateral abdominal sidewall and continued inferiorly to the iliac vessels.

There is no need to identify the ureter along its course; this minimizes the likelihood of compromising its blood supply during dissection.

There is no need to identify the ureter along its course; this minimizes the likelihood of compromising its blood supply during dissection.

Limited dissection is performed between the renal artery and the proximal ureter, thereby maintaining the ureteral blood supply arising from the renal artery. At this point in the procedure, the ureter is left intact. It will not be divided until the kidney is ready for extraction.

Step 4: Dissection of the Upper Pole of the Kidney

An area of Gerota's fascia cephalad to the renal hilum is incised sharply along the anterior aspect of the upper pole, exposing the renal capsule. The surgeon then places his/her left-handed instrument (suction irrigator or Debakey forceps) next to the capsule and retracts medially. This will develop the plane to dissect the adrenal gland from the upper pole of the kidney. The harmonic scalpel is used here, because it easily coagulates small, friable perforating vessels that may be traveling to the adrenal gland.

During dissection of the upper pole of the kidney, upper pole renal vessels may be encountered and potentially injured. Despite potential identification of these vessels on preoperative computed tomography arteriography, meticulous dissection is necessary to prevent injury.

During dissection of the upper pole of the kidney, upper pole renal vessels may be encountered and potentially injured. Despite potential identification of these vessels on preoperative computed tomography arteriography, meticulous dissection is necessary to prevent injury.

Next, the upper pole is elevated with the surgeon's left hand, allowing the harmonic scalpel to divide the posterior upper pole attachments.

Step 5: Release of Lateral and Posterior Attachments

The lateral and posterior attachments are released while the surgeon gently retracts the kidney anteriorly. Because the posterior dissection progresses medially, the surgeon must be aware of the exact location of the renal hilum, to minimize the chance of iatrogenic injury to the renal vessels and their branches. In addition, as the allograft becomes more mobile, great care must be taken to avoid torsion of the kidney about its vascular pedicle. Now, the renal artery, renal vein, and ureter are the only attachments to the kidney.

Step 6: Preparing the Allograft Extraction Site

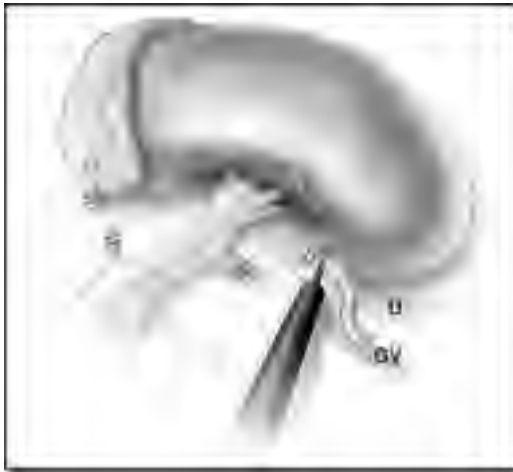
The extraction site is prepared by making a 5 to 6 cm Pfannenstiel incision, which was outlined at the beginning of the procedure. The anterior rectus fascia is skeletonized, making sure to mobilize overlying subcutaneous tissue. The fascia is incised longitudinally in the midline, ensuring sufficient room for extraction of the kidney. The rectus muscle is separated in the midline, and the underlying peritoneum is left intact in order


FIGURE 8 ■ Dissection of the ureter. An instrument is placed under the ureteral packet, including the clipped gonadal vein (GV), elevating it anteriorly because posterior attachments are dissected. The ureter (U) need not be visualized, because attempts to do so may compromise its delicate blood supply.

FIGURE 9 ■ The kidney is elevated with a blunt instrument, assisting in skeletonizing the renal vessels. *Abbreviations*: RA, renal artery; RV, renal vein.

to preserve the pneumoperitoneum. A 15-mm trocar is placed under direct vision in the middle of the extraction incision.

Step 7: Transection of the Ureter

Before initiating final delivery of the kidney, the surgical team must be alerted that the transplantation team is prepared to receive the allograft.

The back table must be equipped with ice slush and an intracellular electrolyte preservation solution. When the recipient surgical team is ready, the ureter and its well-preserved periureteral tissue packet is transected distally at the level of the iliac vessels using an endoscopic vascular stapling device. Alternatively, hemoclips can be placed distally and the ureter divided with endoscopic shears.

> Before initiating final delivery of the kidney, the surgical team must be alerted that the transplantation team is prepared to receive the allograft.

Step 8: Placement of the Allograft in the Entrapment Sac

The 15-mm Endocatch bag is deployed over the kidney toward the splenic fossa. The surgeon gently places the allograft onto its anterior surface and moves the bag behind the graft. The kidney is then gently placed into the bag, making sure that the ureteral stump is entrapped as well (Fig. 9). The bag must be kept in view during this maneuver, taking great care not to injure the bowel or other intraperitoneal structures.

- The advantages of "prebagging" the kidney prior to hilar vessel transection include rapid delivery with minimal warm ischemia time and providing traction to help obtain maximum vessel length.
- The main potential disadvantage of this technique is the possibility of arterial vasospasm. This should not occur if minimal traction is placed on the renal hilum during the extraction process.

Step 9: Transection of the Renal Vessels

Prior to securing the renal hilum, the patient is given 5000 U of intravenous heparin sulfate.

- With the renal vessels on gentle traction, the renal artery is transected flush with the aorta with a linear endovascular stapler or Hem-O-Lok clips (Fig. 10).
- The endovascular TA stapler or Hem-O-Lok clips will secure the patient side of the renal artery while leaving the graft side of the vessel open. This will maximize arterial length, because graft-side staples that are placed with the Endo-GIA stapler have to be excised by the recipient surgical team (22).

In addition, some transplant surgeons are concerned that these graft-side staples may cause intimal injury that may lead to more technical problems with the recipient

FIGURE 10 ■ The kidney with the divided ureter is gently placed into a 15-mm Endocatch® bag. The skeletonized renal vessels are placed on gentle traction for division. Transection of the renal artery (RA) using an Endo-GIA® stapling device. The renal vein (RV) will then be divided medial to the adrenal vein stump.

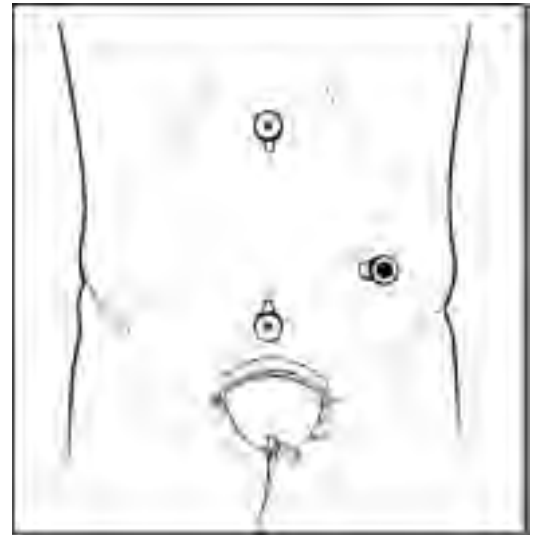

FIGURE 11 ■ Delivery of the kidney within the Endocatch® bag via the Pfannenstiel incision.

arterial anastomosis. Also, avoiding the Endo-GIA stapling device creates a safety net to avoid possible stapler misfire (21). With the Endo-TA or Hem-O-Lok clips, the security of the patient-side staples or clips can be observed prior to vessel transection.

After transection of the renal artery, anticoagulation is reversed with 50 mg protamine intravenously. This is followed by immediate transection of the renal vein as far medial from the adrenal vein stump as possible, affording maximal vessel length.

It is critical to avoid previously placed clips on the adrenal and lumbar veins when placing a stapling device on the renal vein. A misfire on the renal vein will result in almost certain open conversion, because the renal vein stump will retract anterior to the aorta and be difficult to control laparoscopically. If this happens, pressure should be applied in the area of the vein stump and the allograft delivered through the extraction site. Once the kidney is safely extracted, an appropriate incision is made to obtain hemostasis.

If multiple renal arteries are present, each should be transected prior to transection of the renal vein(s) (23).

Small accessory renal vessels (less than 2 mm) may be sacrificed after consultation with the recipient surgical team.

Step 10: Delivery of the Allograft

Once the renal vein is safely divided, the kidney drops into the Endocatch bag. After ensuring that the entire kidney and ureter are in the bag, the ring cord on the device is pulled, closing the sac and entrapping the allograft. The handle of the bag and trocar are removed, and the surgeon's hand opens the peritoneal cavity, creating a defect large enough for atraumatic delivery of the kidney (Fig. 11).

The allograft should not be forced through an incision too small to accommodate it. If necessary, then skin and/or fascial incisions are extended, taking great care to protect intraperitoneal contents that may herniate into the wound.

The allograft is immediately immersed in ice slush and delivered to the recipient surgical team for immediate perfusion with iced preservation solution.

Step 11: Inspection of the Renal Bed/Closure

The anterior rectus fascia is immediately closed with a running 0-polyglactin suture. Pneumoperitoneum is reestablished, and the renal bed is inspected at a low insufflation pressure. The renal artery and vein stumps are closely inspected. In addition, the splenic capsule, colon, and its associated mesentery, pancreas, and adrenal gland are examined for injury and to ensure meticulous hemostasis. Small sites of bleeding can be controlled

---

Sidebar notes:

It is critical to avoid previously placed clips on the adrenal and lumbar veins when placing a stapling device on the renal vein. A misfire on the renal vein will result in almost certain open conversion, because the renal vein stump will retract anterior to the aorta and be difficult to control laparoscopically.

If multiple renal arteries are present, each should be transected prior to transection of the renal vein(s).

The allograft should not be forced through an incision too small to accommodate it.

The allograft is immediately immersed in ice slush and delivered to the recipient surgical team for immediate perfusion with iced preservation solution.

with electrocautery of hemoclips. A hemostatic agent, such as Surgicel, can be placed in the renal bed, if necessary.

The fascial defect from the 12-mm trocar site is closed under direct laparoscopic visualization with 2-0 polyglactin suture using the Carter-Thomason[®][d] fascial closure device. All 5-mm trocars are removed without the need for fascial closure. The remaining pneumoperitoneum is released before the last trocar is removed. The fascial defect created from bladed trocars 10 mm in size or greater must be closed to minimize the risk of port-site herniation. Some surgeons believe that conical blunt trocar insertion may eliminate the need for fascial closure in transperitoneal laparoscopic renal surgery (24). This concept applies to blunt trocar placement through muscular parts of the abdominal wall, relying on muscle splitting and eventual muscle retraction when the trocar is removed. Fascial nonclosure after transperitoneal 12-mm blunt trocar insertion may be safe and efficacious and eliminate the last step in transperitoneal laparoscopic renal surgery. However, port-site hernia at the site of insertion of 10-mm nonbladed trocars has been described (25). It is generally recommended that all trocar sites larger than 5 mm, whether bladed or nonbladed, be closed in patients undergoing transperitoneal laparoscopic live donor nephrectomies.

Laparoscopic Right-Sided Live Donor Nephrectomy

Indications for laparoscopic procurement of the right kidney have been outlined earlier in this chapter. Patient positioning and trocar placement mirror those used for a left-sided dissection (Fig. 12).

An extra 5-mm trocar is placed laterally in the mid-axillary line to accommodate an instrument for retraction of the right lobe of the liver. Alternatively, this fourth trocar may be placed along the costal margin.

The operative steps for a right-sided dissection are similar to that on the left, with modification of the technique used for hilar dissection due to the presence of the inferior vena cava and the anatomically short right renal vein (26–28).

The dissection of the white line of Toldt is carried upward to the lower pole of the kidney at which point it is continued medially, staying several centimeters away from the ascending colon. This allows complete colon mobilization while keeping the lateral attachments of the kidney intact, thereby facilitating the hilar dissection later in the procedure. Continuing in a cephalad direction toward the diaphragm, the triangular and coronary ligaments of the liver are divided up to the diaphragm, allowing mobilization of the lateral aspect of the right lobe of the liver off of the upper pole of the right kidney. The liver may be retracted using a variety of instruments, including the PEER Jarit retractor[e] or the diamond flex triangle retractor.[f]

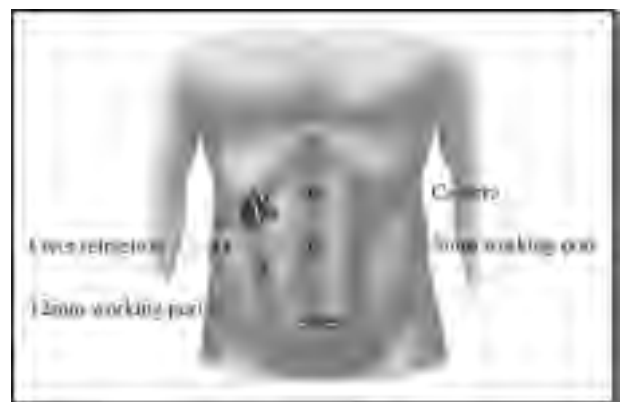
Kocherization of the duodenum is performed to mobilize it medially and skeletonize the anterior and lateral surfaces of the inferior vena cava. Minimal electrocautery is used to avoid thermal injury.

The duodenum must always be identified before dissection of the vena cava is initiated.

Adequate renal vein length and vascular control are primary concerns when performing right laparoscopic live donor nephrectomies. Gently retracting the renal vein and skeletonizing the anterior and lateral borders of the vessel initially identify the renal artery (29).

An extra 5-mm trocar is placed laterally in the mid-axillary line to accommodate an instrument for retraction of the right lobe of the liver. Alternatively, this fourth trocar may be placed along the costal margin.

The duodenum must always be identified before dissection of the vena cava is initiated.

FIGURE 12 ■ Trocar placement for right-sided laparoscopic live donor nephrectomy. An extra port is needed for liver retraction.


Once the posterior and lateral attachments are released, the kidney is gently placed on its anterior surface and the renal artery dissection is completed posteriorly. This allows the retrocaval dissection of the renal artery that is necessary to obtain adequate vessel length. The renal vein is dissected down to the level of the vena cava. Once the allograft is placed in the Endocatch bag, the artery is ligated at a level medial to the vena cava, and the renal vein is transected flush with the vena cava. Although the length of the right renal vein harvested laparoscopically is slightly shorter than that procured via the open technique, meticulous hilar dissection of the vessel on the bench table combined with extensive mobilization of the recipient external iliac vein typically provides sufficient length for a tension-free allograft venous anastomosis.

Technical modifications have been designed to optimize renal vein length and maximize safety during hilar dissection. The use of an articulating stapler positioned parallel to, and flush with, the inferior vena cava allows procurement of the entire length of the right renal vein.

Hand-assisted laparoscopy has been used as a method to improve retrocaval dissection of the renal artery, achieve maximal renal vein length, and simplify kidney extraction (30–34). The hand port incision that is required is usually made in the right lower quadrant. The hand-assisted approach does not add morbidity to the procedure for the donor patient and is an acceptable alternative to the pure laparoscopic transperitoneal approach.

Groups at several institutions have addressed concerns regarding harvesting a shorter renal vein by placing a clamp on the inferior vena cava and including a vessel cuff, mimicking the open approach. Turk et al. describe placing a modified laparoscopic Satinsky clamp[g] across the vena cava after the kidney has been placed inside the Endocatch bag and the artery transected (35). The allograft is then safely delivered, the extraction site closed, and the cavotomy closed with a laparoscopic running suture. Another modification described involves making a transverse subcostal incision over the renal hilum at the end of the procedure as an alternative to a Pfannenstiel extraction site (10). The hilar vessels are transected using the standard open technique, including a cuff of vena cava. Although this incision is not optimal with respect to postoperative pain and cosmesis, it ensures excellent control of the renal hilum with minimal warm ischemia time.

The cumulative experience with laparoscopic live donor right-sided nephrectomy is significantly less compared to the left-sided procedure. However, many studies have specifically examined right laparoscopic live donor nephrectomies and suggest that in experienced hands, it is safe for the donor patient and produces excellent immediate graft function. Boorjian et al. described a series of 40 right-sided laparoscopic live donor nephrectomiess where donor morbidity and recipient allograft function did not differ from those seen with left kidneys procured laparoscopically (33). Similarly, Abrahams et al. reported on a similar series of patients where donor and recipient outcomes were equivalent between left-sided and right-sided procedures, without technical graft loss in either group (26,27). Although technically challenging because of the potential problems with dissection of the renal hilum, the right kidney can be procured laparoscopically when indicated and when an experienced surgeon is present.

Hand-Assisted Laparoscopic Live Donor Nephrectomy

Hand-assisted laparoscopy combines the principles of open and laparoscopic surgery to create a hybrid technique that was initially developed to shorten the learning curve for surgeons not trained in conventional laparoscopy. In addition, more complex laparoscopic procedures that failed to progress with standard laparoscopy could be completed with a hand-assisted approach instead of being converted to an open operation. The surgeon's nondominant hand is placed in the abdomen through a small incision to work in concert with the instrument-bearing dominant hand. A hand-access device is used to prevent the loss of pneumoperitoneum during the procedure.

The hand-assisted technique confers certain advantages to the surgeon, especially the novice laparoscopist. It provides the surgeon with tactile sensation and spatial orientation and allows palpation of vessels and adjacent organs. The surgeon's hand is a versatile instrument for exposing, dissecting, and retracting tissue. In addition, as in open surgery, hemostasis, and intracorporeal suturing and knot tying are facilitated by the surgeon's nondominant hand.

In performing hand-assisted laparoscopic live donor nephrectomies, the operative steps are identical to those already outlined for the standard laparoscopic approach. Unlike the standard technique, the extraction incision is made at the beginning of the procedure for placement of the hand-assist device.

---

[g]Aesculap Inc., Tuttlingen, Germany.

Selection of the proper incision site for placement of the device is critically important. The surgeon must be able to easily reach the superior aspect of the kidney to ensure complete mobilization and gentle handing of the allograft. For a left-sided donor nephrectomy, a periumbilical midline incision is used. For a right-sided donor nephrectomy, a modified muscle-splitting Gibson incision is made in the right lower quadrant.

After insertion of a hand-assist device and establishment of pneumoperitoneum, the camera and working trocars are placed in the same positions as in the standard laparoscopic technique. During the procedure, the intraperitoneal hand is used to present tissues for dissection, and is especially useful in elevating the kidney during transection of the renal hilum. After division of the renal vessels, the kidney is delivered directly through the hand-assist device incision and does not require placement within an entrapment sac. This minimizes warm ischemia time to the allograft.

There are numerous series in the literature describing the hand-assisted technique for live donor nephrectomy and reporting on outcomes for both donor and recipient allograft function (35–41). These series have shown hand-assisted laparoscopic live donor nephrectomies to be a safe, efficacious, and reproducible minimally invasive technique for renal donation. When compared with the open technique, hand-assisted laparoscopic live donor nephrectomies parallels the standard laparoscopic approach in terms of reduced donor morbidity while producing a healthy renal allograft for transplantation.

Direct comparison of the hand-assisted technique to the standard laparoscopic technique reveals similar donor and recipient outcomes. Generally, operative times are slightly less with the hand-assisted technique, whereas postoperative pain and cosmesis favor the standard laparoscopic technique (36,37).

With these results, hand-assisted laparoscopic live donor nephrectomies has emerged as a viable option to the laparoscopic surgeon for performing this technically challenging minimally invasive procedure.

Retroperitoneoscopic Live Donor Nephrectomy

The retroperitoneal approach to laparoscopic live donor nephrectomies initially evolved as an alternative technique to address concern with the low rates of right-sided laparoscopic donor nephrectomy in most series, an apparent reflection of the increased degree of technical difficulty harvesting the right kidney by the transperitoneal approach. As such, most reported series of retroperitoneoscopic donor nephrectomy involve the right kidney (42–45), although a small series of successful left-sided retroperitoneoscopic donor nephrectomy has recently been reported (46).

In performing retroperitoneal laparoscopic live donor nephrectomies, the patient is placed in the flank position, and the operating table is flexed to maximize the space between the iliac crest and the 12th rib. The retroperitoneal space is created by making a 15-mm incision inferior to the tip of the 12th rib through the lumbodorsal fascia. The space is expanded with blunt finger dissection and then a balloon dilator. Balloon dilation is performed anterior to the psoas muscle and outside of and posterior to Gerota's fascia. A three-port technique is used, with the primary 12-mm port placed at the site of entry. Another 12-mm port is placed anteriorly near the anterior axillary line approximately 3 cm cephalad to the iliac crest. A posterior 5-mm port is placed at the junction of the lateral border of the paraspinal muscles and the 12th rib (42).

The renal hilum is identified posteriorly, and the renal artery is isolated and mobilized from the renal hilum to its retrocaval location. The renal vein, along with a segment of inferior vena cava, is skeletonized. The ureter within the periureteral sheath is dissected distally into the pelvis.

An important technical consideration with the retroperitoneal approach is maintaining the attachments of the anterior kidney to the parietal peritoneum during most of the procedure.

Similar to the intact posterolateral attachments during the transperitoneal approach, this prevents the kidney from flopping posteriorly and obscuring the surgeon's view of the renal hilum.

During preparation for extraction, a muscle-splitting Gibson incision is made and developed to the transversalis fascia, avoiding disruption of the pneumoretroperitoneum (47). The renal artery and renal vein are divided in standard fashion. An articulating vascular stapler is positioned parallel to and flush with the vena cava as in the transperitoneal operation, ensuring procurement of the entire length of the right renal vein. Once the renal hilum is secured, the anterior attachments are rapidly divided to free the allograft completely. The intact fascial layer at the Gibson incision is divided, and the retroperitoneum is entered to quickly extract the kidney manually (47). The ureter is then transected using the incision for distal exposure.

The pure retroperitoneoscopic approach does have certain advantages over transperitoneal laparoscopic live donor nephrectomies (48–50). It allows rapid and direct access to the renal hilum, obviating the need to mobilize the liver, ascending colon, and duodenum. The right renal artery is effectively skeletonized in a retrocaval location, ensuring optimal arterial length for transplantation.

The right renal vein and adjacent vena cava can be dissected under direct vision. Intra-abdominal adhesions in patients with prior abdominal surgery are avoided. Because the peritoneal cavity is not violated, iatrogenic injury to intraperitoneal organs and the likelihood of postoperative paralytic ileus are reduced.

Disadvantages of the pure retroperitoneoscopic approach to live donor nephrectomy include a longer warm ischemia time of the allograft, because anteriomedial kidney attachments are not divided until after the renal vessels have been transected. Identification of landmarks is limited, and dissection in obese patients with large amounts of retroperitoneal fat can be quite difficult. Although hand-assisted retroperitoneoscopic live donor nephrectomy has been reported, the smaller working space limits the surgeon's ability to effectively use his/her hand to optimize dissection (48).

The largest experience with retroperitoneal laparoscopic live donor nephrectomies is reported by Ng et al. (45). In this series, right retroperitoneal laparoscopic live donor nephrectomies is compared with left transperitoneal laparoscopic live donor nephrectomies in a consecutive single-institutional experience. Operative times were significantly less with the retroperitoneal approach, whereas hospital stay, analgesic use, and donor–recipient creatinine were similar in both groups. Despite a statistically significant longer warm ischemia time with the retroperitoneal technique, recipient functional outcomes at one week and one month were similar in both groups (45).

> The pure retroperitoneoscopic approach does have certain advantages over transperitoneal laparoscopic live donor nephrectomies. It allows rapid and direct access to the renal hilum, obviating the need to mobilize the liver, ascending colon, and duodenum. The right renal artery is effectively skeletonized in a retrocaval location, ensuring optimal arterial length for transplantation.

SUMMARY

- Laparoscopic live donor nephrectomies is a remarkable technical achievement. It has had a substantial impact on the donor operation by providing a less-invasive approach to kidney procurement.
- Since its inception, it has emerged as the preferred technique for live kidney donation at many institutions.
- Despite technical modifications and development of refined instrumentation, this procedure still remains challenging.
- The donor surgeon must have a thorough knowledge of renal and pararenal anatomical structures, and be aware of specific steps in the operation susceptible to complications in order to proactively optimize complication management strategies.
- The surgeon's individual technique may evolve over time, but the basic steps in laparoscopic live donor nephrectomies have been firmly established.

LAPAROSCOPIC DONOR NEPHRECTOMY: CURRENT STATUS

Michael W. Phelan and Stephen C. Jacobs

Division University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.

INITIAL EXPERIENCE AND MOTIVATION

Clayman et al. first introduced laparoscopic nephrectomy in 1990 (1). Patients who underwent such a "noninvasive" nephrectomy demonstrated less postoperative pain, shorter hospitalization, and faster recovery. With the benefits of laparoscopic nephrectomy becoming more apparent, laparoscopic donor nephrectomy was perceived as a technique that might encourage more individuals to undergo renal donation. Laparoscopic donor nephrectomy was first performed in an animal model in 1994 (2). Soon thereafter, the first laparoscopic donor nephrectomy in a human was performed in 1995 (3).

Initially, laparoscopic donor nephrectomy was treated with healthy skepticism, and the procedure was considered controversial. Complications seen in the early laparoscopic donors were worrisome, especially in the setting of open donor nephrectomy, which had been performed successfully for nearly five decades.

In many open donor series, the complication rates were as low as 1% to 8%, and early graft loss was extremely rare (4–9). To gain wide acceptance, laparoscopic donor nephrectomy appropriately had to meet the standards set by open donor nephrectomy.

The initial concerns revolved around graft function following laparoscopic surgery. Many feared that the pneumoperitoneum with increased abdominal pressure might lead to acute tubular necrosis and delayed graft function. Extraction of the kidney through a small incision might also injure the kidney. Other concerns included adequacy of vessel length and ureteral viability. Lastly, it was believed that the increased warm ischemia time associated with laparoscopic donor surgery would have long-term detrimental effects on graft function. In the rush to embrace new technology and the perceived requirement to compete for patients, many believed that the popularity of the technique would lead transplant programs to compromise the central ethos of leaving the best kidney with the donor in favor of performing the laparoscopic technique.

Table 1 shows that, in current series, the total operating time required to perform laparoscopic donor nephrectomy is comparable to that required for open surgery. In our review of 59 series, comprising 3330 donors, operative time for laparoscopic donor nephrectomy averaged 3 hours 45 minutes.

Overall reported complication rates averaged 5.6% in 2834 donors, although this number is difficult to use for comparison because of the disparate definitions of complications and because any comparison group of open donor nephrectomy is fraught with similar problems.

> In many open donor series, the complication rates were as low as 1% to 8%, and early graft loss was extremely rare. To gain wide acceptance, laparoscopic donor nephrectomy appropriately had to meet the standards set by open donor nephrectomy.

> Table 1 shows that, in current series, the total operating time required to perform laparoscopic donor nephrectomy is comparable to that required for open surgery. In our review of 59 series, comprising 3330 donors, operative time for laparoscopic donor nephrectomy averaged 3 hours 45 minutes.

EARLY CONTROVERSIES

Pneumoperitoneum

With good intraoperative hydration of the donor (5–6 L), initial concerns for renal dysfunction due to increased pressure from pneumoperitoneum have not been realized (69–71). In addition to aggressive hydration, the donors are given 25 g of intravenous mannitol, which provides an osmotic diuresis and has antioxidant properties. Clinically, all renal transplant centers attempt aggressive hydration of the donor prior to and during the nephrectomy, with some services even aiming for 4000 to 6000 mL of intravenous fluids prior to and during the procedure (25).

Warm Ischemia Time

> Laparoscopic donor nephrectomy is associated with longer warm ischemia time when compared to open surgery.

Laparoscopic donor nephrectomy is associated with longer warm ischemia time when compared to open surgery (39). The warm ischemia time for a typical open surgery should be less than a minute, but this has never been precisely measured in a large series. The University of Maryland six-year experience (10) reported a slow but steady decline in the warm ischemia time for the first 400 cases, showing that the early experience in laparoscopic donor nephrectomy did require a learning curve for the development of the procedure. At the time of this writing, we reviewed 36 published series comprising 3137 standard transperitoneal laparoscopic donor nephrectomies (Table 1). The average warm ischemia time reported was four minutes for the 2256 cases in which it was measured. The hand-assisted laparoscopic donor nephrectomy technique allows an even quicker extraction after clamping of the renal vessels, as shown in 18 published series reporting a sum total of 744 hand-assisted donor nephrectomies with an average warm ischemia time of only two minutes in the 354 cases in which this parameter was measured.

> Despite an average warm ischemia time of only 21/2 minutes for their entire series of 722 donors, the University of Maryland group could not detect a correlation between the length of warm ischemia time and recipient creatinine levels or delayed graft function.

Despite an average warm ischemia time of only 21/2 minutes for their entire series of 722 donors, the University of Maryland group could not detect a correlation between the length of warm ischemia time and recipient creatinine levels or delayed graft function (10,72).

The impact of small increments in warm ischemia time is largely unknown. In fact, Opelz et al. (73) have shown that there was no strong correlation between warm ischemia time and long-term graft function even in cadaver kidney grafts. In their large series, warm ischemia times even as long as 30 to 40 minutes resulted in no appreciable difference in graft survival (15). At the current time, it is reasonable to assume that any small increase in warm ischemia time results in a small, but probably immeasurable, renal injury.

The etiology of delayed graft function is multifactorial. Table 2 shows that delayed graft function occurred in 3.2% of the 2888 donors reported. Overall, the recipient's serum creatinine at one week following the transplantation was 1.8 mg% (N = 2610), which is comparable to that of open nephrectomy series.

TABLE 2 ■ Laparoscopic Donor Nephrectomy: Recipient Results

Technique	DGF	Creatinine (at 1 wk in mg%)	Ureteral complications
Standard transperitoneal			
Maryland (10)	2.6%	2.0	4.5%
UCSF (11–13)	5.0%	1.4	6.0%

Ureteral Complications

Early in the laparoscopic donor experience, rates of ureteral complications were high. The ureteral complication rate was 10.5% and 10% in the University of Maryland and the Johns Hopkins series, respectively (74,75). These ureteral complication rates were alarmingly higher when compared to that in the contemporary open donor cohorts (9,75) and led to changes in the technique aimed at preservation of ureteral vascularity (74).

Technical modifications included (i) en-bloc wide removal of the periureteral tissue along with the ureter; (ii) preservation of the triangle between the junction of the gonadal vein–renal vein and the lower pole of the kidney; and (iii) en-bloc removal of the entire gonadal vein along with the ureter and all periureteric tissue and resulted in lower ureteral complications.

At Johns Hopkins, the ureteral complication rate for the first 100 laparoscopic donor nephrectomies was 10%, whereas the complication rate for the next 100 cases dropped to 3% (75). At the University of Maryland, the ureteral complication rate of 14.5% (74) in the initial (76) cases subsequently dropped to less than 3% (10). Overall, the published collective experience of 36 large series reporting on 2206 standard transperitoneal laparoscopic donors shows a ureteral complication rate of 4.5%. These series are now mature enough that one would not expect this number to grow due to late complications. Hand-assisted laparoscopic donor nephrectomy has a low incidence of ureteral complications. In 18 published series of 188 hand-assisted laparoscopic donors, the recipient ureteral complication rate was only 1.1%. However, hand-assisted laparoscopic series are less mature, and late complications might increase the number slightly. Nevertheless, this is still a very low rate that competes favorably with any open nephrectomy series.

Usual presentation of ureteral complications in the recipient includes ureteral leak, necrosis, or stricture. Although the majority of ureteral complications are due to technical errors in harvesting or reimplantation, some distal ureteral strictures can be the result of allograft rejection ischemia.

Most ureteral complications (88%) occur within the first six postoperative months (10). The decrease in ureteral complications seen in the laparoscopic donor nephrectomy series has been attributed to improved technique and preservation of ureteral blood supply in the triangle between the proximal ureter and the lower pole of the kidney. Although definitely not desirable, ureteral injuries are usually reparable and do not have the potential of immediate graft loss.

Laterality of Nephrectomy

Since the inception of living, related kidney donation, the better kidney has always remained with the donor (77).

Historically, the percentage of right kidney donors in the open experience ranges from 26% to 37% (78). Common indications for right-sided donor nephrectomy include multiple left renal arteries or veins, right renal cysts, smaller right kidney, or possibly solitary right-sided nephrolithiasis (79–81).

Sidebar notes (left margin):

Technical modifications included (i) en-bloc wide removal of the periureteral tissue along with the ureter; (ii) preservation of the triangle between the junction of the gonadal vein–renal vein and the lower pole of the kidney; and (iii) en-bloc removal of the entire gonadal vein along with the ureter and all periureteric tissue and resulted in lower ureteral complications.

Although the majority of ureteral complications are due to technical errors in harvesting or reimplantation, some distal ureteral strictures can be the result of allograft rejection ischemia.

Since the inception of living, related kidney donation, the better kidney has always remained with the donor.

The early laparoscopic donor nephrectomy experience concentrated heavily on the left kidney. The reason for this preference included both the known longer left renal vein and the less complex operative exposure of the left renal artery compared to the right one. Also, the short right renal vein presented technical challenges for the recipient surgeon, and a high rate of recipient vein thrombosis following right-sided laparoscopic nephrectomy was concerning. A multicenter review of right-sided laparoscopic donor nephrectomy revealed a higher rate of graft thrombosis (79). As a result, in the initial experience of Johns Hopkins, the University of Maryland, the Washington Hospital Center, and the Seattle group, the left side was preferred in more than 95% of patients (16,18,75,82).

> Right renal vein length is significantly shorter than left donor vein length. Laparoscopic use of the endovascular stapler or multiple clips also contributes to loss of vessel length of approximately 1 to 1.5 cm. The shorter length of the right renal vein may precipitate higher rates of graft thrombosis, because the technical issues of sewing a short renal vein into the recipient can be considerable.

Right renal vein length is significantly shorter than left donor vein length (75). Laparoscopic use of the endovascular stapler or multiple clips also contributes to loss of vessel length of approximately 1 to 1.5 cm (83). The shorter length of the right renal vein may precipitate higher rates of graft thrombosis, because the technical issues of sewing a short renal vein into the recipient can be considerable.

Recipient surgeons have become more comfortable with implanting multiple vessel kidneys (10,21,28,80), and, given the choice, many prefer two arteries with a long left renal vein compared to a single artery and a short right renal vein.

The confidence developed with increased laparoscopic experience and the ability to concentrate on obtaining greater vein length has allowed some programs to start using more right kidneys. The published results of 36 centers on 2691 standard laparoscopic donor nephrectomies show only an 8.6% predilection for the right side, which is higher than the early reports of less than 5% (16,18,75,82).

Technical modifications to maximize renal vein length and thus allow more standard right laparoscopic donations have been made. Mandal et al. at Johns Hopkins report three technical modifications that aid in successful right-sided laparoscopic donor nephrectomies (80). First, ports are placed in a configuration that allows the endovascular stapler to be fired parallel to the vena cava. Second, a small subcostal incision is made at the conclusion of laparoscopic dissection of the right kidney to allow use of a standard Satinsky clamp. This hybrid laparoscopic/open technique allows a cuff of vena cava to be harvested with the right renal vein. Third, the recipient's saphenous vein can be used as a panel graft to lengthen the right renal vein. Buell et al. reported a multi-institutional review of right laparoscopic donors (79). After two early graft losses, Buell et al. modified their technique, including extensive vein mobilization, division of the vein parallel to the vena cava, and incorporation of a portion of the cava into the staple line by stretching the vein with the use of either a hand-assisted device or standard laparoscopic instruments. With these modifications, outcomes of right-sided laparoscopic donor nephrectomy became comparable to that of left donations.

However, the major increase in right-sided donor nephrectomy performance has been due to hand-assisted laparoscopic technique, which affords not only an atraumatic lateral stretch on the kidney to maximize the vein length prior to firing an endovascular stapler, but also superior control of the vena cava in the event of bleeding. Published results from 18 centers on 610 hand-assisted laparoscopic donor nephrectomies show a 40% preference for the right side. Despite the higher and slightly larger extraction site, the hand-assisted laparoscopic technique still offers a similar reduction in convalescence (84,85). The use of the retroperitoneal laparoscopic approach is somewhat more preferentially employed for right donations. Fewer centers use this approach due to lack of anatomic familiarity, but those centers that do report an 11.2% right-sided nephrectomy preference (Table 1).

Turk et al. reported the use of a laparoscopic Satinsky clamp to maximize the length of the right renal vein (86). The clamp was applied to the vena cava at the ostium of the right renal vein, and the entire renal vein with a small cuff of vena cava was harvested. After kidney removal and pneumoperitoneum reestablishment, the cavotomy was closed with a running suture. This maneuver requires a reliable assistant to hold and stabilize the Satinsky clamp during removal of the kidney and closure of cavotomy with delicate laparoscopic suturing technique. Application of this technique is challenging and, therefore, not widely used.

Extraction Sites

Suprapubic, umbilical, lower quadrant, and dorsal lumbotomy extractions all have been performed, and there are only minor differences in discomfort and recovery between these sites. At the time of this writing, transvaginal extraction has not yet been performed. It is hard to imagine any further improvements in outcome with alternative extraction sites because of the size requirement to remove the kidney.

The best site to extract the graft is through an infraumbilical midline or Pfannenstiel incision. Port site hernias may occur and are more common for the larger ports with cutting blades.

Extraction site hernias are fortunately uncommon. They are more likely to occur if an umbilical site or lateral abdominal wall sites are used.

The best site to extract the graft is through an infraumbilical midline or Pfannenstiel incision. Port site hernias may occur and are more common for the larger ports with cutting blades.

UNSOLVED CONTROVERSIES

Vascular Control

Live donor nephrectomy can be a dangerous operation. Five donor deaths have been reported in the United States. Of these, two occurred due to hemorrhage. One of these donors suffered anoxic brain damage and lived in a vegetative state for four years before dying recently (87).

Conversion of a laparoscopic nephrectomy to open nephrectomy is most commonly performed for vascular control. The overall rate of conversion reported is 2.1% in 3478 donors (Table 3).

Vascular injuries are the most feared complication in laparoscopic surgery (88–90). Vascular injuries may occur at the time of peritoneal entry, during placement of the Veress needle or the trocars. Injuries may also occur at any step of the surgical dissection or vascular stapling. Vascular injuries occurring during laparoscopic donor nephrectomy may be classified as minor or major injuries. Minor injuries are defined as those that can be handled laparoscopically without jeopardizing the outcome of the surgery for either the donor or the recipient. Minor bleeding from injury to gonadal, lumbar, or adrenal veins falls into this category. However, if these injuries are not controlled rapidly, they can quickly become major problems. Major vascular injuries are defined as those that result in conversion to open surgery or graft loss. Major vascular injury is the most common cause for conversion to open surgery.

Sixty percent of the vascular injuries requiring open conversion occur during the use of the endovascular stapler. Therefore, complete dissection prior to use and great care in avoiding other clips and staples when applying the endovascular staplers are essential. With major vascular injuries, quick conversion will minimize blood loss and maximize the chances for a successful outcome for both the donor and the recipient.

Sixty percent of the vascular injuries requiring open conversion occur during the use of the endovascular stapler (10). Therefore, complete dissection prior to use and great care in avoiding other clips and staples when applying the endovascular staplers are essential. With major vascular injuries, quick conversion will minimize blood loss and maximize the chances for a successful outcome for both the donor and the recipient.

The optimal technique for vessel control is another point of debate in laparoscopic donor surgery. The current methods of control of renal vessels are laparoscopic clips, endovascular staples, or Hem-O-Lok clips. These methods fail infrequently, but when they do fail, major complications and even donor death may occur. Most centers, including ours, use some form of endovascular staples. Although not perfect, the endovascular staples provide reliable division and simultaneous hemostasis of the renal vessels. As per our experience, staple failure may occur, and one must always be prepared for staple failure (91). Prior to firing any vascular staples, we always double check to ensure that we have vascular clamps and an open tray immediately available for rapid conversion to control bleeding if needed. In the event of a staple misfire and a major vascular injury, a delay in conversion could result in a surgical catastrophe. Another method followed by some centers for achieving vascular control is the use of Hem-O-Lok clips. Proponents of this technique argue that the vascular length is better preserved with this device. However, a single Hem-O-Lok slipping off the renal artery within 24 hours did lead to exsanguination

and a donor death. Therefore, multiple clips should be used for safety. The ultimate goal is to provide the maximum vessel length with the safest method; the renal vein length is especially important. However, this should not in any way comprise donor safety.

Currently, the biggest risk to the donor is potential vascular catastrophe. There is room for device reliability improvement even for the available excellent products.

Skill Levels Required for Teaching

The common obstacle to overcoming high rates of complications in laparoscopic donor nephrectomy has been the steep learning curve. Laparoscopic donor nephrectomy requires much more skill and finesse than laparoscopic radical nephrectomy. There is no margin of error. Superb technique is absolutely essential to obtaining good donor outcome and recipient graph function.

Training laparoscopic donor surgeons is particularly difficult. It is certainly helpful if the donor surgeon trainees already know how to perform an open nephrectomy and have laparoscopic skills. The surgeon needs to be fully trained in open surgery first. In a donor, if conversion to open surgery is required, this will need to be done very quickly and with no warning. The surgeon must pay attention to many little details constantly. The best approach is to have a team of surgeons, and constant interplay between the surgeons is valuable to constantly reaffirm safety. The stress level of these cases is an order of magnitude higher than that with ordinary laparoscopic surgery. In general, an individual surgeon does not really feel comfortable until he has performed more than 100 cases. However, mastering the technical skills is only one part of the equation to a successful donor program.

The real challenge with laparoscopic donor nephrectomy is achieving and maintaining the skill levels required for the entire laparoscopic team. The team participating in the surgery includes surgeons, anesthesiologist, circulating nurses, and surgical technicians. Each one of these team members plays a vital role. Team cohesion, consistency, and skill are all vital to successful outcomes—especially in the event of an emergency.

In these situations, the surgical team's immediate action is paramount. The anesthesia team must try to optimize the renal function and be prepared for potential problems such as bleeding, pneumothorax, and position-induced injuries. Skilled operating room personnel need to know where each piece of equipment is and how to retrieve elements quickly. A kidney donor is ostensibly a *healthy* adult and the requirement for safety is absolutely paramount. Assembling a correct and committed team is the first step to assuring donor safety.

SURGICAL TECHNICAL ISSUES

Approach

There are several laparoscopic techniques in clinical practice that provide good results. Standard transperitoneal, hand-assisted, or retroperitoneal laparoscopy are all techniques that are commonly used. Each technique is associated with advantages and disadvantages, which are shown in Table 3.

The authors prefer a standard transperitoneal approach. The main advantages of the transperitoneal approach are twofold. First, the transperitoneal approach allows for a large working space and good visualization of the entire operative field. Second, in cases of surgical emergency and conversion to an open technique, rapid visualization and access to the great vessels is optimal with the transperitoneal approach. The disadvantage of the transperitoneal approach is the dissection of the intraperitoneal organs in accessing the retroperitoneum. Mobilization of the intra-abdominal organs exposes these organs to potential injury.

Some centers use the retroperitoneal laparoscopic approach for donors (68,92,93). The main advantage of this approach is rapid access to the kidney with minimal dissection. The main disadvantages of this approach are twofold. First, the small working space afforded in this approach allows more limited visualization. Second, in cases of surgical emergency, rapid access and visualization of the great vessels may be cumbersome. A group in Tokyo recently performed retroperitoneal laparoscopic donor nephrectomy and removed the kidney at an extraperitoneal suprapubic extraction site (93). This combination may well prove the least morbid for the doors. Most surgeons, however, are more familiar with the transperitoneal approach and, therefore, it is likely to remain the most popular approach.

The disadvantage of the transperitoneal approach is the dissection of the intraperitoneal organs in accessing the retroperitoneum. Mobilization of the intra-abdominal organs exposes these organs to potential injury.

Rudich et al. reported good results with the hand-assisted laparoscopic approach (94). The main advantage of hand-assisted laparoscopic surgery is the ability to maintain tactile sensation. Because of the tactile feedback and the ability to use effective compression, the actual conversion rate for hand-assisted laparoscopic donor nephrectomy is lower compared to that for standard laparoscopy. The 1.2% conversion rate for hand-assisted laparoscopic donor nephrectomy is half of the rate for the other approaches (Table 1). Many argue this advantage of hand assistance may lower the steep learning curve associated with pure laparoscopic techniques. The main disadvantages of hand-assisted surgery are forearm fatigue that the surgeon experiences at the site of the hand port and cost of the device. Hand-assist devices add considerable cost to the procedure, which Wolf et al. estimated as high as 11% of the total operating room cost (95).

Robotics

Robotic laparoscopic donor nephrectomy has been documented. The use of robotics is not accepted as advantageous for this procedure. In the donor nephrectomy procedure, the camera movements require wide swings, which are too frequent and complex for the robot to react as quickly as a human assistant. It seems unlikely that robotic technology will provide any improvements in technique in the immediate future.

DONOR EVALUATION

A multidisciplinary team of transplant coordinators, social workers, psychiatrists, nephrologists, transplant surgeons, and donor surgeons provides protection for the donor. The evaluation process includes questionnaire screening of medical and psychosocial status, diagnostic studies, and, finally, informed consent. Contraindications to donation are shown in Table 3. Total creatinine clearance over 80 mL/min is required to qualify as a donor. Obese individuals and those who have a diabetic first-degree relative should undergo glucose tolerance testing. All donors undergo screening chest X-ray and electrocardiogram. Patients over 50 years of age should undergo additional cardiac stress testing. Female candidates should undergo PAP Anicolav smear and mammography (over 40 years of age). Prostate specific antigen and digital rectal exam screening is performed in men over 40 years. Repeated routine blood pressure measurements recording a systolic pressure below 140mmHg and a diastolic blood pressure below 80 mmHg are required. Borderline readings are evaluated with 24-hour blood pressure monitoring. After all the tests are done, a helical computed tomography (CT) arteriogram of the abdomen and pelvis is performed. This study is accurate in determining vascular anatomy (96–98), renal volume, renal masses, and stones. The excretory phase provides anatomic detail of the collecting system and ureters. The donor surgeon is responsible for obtaining informed consent. Just prior to the surgery, a final repeat crossmatch is performed.

EXPANSION OF LIVE RENAL DONATION

The frontier of laparoscopic donor nephrectomy is now focused on safely broadening the donor pool (99). Acceptable candidates may now include older donors, unrelated donors, on call emergency donors for recipients needing concomitant pancreas transplantation (100), obese donors (101), voluntary prisoners, paired-exchange donors, and Good Samaritan donors. Table 4 shows the remaining contraindications for live renal donation, although some of these contraindications may be overcome.

Patients who may ultimately be significantly harmed by the donor surgery or suffer long-term consequences from having a solitary kidney must be protected. There have been five known donor deaths (87) (personal communication), due to embolism, hemorrhage, respiratory failure, or undetermined cause. Reporting to United Network for Organ Sharing is voluntary and, therefore, it is possible that underreporting exists.

In expanding the spectrum of donors, there are controversial areas. Clearly, the demand for kidneys is growing at a far greater rate than the supply. While the cadaver pool has remained stable, living donor nephrectomy has grown steadily. Since 2001, live donor renal transplants have exceeded cadaveric transplants according to United Network for Organ Sharing reports.

Age

Aging of the general population and the attendant increase in End stage renal disease has widened the gap between available cadaver kidneys and demand. It appears that there is the development of an organ "social security" system in which younger donors

> In expanding the spectrum of donors, there are controversial areas. Clearly, the demand for kidneys is growing at a far greater rate than the supply. Absolute	Comments	Relative	Comments
Positive crossmatch	Desensitization protocol	Blood type incompatibility	Desensitization protocol
Monetary incentive		Positive flow cytometric crossmatch	Desensitization protocol
Chronic kidney disease			
Anatomic kidney abnormalities		Heart disease	Age above 50 yrs; require stress test
Diabetes		Hypertension	Blood pressure above 140/85 mmHg; may require 24 hr home monitoring
Pregnancy	Donate after delivery		
Active infection			
		Abnormal glucose tolerance	
		Obesity	Above 35 kg/m^2 (body mass index); may require weight loss
		Malignancy	No evidence of disease
		Hepatitis	
		Tuberculosis	
		Psychiatric disease	
		Chronic nephrotoxic drugs	
		Kidney stone history	Metabolic workup, 24 hr urine studies, and CT scan

Abbreviation: CT, computed tomography.

supply kidneys for older end-stage renal failure patients. Laparoscopic renal donation by elderly donors has been shown to be safe and efficacious (102), and an elderly source may alleviate some of the pressure on the younger generation.

Obesity

Obese donors present technical challenges. Jacobs et al. reported that markedly obese patients required longer operative times (approximately 40 minutes) when compared to nonobese donors (101). Obese donors are also more likely to require conversion to open surgical nephrectomy. Chow et al. (56) have recommended using the hand-assisted technique with a paramedian hand port as an alternative to standard laparoscopic donor nephrectomy in the obese donor.

There is no difference in recipient graft function when received from obese donors. However, the future health and well-being of obese donors is a real concern due to the significant risk factor for future diabetes and hypertension. The long-term health and renal function of obese donors with a solitary kidney is unknown.

However, because obesity becomes pandemic in some donor subgroups (e.g., African-American females), the inclusion of obese donors will be required to keep transplant programs functioning.

Renal Stones

Donors with stones or a history of stones require additional workup and considerations. First, the age of the donor must be considered. Young adults with stones or a history of stones are probably not good candidates for donation. In older adults, a history of stones may not necessarily disqualify them as donors.

Many remote stones were never well documented, and often, muscle skeletal pain is assigned the diagnosis of "kidney stone." Metabolic workup including serum studies and two random 24-hour urine studies are recommended. When metabolic studies are normal and imaging shows no evidence of stones, the donor evaluation should be continued. In older adults with a small, unilateral stone, the affected kidney may be taken in donation because the future risk of stones is very low.

Renal Cysts

Simple renal cysts are common in the older adult population and should not disqualify a donor. Complex cysts should be approached with caution, because some of these may, in fact, harbor a malignancy.

There is no difference in recipient graft function when received from obese donors. However, the future health and well-being of obese donors is a real concern due to the significant risk factor for future diabetes and hypertension. The long-term health and renal function of obese donors with a solitary kidney is unknown.

Young adults with stones or a history of stones are probably not good candidates for donation. In older adults, a history of stones may not necessarily disqualify them as donors.

Simple renal cysts are common in the older adult population and should not disqualify a donor. Complex cysts should be approached with caution, because some of these may, in fact, harbor a malignancy.

Potential donors with previous malignancy can still be donors. However, donor age, the type of malignancy, and the potential need for chemotherapy affect their candidacy.

With the fine-cut computed tomography scans currently in use, many patients are now being diagnosed with "too small to characterize" lesions. These are likely to represent simple cysts and should not disqualify the donor. In general, we advocate removing the kidney with the renal cyst. However, we tend to remove the left kidney if the cyst is a "too small to characterize" lesion on the right kidney. Patients with simple small bilateral cysts are not disqualified and the kidney with the largest cyst is chosen.

Malignancies

Potential donors with previous malignancy can still be donors. However, donor age, the type of malignancy, and the potential need for chemotherapy affect their candidacy.

Further, the malignancy must not adversely affect the recipient by transmission to the recipient (103). The risk of transferring malignancy from a donor with a history of common malignancies, such as localized prostate, skin, or colon cancer, is low. In general, the donor must be without any evidence of disease for at least 18 months prior to their donating.

Kidneys with small renal tumors (less than 3 cm) have been successfully transplanted into marginal recipients following excision of the renal tumor (104). No recipients have developed malignancy with a mean follow-up of 33 months.

Other Measures

A number of research developments or social changes may open up a larger number of potential living donors. These include bridging the problem of ABO-incompatible transplants (105,106) and evading the positive recipient–donor crossmatch by either recipient treatment (107–109) or paired exchanges (110,111). Paid renal donation (112–114), as is done in parts of the world, might profoundly alter the application of laparoscopic nephrectomy.

CURRENT STATUS OF LAPAROSCOPIC APPROACH

It has long been documented that grafts from living kidney donors show superior function and survival when compared to those from cadaver donors. Open donor nephrectomy has been performed successfully for nearly five decades with low rates of complications and graft loss. Donor nephrectomy is a unique surgery because the outcomes and complications affect both the donor and the recipient. Mis-steps that occur during the harvest may ultimately affect the donor and graft function. The initial laparoscopic experience did not meet the standards of the traditional open surgery technique. The University of Maryland and Johns Hopkins demonstrated an overall complication rate of 14.3% and 17%, respectively (9,75). The most common areas of initial concern, such as ureteral injury, vascular injury, and warm ischemia time, have diminished but not completely disappeared, with increased surgical experience.

Laparoscopic donor grafts have been shown over the short term to function as well as open donor grafts (10,115). Many centers have demonstrated good short-term follow-up of graft survival in kidneys procured with the laparoscopic techniques. Montgomery and coworkers report 94% graft function at five years (115). The jury is still out as regards how long these grafts will function. Living donation is a personal sacrifice for the donor. Therefore, every effort should be made to maximize long-term graft survival. In a large series of living donors from the University of Minnesota, risk factors for worse long-term recipient graft survival included pretransplant smoking, pretransplant peripheral vascular disease, pretransplant dialysis for more than one year, acute rejection episodes, and donor age over than 50 (116). Out of respect to the donor, detrimental factors in the recipient should be modified as much as possible.

Expansion of Laparoscopic Approach

Pain, extended hospitalization, time away from work, and long-term disability are barriers to potential donors. The laparoscopic approach provides potential donors with a minimally invasive alternative to open donor nephrectomy. Laparoscopic donor nephrectomy has definitely decreased hospitalization. The average hospital stay for 2339 standard transperitoneal donors reported has been 2.9 days. There is a clear difference between the United States and the rest of the world, where pressure for decreasing length of stay is not as strong. In the United States, transplant programs are even moving to 24-hour stays for donors (27).

In addition to decreasing convalescence, laparoscopic donor nephrectomy is associated with less blood loss when compared to open surgical techniques, though transfusion rates are probably indistinguishable from open surgery.

The introduction of laparoscopic donation has increased the number of donors at many transplant centers (40,117). By the year 2001, nearly two-thirds of the living donor nephrectomies in the United States were performed using a laparoscopic technique (118).

At the University of Maryland, 925 laparoscopic donor nephrectomies have been performed from 1996 to 2004; over the same time frame, only 37 open donor nephrectomies have been performed (3.8%).

It is evident that the laparoscopic approach, while not perfect, has done well enough to be considered the first-choice approach for a majority of donors. However, laparoscopic donor nephrectomy is more expensive than open donor nephrectomy, as shown by Mullins et al. (119) in a study evaluating the actual Medicare expenditures, which found that all transplantations were less expensive than dialysis in the long term.

Cadaveric transplantation reaches a break-even point in costs over dialysis at 18 months posttransplant. Laparoscopic living donation reaches the break-even point at 14 months posttransplant. Open donor nephrectomy was most efficient costwise, reaching a break-even point at only 10 months posttransplant compared to dialysis. So, there is a dollar cost to the benefits of laparoscopy for the donors.

However, living donors are not always the best transplant option for all recipients. There are situations when a cadaver kidney may be better than one from a living donor. Mandal et al. suggest that a young cadaver kidney with fewer human leukocyte antigen mismatches may be better than an older living donor kidney (80).

International Experience

Laparoscopic donor nephrectomy has rapidly spread from its origins, largely in Maryland, throughout the United States. Moreover, it has grown rapidly on the international scene as well. Laparoscopic donor nephrectomy is being performed successfully in Europe, Asia, the Middle East, Australia, Africa, and South America. Laparoscopic donor nephrectomy is performed by urologists, transplant surgeons, or general surgeons.

Because laparoscopic nephrectomy is currently more commonly performed than the open technique, a potential problem for donor surgery in the future is the lack of open nephrectomy experience. Open surgical techniques and skills are essential for emergency conversions, and their lack thereof is a big concern.

SUMMARY

- The introduction of laparoscopic donation has increased the number of donors at many transplant centers. By the year 2001, nearly two-thirds of the living donor nephrectomies in the United States were performed using a laparoscopic technique.
- Laparoscopic donor nephrectomy requires much more skill and finesse than laparoscopic radical nephrectomy. There is no margin of error. Superb technique is absolutely essential for good donor outcome and recipient graft function.
- The laparoscopic approach, while not perfect, is considered the first-choice approach for the majority of donors.
- Good short-term follow-up of graft survival after laparoscopic donor nephrectomy has been demonstrated at many centers.
- During laparoscopic donor nephrectomy, the biggest risk to the donor is potential vascular catastrophe.
- Laparoscopic donor nephrectomy is associated with longer warm ischemia time when compared to open surgery. However, the duration of warm ischemia does not correlate with recipient creatinine levels or delayed graft function.
- Total operating time of laparoscopic donor nephrectomy is comparable to that of open surgery, whereas blood loss and hospitalization are decreased.
- The laparoscopic approach is more expensive than open donor nephrectomy.

COMMENTARY

John M. Barry
Division of Urology and Renal Transplantation, The Oregon Health & Science University, Portland, Oregon, U.S.A.

Laparoscopic donor nephrectomy is a remarkable technical achievement. This chapter traces the evolution of the technique in the center with the world's largest experience. As the authors correctly state, in order for laparoscopic donor nephrectomy to gain wide acceptance, it had to meet the standards set by open nephrectomy. It has come close.

Warm ischemia time continues to be a bit longer than that reported for open donor nephrectomy, simply because of the extraction procedure, which includes, in some cases, resection of staple lines on the renal artery and renal vein so that the kidney graft can be flushed with ice-cold preservation solution. The citation that reportedly showed that there was not a strong correlation between warm ischemia time and long-term graft function for first cadaver kidney transplants is a bit misleading because the warm ischemia times greater than 20 minutes seem to have been confused with reanastomosis or rewarm times (1). In that reference, five-year first cadaver kidney graft survival rates were appropriately decreased in a stepwise fashion from 66% to 59% when warm ischemia times increased from 0 to 20 minutes; however, five-year corresponding kidney graft survival rates when warm ischemia times increased from 21 to 40 minutes were 66% and 61%, respectively.

Although many single-center studies that compared laparoscopic donor nephrectomy with open donor nephrectomy reported similar short- and intermediate-term results for both techniques, the United Network for Organ Sharing (United Network for Organ Sharing) registry reported poorer graft survivals by 3% at three years and reduced kidney transplant half-life projections by 2.1 years for laparoscopically retrieved kidney transplants when compared with kidney grafts removed by an open flank approach (2).

The preponderance of laparoscopic left donor nephrectomies suggests that the principle of leaving the better kidney with the donor (3) has been compromised because of the more favorable anatomy of the left kidney. The more normal kidney should be left with the donor and, in the case of women who may become pregnant and who otherwise have two equivalent kidneys, we think the right kidney should be used because pyelonephritis and hydronephrosis of pregnancy are more common in that kidney (4).

As the authors state, laparoscopic donor nephrectomy has become routine for kidneys with multiple renal arteries, and it has been reported that heparinization of the laparoscopic kidney donor is unnecessary (5).

The problem of short donor renal vessels in the laparoscopically retrieved organs has been lessened by the complete mobilization of the pelvic vessels in the recipient to allow anterior displacement of the vascular targets.

Although laparoscopic donor nephrectomy teams have apparently solved the technical problems associated with donor obesity, this donor source should be used with caution because obesity has been shown to put these uninephrectomized patients at risk for subsequent proteinuria and chronic renal failure (6).

The more rapid recovery of the patient from laparoscopic donor nephrectomy has made living donor nephrectomy more acceptable to donors and recipients, the latter because there is less guilt associated with what is perceived by the recipient to be a lesser procedure for a donor who undergoes the laparoscopic procedure.

To the authors I say, "Well done, but please leave the better kidney with the donor, and do not take kidneys from donors who are at risk for developing proteinuria and/or renal failure in the years following donation."

CHAPTER 29

LAPAROSCOPIC URETERAL SURGERY: NONCALCULOUS APPLICATIONS

Thomas H. S. Hsu and Keith L. Lee

Department of Urology, Stanford University Medical Center, Stanford
University School of Medicine, Stanford, California, U.S.A.

INTRODUCTION

With most published data based on case reports and small case series, utilization of laparoscopy for noncalculous ureteral surgery remains in its infancy. However, as the urologic community's experience with laparoscopy grows, a dramatic increase in laparoscopic applications to the ureter is likely to be seen in the next decade. The principles of surgical approaches to the retrocaval ureter, idiopathic retroperitoneal fibrosis, transureteroureterostomy, cutaneous ureterostomy, and ureteroneocystostomy in adults are discussed in this chapter.

RETROCAVAL URETER

Persistence of the lumbar segment of the subcardinal vein beyond early development results in the formation of the retrocaval ureter (also known as the circumcaval ureter or preureteral vena cava).

Anatomically, the right ureter is affected, and the retrocaval segment is located dorsal to the vena cava as it travels down from the kidney to the bladder. The retrocaval ureter can either encircle the cava by crossing it ventrally from medial to lateral before reaching the bladder or simply lie dorsal to the cava for a segment without wrapping around the cava completely and end in the bladder distally. In both anatomic forms, the retrocaval ureteral segment is susceptible to proximal urinary obstruction as the ureter takes this tortuous "reverse-J" or "S-shaped" course down to the bladder. When obstructive symptoms of flank pain or renal parenchymal loss develop, surgical repair is indicated.

The principles of repair with the laparoscopic approach are similar to those of open surgery. The retrocaval ureteral segment has to be mobilized to a location anterior and lateral to the cava. When the ureter encircles the cava, dismemberment with reanastomosis is needed. When the ureter does not encircle the cava, a simple ureterolysis may be sufficient.

Baba et al. first reported the transperitoneal laparoscopic management of the retrocaval ureter in 1994 (1). Their success was subsequently confirmed by several other investigators (2,3). In the typical transperitoneal approach, cystoscopy is first performed with placement of a double J-stent in the ureter (1–3). The patient is then placed in a right lateral position with 45 to 70 degree of table-tilt to allow the ascending colon to fall away from the operative field. The camera port is usually placed at the umbilicus, and three working ports are placed at the ipsilateral mid-clavicular line subcostally, at the iliac fossa, and in the ipsilateral flank. The last port at the flank may be optional depending on the patient's anatomy (4). Following successful trocar placement and establishment of pneumoperitoneum, the white line of Toldt is incised, and the ascending colon is mobilized and reflected medially. Upon entering the retroperitoneum, the ureter is mobilized with sharp and blunt dissection. Once mobilized, the ureter is transected just distal to the obstructive, circumcaval segment, and the ureteral catheter is withdrawn distally. If stenotic, the retrocaval segment is then

369

excised, and the distal ureteral stump may be spatulated prior to reanastomosis to the proximal ureteral segment. In cases where the retrocaval ureteral segment cannot be freed easily from the cava, it can be left in situ after dividing the ureter both proximally and distally to this segment. The proximal and distal ureteral ends are then brought anterior and lateral to the cava for reanastomosis with interrupted absorbable sutures over the ureteral stent. In the end, a closed suction drain is placed in the retroperitoneal space, and a Foley catheter is left in the bladder for one to two days after surgery.

The retroperitoneoscopic approach has also been used by several investigators with success (5–8). The patient is similarly placed in a modified flank position with a more exaggerated table-tilt. The surgical approach to ureterolysis, ureteral transection and reanastomosis to create a more anterolateral position for the ureter is similar to that for the transabdominal approach.

The advantage of retroperitoneoscopic approach compared to the transperitoneal method is that bowel mobilization is minimized. In addition, the retroperitoneal approach avoids urinary spillage into the peritoneum, which may reduce the risk of subsequent intraperitoneal adhesion formation. The main disadvantages include limited working space (9).

The first reported cases on laparoscopic surgical management of retrocaval ureter took 9.3 hours with the end-to-end ureteral anastomosis requiring almost 2.5 hours. The authors found that laparoscopic suturing of the anastomosis was the most difficult part of the operation (1). Despite the long operative duration, the patient's recovery was uneventful, and he did not require any analgesics postoperatively. Although not commented on specifically, the patient remained in the hospital until postoperative day 9 and subsequent convalescence was "brief."

With refinement in laparoscopic techniques, experience, and perioperative management, operative times have decreased in contemporary cases to 3.5 to 4.1 hours with the transperitoneal approach (2,4,9), and to 3.5 to 4.5 hours with the retroperitoneal approach (5,6). In either approach, patients do remarkably well after surgery with minimal postoperative pain and short convalescence. Ramalingam and Selvarajan and Gupta et al. reported the use of only nonopiate analgesics after surgery (2,5); while Polascik and Chen found that analgesics were not required beyond postoperative day one (4). Operative blood loss is insignificant in these cases, and patients now stay two to five days after surgery. The ureteral stent may be removed at four to eight weeks depending on the surgeon's preference, and follow-up nuclear drainage studies may be obtained afterwards to evaluate drainage.

Given the small number of cases reported in the literature and bias from case selection and the surgeon's experience, it is difficult to compare the transperitoneal approach to the retroperitoneal approach critically.

In the hands of experienced surgeons, operative time today is approximately four hours. Both approaches are well tolerated by patients with minimal blood loss and little need for postoperative analgesic beyond several days. Most investigators report a short convalescence, and patients are back to work in one to two weeks.

IDIOPATHIC RETROPERITONEAL FIBROSIS

Idiopathic retroperitoneal fibrosis is a chronic inflammatory process that comes to urologic attention when extrinsic compression and encasement of the ureter by surrounding retroperitoneal tissues cause ureteral obstruction. The progressive nature of the inflammatory process can lead to flank pain and renal deterioration. Radiographic findings on intravenous pyelogram or retrograde pyelogram may include medial deviation of the involved ureter and the absence of intraluminal obstruction. Whitaker test as well as nuclear functional studies often demonstrates delayed drainage as a result of extrinsic ureteral compression. Causes of retroperitoneal fibrosis are myriad and include inflammatory bowel disease, vascular aneurysms, radiation, malignancies, retroperitoneal bleeding, and idiopathic, which accounts for the majority of cases.

The laparoscopic approach to the idiopathic retroperitoneal fibrosis ureter remains challenging with only a few cases described in the literature (10–14).

The principles of the laparoscopic approach include biopsy of the retroperitoneal tissues for histologic diagnosis and complete ureterolysis.

First reported by Kavoussi et al. in 1992, laparoscopic dissection and mobilization of the entrapped ureter are feasible but can be technically challenging (10). The extent of retroperitoneal fibrosis often determines the level of technical difficulty, as

longer affected ureteral segments (≥5 cm) require longer operative time than shorter ones (≤2 cm) (11).

The laparoscopic surgical approach to idiopathic retroperitoneal fibrosis is similar to that used for the retrocaval ureter (1–4,10,11). After the placement of a ureteral stent, the patient is typically placed in a modified flank position (10,11). The laparoscopic camera port can be placed along the anterior axillary line 2 cm above the umbilicus. Typically three other working ports are needed on the ipsilateral side: one port along the mid-clavicular line at 2 to 3 cm below the costal margin, one at the level of the umbilicus, and one at 2 to 3 cm above the anterior superior iliac spine. In cases where both ureters are affected and require surgical mobilization, additional ports are placed in the corresponding locations on the contralateral abdomen. In more difficult cases, surgical management of the second ureter can be performed in a staged manner (12).

Following mobilization of the colon, a biopsy of the retroperitoneal fibrotic tissue is first taken for diagnostic purposes. Then ureterolysis can be initiated either near the renal hilum or below the iliac vessels, the two locations where the ureter is typically not involved with the fibrotic process. Using blunt and sharp dissection techniques, the ureter is mobilized circumferentially. Use of a vessel loop or Penrose drain around the freed portion of the ureter can provide needed traction and facilitate dissection. Once ureteral mobilization is complete, the ureter is retracted anteriolaterally into the peritoneal cavity. The parietal peritoneum is reapproximated with sutures or clips to close the retroperitoneal defect, and normal intraperitoneal fatty tissue or the greater omentum can be interposed between the ureter and the retroperitoneal defect. It is important not to kink the ureter excessively in its lateral intraperitoneal placement. The ureteral stent is left in place for two to three weeks, and follow-up nuclear functional studies are recommended at three to six months postoperatively to evaluate urinary drainage.

The laparoscopic approach remains technically challenging with operative times for unilateral ureterolysis that range from 195 to 330 minutes (10,12,14). In certain cases, bilateral ureterolysis at the same setting maybe successful; however, it is not unreasonable to approach each side at a different setting should dissection become too difficult (12). Postoperative hospitalization ranged from 3 to 10 days, and blood loss was negligible in these cases (10,12,14). In the casecontrol report by Elashry et al., laparoscopic unilateral ureterolysis for idiopathic retroperitoneal fibrosis was compared to open surgery (14). In the two laparoscopic cases, mean estimated blood loss was 100 cc compared to 400 cc in the five open cases for idiopathic retroperitoneal fibrosis. Blood transfusions were required in two of the five open cases and not in either of the laparoscopic cases. Parenteral analgesic (morphine) requirement after surgery was dramatically different in the two groups with the laparoscopic group requiring only 2 and 3 mg compared to an average of 143 mg (range, 50–267 mg) in the five open cases. Convalescence was two to three weeks from the laparoscopic group and six to eight weeks for the open group. However, given the small number of cases in this report and possible bias in case selection, the data must be interpreted with caution.

When considering the body of literature on laparoscopic ureterolysis in idiopathic retroperitoneal fibrosis, the advantages include lower operative morbidity, blood loss, postoperative analgesic requirements, and shorter convalescence compared to traditional open approaches. Given the rarity of idiopathic retroperitoneal fibrosis, its uncertain natural history, and the lack of long-term outcome data, close patient follow-up is crucial in the postoperative setting.

TRANSURETEROURETEROSTOMY

The laparoscopic approach to transureteroureterostomy remains in its infancy with no documented clinical case in the literature. This may be due to the fact that there are few indications for a transureteroureterostomy and that there are more attractive alternatives such as bladder flaps or ileal ureteral replacements that would not affect the "contralateral" renal unit. Similarly, in cases of palliative surgery to relieve urinary obstruction, simple percutaneous drainage or a laparoscopic cutaneous diversion is much easier. Nevertheless, Dechet et al. demonstrated that laparoscopic transureteroureterostomy is technically feasible in a porcine model (15). Operative times ranged from 2.5 to 6 hours and eight out of nine procedures were successful. Whether this technique will be applied clinically remains to be seen.

CUTANEOUS URETEROSTOMY

Laparoscopic cutaneous ureterostomy is a valuable palliative procedure in the management of distal ureteral obstruction from advanced pelvic cancers such as prostate, bladder, and uterine cancer.

It is a more permanent form of urinary diversion than percutaneous nephrostomy and may be more advantageous in patients who require repetitive nephrostomy tube exchanges (16). Puppo et al. reported their initial experience in four cases with excellent results. Operative times ranged from 1.2 to 2.2 hours, and estimated blood loss was negligible in one, less than 50 cc in two, and less than 150 cc in the fourth case. All patients tolerated the procedure well and were discharged home between postoperative day 5 to day 11 (17). These same investigators then reported six more laparoscopic cutaneous ureterostomies via both the transperitoneal and retroperitoneal approach with similar success (18). Operative times were similar between 35 minutes to 2.2 hours minutes, and postoperative patient analgesic requirements were minimal. The technical approach to the ureter is similar to that already described in the above sections. The cutaneous stoma can be matured at any convenient site on the abdominal wall as performed in open surgery.

In a slight variation of simple diversion, cutaneous ureterostomy can also be used for urinary bladder diversion in the form of a catheterizable stoma for selected patients with a neurogenic bladder. Strand et al. reported an interesting case where the ipsilateral ureter from the nonfunctioning renal unit was brought out to the skin and used as a cutaneous catheterizable ureterovesicostomy (19). The laparoscopic portion of the case was 250 minutes, and postoperative recovery was uneventful.

URETERONEOCYSTOSTOMY

Distal ureteral reimplantation or ureteroneocystostomy in adults is indicated in the setting of distal ureteral stricture disease or ureteral injury sustained during gynecologic or pelvic laparoscopic surgery. While both refluxing and nonrefluxing reimplantations have been performed laparoscopically in adults, the former is much more common. The first laparoscopic ureteroneocystostomy was reported by Reddy and Evans for the treatment of a 1-cm distal obliterate ureteral stricture that developed in a 74-year-old man as a delayed complication of transurethral resection of the prostate (20). Operative time in this transperitoneal refluxing reimplant was 4.5 hours, and estimated blood loss was less than 50 cc. The patient required only four tablets of acetaminophen/codeine for pain control during the first 36 hours after surgery and was discharged home on postoperative day 2. His recovery was unremarkable and at one-year follow-up, he had excellent urinary drainage documented by excretory urogram.

Attesting to the feasibility of laparoscopic ureteroneocystostomy, other investigators have reported excellent results in the treatment of secondary ureteral stricture due to perforations from ureteroscopy as well as in gynecologic cases where infiltrative ureteral endometriosis or inadvertent ureteral injuries necessitate distal ureteral resection and reimplantation (21–25).

In performing laparoscopic ureteroneocystostomy, placing the patient in a low dorsal-lithotomy position is ideal, and the table is tilted at 15 to 45 degree of Trendelenburg to allow overlying bowel fall out of the pelvis (20–25). A transperitoneal approach provides excellent exposure and is important in longer strictures where a bladder psoas hitch may be needed for a tension free repair. Typically, four ports are needed. After creation of pneumoperitoneum and medial mobilization of the colon, the ureter is identified and circumferentially mobilized where it crosses the iliac vessels. An umbilical tape or vessel loop can be placed around the ureter and used for traction during dissection distally toward the bladder. Care is taken to preserve periureteral blood supply and avoid thermal injury from overly aggressive use of coagulation. The ureter is transected, and the pathologic ureteral segment is resected or ligated and left in situ. The proximal end of the ureter is inspected and then spatulated in preparation of reimplantation. The bladder is filled with saline, and under both cystoscopic and laparoscopic visualization, a location closest to the spatulated ureter is selected for the cystostomy. A 1–2 cm full-thickness cystostomy is made.

The typical refluxing anastomosis is created with four to five interrupted fine absorbable sutures that traverse all layers of the bladder and the ureter.

Intracorporeal and extracorporeal knot-tying as well as the Endostitch device can be used to bring the ureter and bladder together. Nonrefluxing anastomosis has also

been reported in the clinical setting with success (25–27). In either nonrefluxing or refluxing reimplants, it is also important to avoid tension, ureteral torsion and angulation. When additional length is needed, the ureter can be mobilized further proximally or a vesicopsoas hitch can be used (22,23). At the end, the repair is then tested by bladder filling and direct laparoscopic visualization. At the conclusion of the repair, a pelvic drain is left for one to two days, and the ureteral stent is left for four to six weeks. Follow-up intravenous pyelograms or retrograde pyelograms should be obtained to ensure continuity and patency. Given the fact that indications for ureteral reimplant vary and that reimplantations are sometimes performed at the same setting of other gynecologic procedures such as hysterectomies, data on operative times, blood loss, and postoperative hospitalization are difficult to compare. In general, laparoscopic ureteroneocystostomy takes three to four hours (3.5–4.5 hours) with estimated blood loss of less than 50 cc (20,21,25). Patients can expect minimal postoperative pain, a short convalescence and excellent urologic outcomes.

SUMMARY

- The laparoscopic approach to the ureter is not only feasible but has been shown to provide significant advantages over traditional open surgery in terms of lower postoperative analgesic requirements, shorter convalescence and improved cosmesis.
- Although the acceptance of laparoscopic ureteral surgery trails that of ablative surgeries such as radical nephrectomy and nephroureterectomy, the minimally invasive approach to the ureter will likely become a powerful tool in the urologist's surgical armamentarium.
- Different laparoscopic approaches to the retrocaval ureter, idiopathic retroperitoneal fibrosis, transureteroureterostomy, cutaneous ureterostomy, and ureteroneocystostomy have been used successfully.
- Greater clinical experience is expected to be available with increasingly wider acceptance and application of laparoscopy in urology.

INTRODUCTION

Lymphocele has been reported after a variety of different procedures. Typically, it occurs after pelvic lymphadenectomy or renal transplantation but has also been observed after retroperitoneal lymphadenectomy or aortic graft placement. Etiologic factors associated with lymphocele development include transected lymphatics, increased lymphatic flow, delayed healing, or deficiencies with the intrinsic clotting mechanism. Specifically, these include prior radiotherapy, extensive dissection, lack of peritoneal communication, reoperations, and the administration of perioperative mini-dose heparin, diuretics, high-dose steroid medication, or immunosuppressants. The surgical approach, the number of transected lymphatics around renal grafts, and transplant rejection episodes are also factors associated with the development of lymphocele (1–4) Whatever the causative agent(s), the result is accumulation of lymphatic fluid in an epithelialized, confined space, which may or may not result in symptoms.

Studies have shown that both open and laparoscopic pelvic lymphadenectomies result in similar amounts of lymph node extirpation (5). However, open pelvic lymph node dissection for prostate cancer has been reported with a lymphocele formation rate of 3.2% to 14.8% (3,6,7). Additional studies have focused on the occurrence of lymphocele formation after laparoscopic transperitoneal lymphadenectomy for prostate cancer. Earlier observations by Fried et al. reported on symptomatic lymphoceles after laparoscopic transperitoneal lymphadenectomy and noted a 3.5% incidence in a group of 57 patients when compared with 6.5% incidence of lymphoceles after extraperitoneal laparoscopic transperitoneal lymphadenectomy (8). More recently, additional authors have reported rates of 1.1% in a large series of 177 laparoscopic transperitoneal lymphadenectomys in comparison to 1.54% to 2.4% after laparoscopic extraperitoneal approach (9,10).

> The exposure to the peritoneal surface results in the absorption of lymphatic fluid and forms the basis of surgical therapy for lymphocele treatment through either an open or laparoscopic approach.

The exposure to the peritoneal surface results in the absorption of lymphatic fluid and forms the basis of surgical therapy for lymphocele treatment through either an open or laparoscopic approach.

Traditionally, treatment of a lymphocele required open surgical fenestration to allow the lymphatic drainage to be reabsorbed by the peritoneal cavity. However, since the initial description by McCullough et al. in 1991, along with technologic advances and increased surgical experience, laparoscopic marsupialization of lymphoceles is now the proposed first-line approach (11,12).

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

> Since the initial description by McCullough et al. in 1991, along with technologic advances and increased surgical experience, laparoscopic marsupialization of lymphoceles is now the proposed first-line approach.

The indications for lymphocelectomy are based on the development of clinical symptoms as the majority of lymphoceles remain asymptomatic (13,14). Most lymphoceles tend to be small in size and remain clinically insignificant. In a longitudinal study by Spring et al. spontaneous resolution of the majority of lymphoceles after open pelvic lymph node dissection was observed. However, larger lymphoceles or those that persisted became clinically significant and required some form of intervention (3,9,15).

Albeit rare, clinically significant lymphoceles develop in approximately 1.1% to 10% following pelvic lymph node dissection and 0.5% to 12% following renal transplantation and are one of the most important predisposing factors for incisional hernia in the transplant population (13,16,17).

Clinically significant lymphoceles present in several different manners depending on their precipitating cause. The most common occurence is after a pelvic lymph node dissection, In these cases, patients will present with lower abdominal discomfort or swelling, fever, ipsilateral lower extremity swelling, deep venous thrombosis, scrotal swelling, lymphocutaneous fistula, or incidentally on computed tomography for adjuvant radiotherapy to treat prostate cancer. Presentation following pelvic renal transplantation is similar, with the addition of perinephric fluid collections, renal failure, or suspected graft rejection.

In the largest series to date, Hsu et al. performed a multicenter study evaluating current treatment strategies used for the treatment of lymphoceles. In the cohort evaluated, 96% of lymphoceles developed after renal transplantation and 4% after pelvic lymphadenectomy (13). Hence the majority of lymphoceles encountered will be in those patients who have undergone renal transplantation.

Percutaneous needle aspiration has been described as an initial attempt to manage symptomatic lymphoceles. However, high recurrence rates are reported ranging from 42% to 100% (17–19).

Percutaneous needle aspiration has been described as an initial attempt to manage symptomatic lymphoceles. However, high recurrence rates are reported ranging from 42% to 100% (17–19).

Moreover, attempts at percutaneous aspiration with concomitant instillation of sclerosing agents such as minocycline, tetracycline, ampicillin, alcohol, povidine-iodine, and fibrin sealants may cause an inflammatory reaction such that ureteral obstruction may occur, increasing the difficulty of dissection by either laparoscopic or open technique (13,20,21). Furthermore, the potential for contaminating a potentially sterile space exists as well.

Like most procedures, experience of the surgeon is inversely proportional to complication rates. The clinically significant lymphoceles that follow pelvic lymphadenectomy will share a common wall with the parietal peritoneum. Access to those that are in close juxtaposition to the peritoneal cavity are relatively straightforward and require an opening and wide marsupialization of the overlying peritoneum for durable success.

The most frequent location of posttransplantation lymphoceles was superomedial or inferomedial to the renal graft (19). Small lymphoceles (<100 mL) lying near the renal hilum, or lateroposterior, lateroinferior, or inferomedial lymphoceles are the most difficult to drain laparoscopically. If laparoscopic experience is limited, other modalities for drainage should be employed (13,14,19).

Small lymphoceles (<100 mL) lying near the renal hilum, or lateroposterior, lateroinferior, or inferomedial lymphoceles are the most difficult to drain laparoscopically. If laparoscopic experience is limited, other modalities for drainage should be employed.

Intervention is indicated for symptomatic lymphoceles or those causing graft dysfunction. Conservative management, including percutaneous drainage or sclerotherapy, may be considered for small lymphoceles or those causing minor symptoms. However, for larger lymphoceles, or those causing serious complications such as renal insufficiency, surgical therapy is required. Laparoscopic techniques may be used in these patients or in patients with recurrent lymphoceles after conservative therapy had failed.

Laparoscopic drainage is contraindicated if the lymphocele is infected. These patients should undergo open surgical drainage with concomitant administration of intravenous antibiotics.

Laparoscopic drainage is contraindicated if the lymphocele is infected. These patients should undergo open surgical drainage with concomitant administration of intravenous antibiotics.

PREOPERATIVE PREPARATION

The patient should be explained the procedure in detail along with risks, benefits, and potential complications. Furthermore, the patient should be informed that conversion to an open approach occurs in 5% to 9% of laparoscopic cases (13,19)

Prior to intervention, basic laboratory evaluation, including blood counts, serum chemistries, and blood typing and screening should be obtained. A preoperative computed tomography scan with and without contrast should be performed to delineate the lymphocele size and relationship to other anatomical structures. Aspirin, nonsteroidal anti-inflammatory drugs, and anticoagulant medications should be stopped at least one week prior to surgery. As with any surgical procedure, the patient should be instructed not to eat after midnight prior to the surgery.

LAPAROSCOPIC TECHNIQUE

The patient is placed in the supine position on the operative table, prepped and draped in a standard sterile fashion. A Foley catheter is placed along with a nasogastric tube to

decompress the bladder and stomach, respectively. In the absence of a previous midline scar, access and insufflation are accomplished with a Veress needle using conventional laparoscopic techniques. Once pneumoperitoneum has been achieved, a 3-trocar transperitoneal approach is used. The placement of trocars is similar to a laparoscopic pelvic lymph node dissection (Fig. 1). A 12-mm trocar is placed for use by the camera along with an additional 12-mm trocar for potential use of a clip applier. A 5-mm trocar is placed for laparoscopic instruments. The peritoneal cavity is inspected for adhesions. Careful attention should be paid to check whether the adhesions will complicate marsupialization of the lymphocele and potential mobilization of the omentum. Identification and extent of the lesion may be facilitated by a percutaneous needle or catheter placed into the lymphocele either by preoperative or intraoperative ultrasound guidance. Often the lymphocele appears as a blue-tinged dome protruding into the peritoneal cavity. In patients who have undergone renal transplantation care should be taken to identify the ureter as well as the renal vessels.

After complete visualization, the wall of the lymphocele is grasped and the cavity is opened using electrocautery scissors (Fig. 2). Lymphoceles typically contain straw-colored fluid, which may exude upon opening. The interior of the lymphocele should be aspirated with the irrigator-aspirator after opening. A large window from the peritoneal cavity into the interior of the lymphocele should be created by incision. Inspection of the lymphocele cavity is followed by gentle irrigation with an antibiotic solution. Pathologic analysis should be performed on the excised portion of the lymphocele.

Significant bleeding is a rare complication of the laparoscopic marsupialization of lymphocele.

If needed, hemostasis can be achieved through the use of electrocautery or the application of titanium clips. The patency of the peritoneal window can be maintained by the placement of a pedicle flap of omentum into the cavity. The pedicle flap should be secured with titanium clips to prevent closure of the window and also bowel herniation through the peritoneal opening. A permanent peritoneal dialysis catheter can be placed in lieu of omentum in recurrent lymphoceles, those with limited peritoneal openings or those that are anatomically difficult to access. Similar to omentoplasty, peritoneal dialysis catheters must be fixed to the lymphocele wall to prevent migration. They are, however, contraindicated in those lymphoceles that are infected (20) As with any laparoscopic procedure, careful inspection for hemostasis is critical.

If dissection occurs near the transplanted ureter, indigo carmine can be given intravenously to confirm the integrity of the ureter.

Following hemostasis, the pneumoperitoneum is released. The larger trocar sites (>5 mm) are closed with a fascial suture and steri-strips are applied over the incisions.

Postoperatively, patients typically require only oral analgesics. Shoulder pain, although uncommon, may result from diaphragmatic irritation caused by the carbon

Significant bleeding is a rare complication of the laparoscopic marsupialization of lymphocele.

If dissection occurs near the transplanted ureter, indigo carmine can be given intravenously to confirm the integrity of the ureter.

dioxide insufflation. Diaphragmatic irritation will resolve as the carbon dioxide is reabsorbed by the peritoneum. Patients are given a liquid diet immediately. Hospital discharge typically occurs on the first or second postoperative day. Lymphocele resolution is confirmed with a postoperative computed tomography scan.

TECHNICAL CAVEATS AND TIPS

- A preoperative computed tomography scan gives the best definition of size and location of the lymphocele cavity. This study can determine the relationship of the lymphocele cavity to the bladder and the renal allograft.
- Aspirated fluid creatinine and blood urea nitrogen are helpful to distinguish between a lymphocele and an urinoma. A gram stain and culture help to determine if the lymphocele is infected.
- Careful laparoscopic dissection will prevent injury to the transplanted ureter or renal vessels.
- In selected cases, a portion of the omentum can be placed in the lymphocele cavity to keep the cavity open for drainage.

AVOIDING COMPLICATIONS

> The most common complication (7% of cases) of laparoscopic marsupialization of lymphocele is injury to adjacent structures, especially transection of the transplanted ureter.

The most common complication (7% of cases) of laparoscopic marsupialization of lymphocele is injury to adjacent structures, especially transection of the transplanted ureter (22).

Bowel is less commonly injured, but both complications may be avoided by careful and complete visualization of the lymphocele. As noted earlier, a needle or catheter placed into the lymphocele may assist in localizing the cavity. Meticulous dissection with identification of the transplanted ureter helps to avoid injury. Stent placement into the transplanted ureter is technically demanding and is not routinely performed. If intraoperatively the lymphocele is found to be infected, conversion to an open procedure is required.

> If intraoperatively the lymphocele is found to be infected, conversion to an open procedure is required.

Peritonitis may result from opening an infected lymphocele with subsequent seeding of the peritoneal cavity. Careful patient selection will prevent attempting to open an infected lymphocele laparoscopically.

Peritonitis may also occur secondary to an undetected bowel injury. Careful inspection of the peritoneal cavity prior to removing the trocars is required to detect and repair any injured bowel.

Finally, a rare complication of laparoscopic lymphocele fenestration is herniation of bowel through the peritoneal window with entrapment in the lymphocele cavity. This can cause a recurrent lymphocele or bowel injury. Attachment of a pedicle flap of omentum to the lymphocele cavity helps maintain the patency of the peritoneal window, as well as preventing migration of bowel into the lymphocele cavity.

SUMMARY

- Lymphoceles most commonly occur after renal transplantation and pelvic lymphadenectomy.
- The use of laparoscopy for drainage of a lymphocele cavity is safe and effective. This procedure has lowered the morbidity as well as the hospitalization rate when compared with its open counterpart and is associated with a low recurrence rate.
- Laparoscopic marsupialization is now the proposed first-line approach to lymphoceles.

LAPAROSCOPIC BLADDER AUGMENTATION: WITH AND WITHOUT URINARY DIVERSION

Raymond R. Rackley and Joseph B. Abdelmalak

Section of Voiding Dysfunction and Female Urology, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

Augmentation cystoplasty remains the most widely accepted reconstructive technique for creating a compliant, large capacity bladder that protects the upper urinary tract and provides urinary continence in people with bladder dysfunction secondary to noncompliance or reduced functional capacity (1–4).

Augmentation cystoplasty may be combined with continent catheterizable stoma formation for use as an accessible port for bladder emptying. In 1888, Tizzoni and Foggi demonstrated the feasibility of performing ileocystoplasty in a canine model. Ten years later, Mikulicz performed the first clinical ileocystoplasty (5). Since that time, the standard enterocystoplasty has classically evolved as a procedure performed through an open laparotomy incision utilizing various segments of well-vascularized segments of the gastrointestinal system that are reconfigured before anastomosis with the urinary bladder (6). One hundred years have passed since the original open approach for this procedure has become an established reconstructive technique performed laparoscopically.

No matter what surgical approach is chosen, the use of any bowel segment for augmentation is associated with advantages and disadvantages. However, the versatility of choosing a particular bowel segment, for both open and laparoscopic approaches, provides a variety of clinical options based on an individualized set of objectives for the person requiring this form of bladder reconstruction.

Enterocystoplasty effectively provides a durable increase in bladder capacity and compliance; however, the morbidity and postoperative discomfort associated with the open laparotomy incision are major deterrents.

For patients with pre-existing debilitating neurologic and other comorbid conditions, the open surgical approach may significantly prolong the hospital stay, increase the metabolic needs for wound healing, and delay postoperative recovery. Laparoscopy has distinct advantages when compared with open surgical procedures with regard to postoperative pain and morbidity, a shorter hospital stay, decreased convalescence period, and improved cosmoses. Furthermore, postoperative intra-abdominal adhesions are significantly reduced after laparoscopic surgery when compared with open surgery (7).

Laparoscopy has an established role in diagnostic and ablative urologic surgery. The use of laparoscopic techniques in reconstruction has been limited because of the technical complexity of the procedures involved. The technical steps in performing a laparoscopic bladder augmentation are designed to emulate the open surgical counterpart in every aspect, thereby producing similar functional results with improved recovery.

PATIENT SELECTION: INDICATIONS AND CONTRAINDICATIONS

The goal of augmentation cystoplasty is to restore the compliant storage properties of the urinary bladder. Noncompliant, small capacity bladders that typically do not respond to

---

Augmentation cystoplasty remains the most widely accepted reconstructive technique for creating a compliant, large capacity bladder that protects the upper urinary tract and provides urinary continence in people with bladder dysfunction secondary to noncompliance or reduced functional capacity.

Enterocystoplasty effectively provides a durable increase in bladder capacity and compliance; however, the morbidity and postoperative discomfort associated with the open laparotomy incision are major deterrents.

The use of laparoscopic techniques in reconstruction has been limited because of the technical complexity of the procedures involved. The technical steps in performing a laparoscopic bladder augmentation are designed to emulate the open surgical counterpart in every aspect, thereby producing similar functional results with improved recovery.

more conservative forms of treatment can be surgically augmented. Interruption of the bladder innervation and musculature with the use of detubularized bowel to augment the resultant defect may decrease efficiency of the spontaneous voiding mechanism. People with neurogenic bladder dysfunction will generally require clean intermittent catheterization for prolonged or indefinite periods postoperatively to empty the bladder effectively. In addition, the physical disabilities or limitations due to neurologic conditions may prevent one's ability to catheterize via the urethra; thus, a continent catheterizable abdominal stoma should be considered in addition to bladder augmentation.

> A relative contraindication specific to laparoscopic bladder augmentation is the presence of extensive intra-abdominal and pelvic adhesions that would preclude a laparoscopic bowel dissection.

A relative contraindication specific to laparoscopic bladder augmentation is the presence of extensive intra-abdominal and pelvic adhesions that would preclude a laparoscopic bowel dissection.

Our experience in open and laparoscopic approaches for this procedure suggests that people with ventriculoperitoneal shunts typically have increased abdominal adhesions that may preclude a successful laparoscopic approach. Routine laboratory studies include renal function and serum electrolytes, whole blood cell count, urinalysis, and when appropriate, a urine culture. Upper and lower urinary tract studies are important baseline evaluations. A urodynamic study and cystoscopy will provide additional useful information about the competence of the urinary sphincter and pre-existing bladder pathologies.

PREOPERATIVE PREPARATION

Mechanical and antibiotic bowel preparation includes a low residue, clear liquid diet for two days before the operation, a bowel preparation the day before the operation, preoperative antibiotics for bowel and urinary tract surgical prophylaxis, and antifungal medication when indicated.

> Patients with neurologic diseases have chronic constipation and may need more time for an adequate bowel preparation.

Patients with neurologic diseases have chronic constipation and may need more time for an adequate bowel preparation.

The patient is placed in the supine position and pneumatic compression stockings are applied to both legs. After induction with general anesthesia and endotracheal intubation, an oral gastric tube is inserted, and the patient is placed in the low-lithotomy position for the remainder of the operation. Both arms are tucked in and protected along the sides so that the surgical team may direct their operative movements deep into the pelvis. Effective intraoperative urine and pelvic fluid drainage by intermittently opening the urethral catheter to preserve the pneumoperitoneum augments the suction removal of any excessive fluid collections.

SURGICAL TECHNICAL STEPS

For laparoscopic or open approaches the surgical technique of enterocystoplasty is based on the following fundamentals: (i) selection of an optimal segment of bowel based on a broad, well-vascularized mesenteric pedicle, (ii) isolation of the bowel segment, (iii) re-establishment of bowel continuity and closure of the mesenteric defect, (iv) detubularization and reconfiguration of the bowel segment without peritoneal soiling of bowel contents, (v) bladder mobilization with formation of an adequate sized cystotomy, (vi) creation of a tension-free, watertight, full-thickness, circumferential anastomosis of the bowel to the bladder, and (vii) confirmation of adequate postoperative urinary drainage.

Port Placement

An incision is made at the infraumbilical crease, and a disposable 10-mm port with occluding balloon and cuff is introduced under direct vision into the peritoneal cavity. A 10-mm, 0° laparoscope is introduced and the subsequent ports are introduced under visual guidance. For the right-handed surgeon, the right-sided 10 mm and left-sided 5 mm ports are inserted bilaterally at the lateral borders of the rectus muscle at the level of the umbilicus (Fig. 1). Most of the operative suturing takes place via the two paraumbilical ports. The 10-mm port not only facilitates the introduction of sutures on large needles but also is useful for extracorporeal knot tying. Additional 5-mm ports are inserted bilaterally at the level of the anterior superior iliac spines. Other ports may be placed depending on the bowel mobilization required and surgeon's preference.

Selection and Mobilization of the Bowel Segment

Various segments of the gastrointestinal system may be used for the procedure depending on the clinical requirements of the patient. A length of 20 cm of bowel is usually desirable to attain an adequate augmented bladder capacity. An appropriate segment of bowel is identified based on the following criteria: (i) the bowel segment will reach the area of the bladder neck without tension and (ii) a well-defined arterial arcade should be present in the isolated bowel mesentery.

In laparoscopic ileocystoplasty, the initial step is identification of the ileocecal junction. With the use of laparascopic small bowel clamps, a 20-cm segment of ileum at least 15 cm proximal to the ileocecal junction is identified (Fig. 2). The mesentery adjacent to the proximal and distal ends of the selected bowel loop is scored with laparoscopic electrosurgical scissors for subsequent extracorporeal identification.

In laparoscopic sigmoidocystoplasty, a loop of sigmoid colon is selected using similar techniques. Many patients with neurogenic bladder dysfunction also have defecating dysfunction resulting in a redundant sigmoid colon. In patients planning to perform intermittent catheterization via the urethra, the sigmoid colon may be the preferred segment of bowel for harvesting if continent stoma formation is not required. Extracorporeal manipulation of the sigmoid is best achieved via extension of the left lower abdominal port defect (Fig. 3).

The right colon and terminal ileum are selected in patients who require continent abdominal stoma formation in addition to bladder augmentation. The cecum and ascending colon are used for the bladder augmentation, and 10 cm of terminal ileum is used to create the catheterizable conduit and stoma at the umbilicus. The peritoneum lateral to the cecum and ascending colon and the peritoneum of the terminal aspect of the Z line are incised. The entire right colon and terminal ileum are mobilized for extracoporeal manipulation via the extended incision of the umbilical port. Ensuring a low position of the patient's thighs via low-lithotomy enables proper manipulation of the laparoscopic instruments through the lower abdominal ports for mobilization of the right colonic flexure.

Exclusion and Re-Anastomosis of the Bowel

Following mobilization of the bowel for extracorporeal manipulation, the pneumoperitoneum is desufflated and the umbilical port removed. Except for the sigmoidcystoplasty procedure as described earlier, the umbilical incision is enlarged

> In laparoscopic ileocystoplasty, the initial step is identification of the ileocecal junction.

> In laparoscopic sigmoidocystoplasty, a loop of sigmoid colon is selected using similar techniques.

> Bowel continuity is re-established using traditional open techniques and the mesenteric window is closed. The bowel anastomosis is performed cephalad to the excluded segment of bowel, and the reanastomosed bowel is returned to the abdominal cavity before any further manipulations are performed. This step reduces the potential need to enlarge the circumumbilical incision for re-introduction of an edematous combination of both the bowel reanastomosis and the reconfigured bowel segment for augmentation.

circumumbilically and extended inferiorly in obese patients for an additional 2 cm. The preselected loop of bowel is delivered extracoporeal through this incision. Care is taken to prevent any twisting of the mesenteric pedicle and to ensure proper proximal–distal orientation of the loop. Using traditional open surgical techniques, the 20-cm bowel segment with its vascular pedicle is divided between bowel clamps and isolated as in ileocystoplasty.

Bowel continuity is re-established using traditional open techniques and the mesenteric window is closed. The bowel anastomosis is performed cephalad to the excluded segment of bowel, and the reanastomosed bowel is returned to the abdominal cavity before any further manipulations are performed. This step reduces the potential need to enlarge the circumumbilical incision for re-introduction of an edematous combination of both the bowel reanastomosis and the reconfigured bowel segment for augmentation.

Refashioning of the Isolated Bowel Segment

The excluded bowel segment is draped in moist, warm sponges and then irrigated thoroughly with normal saline until the returning irrigation is clear. The antimesenteric border of the bowel is incised using electrocautery. For the small bowel or sigmoid, a U-shaped plate is created by a side-to-side anastomosis with a 2-0 absorbable suture (Fig. 4). After the isolated bowel segment for augmentation is reintroduced into the peritoneal cavity, the ports are replaced to re-establish the pneumoperitoneum.

In ileocystoplasty, reintroducing a disposable 10-mm blunt-tip port with a fascial retention balloon and foam cuff to minimize gas leakage is warranted. In sigmoidocystoplasty, the extended left lower abdominal port incision is reduced to accommodate a 5-mm port. The pneumoperitoneum is then re-established and the laparoscope inserted. The isolated bowel segment is oriented appropriately and inspected to exclude torsion of the pedicle.

For patients requiring a continent catheterizable stoma, the right colon and terminal ileum are utilized. Following detubularization of the cecum and proximal colon, an appendectomy is performed. The terminal ileum is narrowed over a 16-French red rubber catheter using a gastrointestinal anastomosis stapling device, and the ileocecal junction is imbricated and intussuscepted to augment the continence mechanism of the ileocecal valve using 2-0 permanent sutures (Fig. 5). Orientation sutures are placed at the cephalic ends of the bowel patch to facilitate intracorporeal laparoscopic identification and manipulation. The 16 French red rubber catheter is

FIGURE 5 ■ Detubularization and reconfiguration of the right colon and ileum for cecocolocystoplasty in preparation for formation of a catheterizable stoma. *Source*: Courtesy of the Cleveland Clinic Foundation.

FIGURE 6 ■ Intracorporeal suturing of the isolated bowel segment to the bladder. Point A is at the apical aspect of the newly formed bladder flap that was derived from the anterior aspect of the bladder wall near the bladder neck. *Source*: Courtesy of the Cleveland Clinic Foundation.

secured to the terminal end of the catheterizable segment of ileum with a suture for atraumatic intracorporeal manipulation and for delivering this terminal segment to the umbilicus for stoma maturation at the end of the procedure. The isolated bowel patch is then returned to the abdominal cavity and the pneumoperitoneum is re-created as described earlier.

Exclusion of the bowel segment and subsequent restoration of bowel continuity can be performed intracorporeally using stapling devices and is thought to reduce any theoretical complications from undue tension placed on the bowel mesentery during the extracorporeal manipulation of the bowel in obese patients. We have not experienced any complications related to this proposed concern using this extracoporeal maneuver in obese patients. We prefer to routinely perform these manipulations extracorporeally by delivering the bowel outside the abdomen through the umbilical or lower abdominal port site, respectively, for the following several reasons: (i) the bowel segment can be measured precisely and the mesentery incised after ensuring good vascularity, (ii) the bowel may be reanastomosed meticulously using open surgical techniques with increased confidence; (iii) the excluded loop may be irrigated without any peritoneal spillage, thereby eliminating the potential for subsequent pelvic abscess formation; (iv) the detubularization and desired modification of the isolated loop can be performed expeditiously by traditional open suturing; (v) if the mesenteric length allows the segment to be delivered outside the anterior abdominal wall comfortably without evidence of bowel ischemia, it is also likely to reach the bladder without tension; and (vi) the extracorporeal approach allows considerable savings in overall operative time and cost.

Bladder Mobilization and Cystotomy

Placing the patient in extreme Trendelenburg position aids in displacement of the bowel loops from the pelvic cavity and facilitates the subsequent steps of the procedure. The bladder is distended with saline through the uretheral catheter. The peritoneum overlying the bladder is incised at the medial border of the left medial umbilical ligament and extended to the right in a linear fashion to the right medial umbilical ligament. The median umbilical ligament is taken down during the procedure using electrosurgical scissors. If needed, the lateral peritoneum incisions are extended down along the medial umbilical ligaments to increase exposure. The loose areolar tissue surrounding the bladder is bluntly dissected to expose the anterior bladder neck and perivesical spaces. A large cystostomy is created by making an anterior bladder wall flap through a curvilinear incision that positions the apex at the dome of the bladder and the base extending to the level approaching the trigone (Fig. 6). This type of cystostomy ensures a large dysfunctional disruption of the bladder musculature for increasing the linear length of bladder wall for bowel anastomosis. It is most useful in cases where the uterus

> Placing the patient in extreme Trendelenburg position aids in displacement of the bowel loops from the pelvic cavity and facilitates the subsequent steps of the procedure.

is present and potentially prevents an adequate cystostomy incision. Furthermore, adequate exposure for enterovesical anastomosis in all of the procedures described previously is preserved by avoiding a closure of the deep posterior bladder wall incision in the pelvis that will be obscured by bowel and the isolated bowel segment to be used for the augmentation.

Enterovesical Anastomosis

Although different approaches can be used for intracorporeal suturing of the bowel segment to the bladder as shown in Figure 6, we prefer to begin by running the preplaced suture on the "posterior" wall of the reconfigured bowel patch to the apical aspect of the bladder flap in a medial to lateral direction on each side.

Completion of the posterior wall of the reconfigured bowel segment from an intravesical approach beginning medially (point A) and finishing laterally (points B and C, respectively) facilitates the best exposure to ensure a watertight anastamosis.

If one attempts to complete the anterior wall of the reconfigured bowel patch to the bladder first as shown in Figure 6, it may be difficult to visualize the suturing of the posterior wall anastomosis to the bladder owing to the constraints of pelvic anatomy. To complete a circumferential, continuous, full-thickness, single-layer anastomosis of the bowel to the bladder, we finish by running the preplaced sutures of the anterior wall of the reconfigured bowel patch and additional sutures as required. Free hand laparoscopic suturing and intracorporeal knot tying techniques are used exclusively for the entire procedure. Exposure of the operative field for intracorporeal suturing can be improved by temporarily fixing the anterior bladder flap to the abdominal wall. This not only opens the operative suturing field for easier identification of the bladder and bowel mucosal edges, but also stabilizes the tissues for rapid suture placement. At the completion of the anastomosis, the bladder is distended to confirm a watertight anastomosis.

A suction drain is inserted into the pelvic cavity through one of the lower lateral 5-mm port sites. Postoperative bladder drainage is maintained with a 22 French urethral catheter. Because a smaller urethral catheter may be preferred for postoperative drainage in males, a suprapubic tube may be placed through the bladder wall and externalized via the remaining lower port site.

The umbilical and remaining 10-mm ports are closed in layers. In patients who require a catheterizable stoma, the previously refashioned ileal segment is located and the attached red rubber catheter is grasped with an endoscopic clamp via the umbilical port site. After the pneumoperitoneum is decompressed, the terminal end of the ileal segment is delivered to the umbilicus and secured to the anterior rectus fascia and skin at the level of the umbilicus (Fig. 7). A Y-V flap maturation of the stoma to the skin of the umbilicus is performed using 4-0 chromic sutures. In obese patients, use of the umbilicus at the site of stoma formation decreases the amount of ileum needed to mature the stoma to the skin. A 16-Fr catheter is placed through the stoma and into the bladder to optimize bladder drainage and healing of the newly created catheterizable segment in the early postoperative period.

Postoperative Management

The oral-gastric decompression tube is removed before extubation. The suction drain is removed when the drainage is less than 25 mL or fluid chemistries suggest peritoneal fluid. The patient can be discharged when they are afebrile and able to complete three consecutive meals without abdominal distension, the first meal is usually started on the first postoperative day. Patients are discharged with the indwelling urethral catheter used for bladder drainage and three times daily bladder irrigation with 100 mL of sterile saline. Low-dose prophylactic antibiotics are continued during the first three postoperative weeks. At that time, the urinary catheter is removed and intermittent catheterization is initiated. For patients who have an indwelling catheter via the umbilical stoma, the catheter is usually capped at the time of hospital discharge, but may be used to flush the augmented bladder at the time of bladder irrigations.

Results

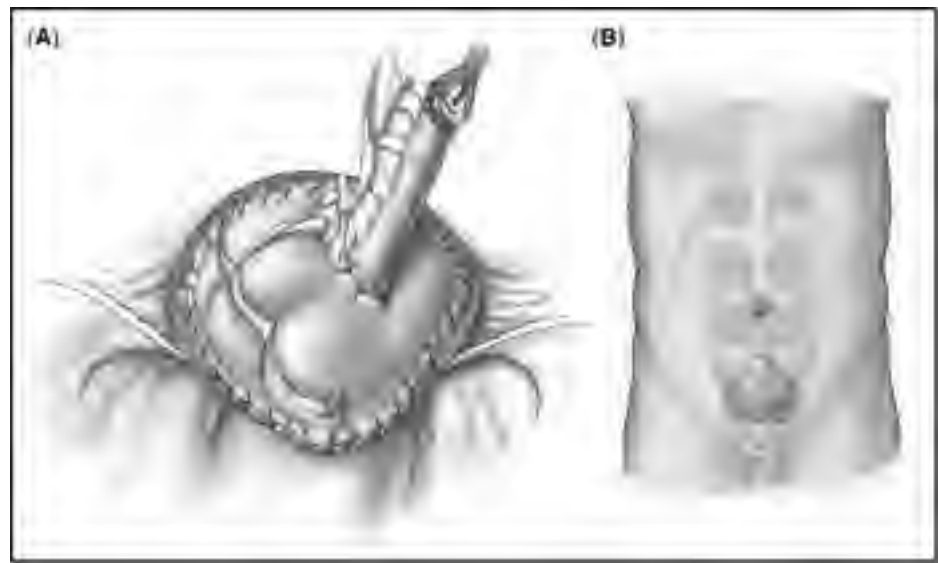
From 1999 to 2001, we performed laparoscopic enterocystoplasty in 18 patients with functionally reduced bladder capacities owing to neurogenic causes (Table 1). The procedures included ileocystoplasty (5), sigmoidocystoplasty (3), colocystoplasty (1),


FIGURE 7 ■ Augmentation cecocystoplasty with formation of a continent catheterizable stoma. Complete view of the bowel to bladder anastomosis (A) in preparation for maturation of the catheterizable stoma to the umbilicus (B). *Source*: Courtesy of the Cleveland Clinic Foundation.

and cecocolocystoplasty with a continent catheterizable ileal stoma (9). Total surgical time from patient arrival to the OR until transportation to the recovery room ranged from 5.3 to 8 hours (average 7.0 hours). The time for laparoscopic suturing ranged from 1.7 to 3.1 hours (average 2.4 hours). Blood loss was minimal and did not exceed 250 mL in any of the cases (average 175 mL). The only intraoperative complication was a trocar-induced rectus sheath hematoma during the course of the sigmoidocystoplasty that was controlled laparoscopically. Oral feeding was resumed by 24 hours in 17 of 18 patients. Our first patient had a self-limited paralytic ileus that responded to conservative treatment. Despite the fact that most of the patients in this initial experience had moderate to severe forms of neurological dysfunction owing to multiple sclerosis, the average hospital stay until the patient was discharged home was only 5.7 days (range 3–7). Most

notable was the absence of long-term or extended care needs for the patients with multiple sclerosis because of demands of wound healing or functional neurological loss that typically occur with an open procedure in this subset of patients.

All patients have been evaluated with preoperative and postoperative questionnaires concerning bladder (bladder control scale; BLCS) and bowel control (bowel control scale; BWCS). Fourteen patients [2 (14.4%) male and 12 (85.6%) female; mean age, 40 years (range 18–62)] have completed at least the sixth month postoperative questionnaires based on a mean follow-up of 17 months (range, 7–27). With regard to the quality of life measure using the BLCS, there was significant clinical improvement. The average improvement revealed a significant reduction from the baseline score of 14.9 ± 5.0 to 1.6 ± 1.8, $P = 0.0002$. In regards to the potential risk of causing bowel dysfunction by harvesting various bowel segments for augmentation cystoplasty, there was no clinically significant difference in the bowel control score before or after the procedure when comparing the average change from 6.4 ± 6.5 to 5.3 ± 6.0, $P = 0.30$.

Comparative Analysis of Open and Laparascopic Approaches

In order to define the clinical outcomes of a laparascopic approach to bladder reconstruction, we compared prospectively, our initial experience in laparoscopic augmentation cystoplasty with continent catheterizable ileal stoma to a similar cohort of patients who underwent an open approach. Eighteen consecutive cases of augmentation colocystoplasty with continent catheterizable ileal stoma were performed at our Institute; nine patients underwent the open approach (eight women and one man; mean age, 45 years, range 21–56), and nine cases underwent the laparoscopic approach (eight women and one man; mean age, 36 years; range, 18–46). All cases were performed by the same surgical team. Indications for the operation were reduced bladder capacity and/or compliance either due to a neurologic condition (mostly multiple sclerosis), or idiopathic refractory detrusor overactivity. Before the operation, all patients had urodynamically proven detrusor overactivity with incontinence that had failed conservative therapy. The right colon and terminal ileum were used in the operation with the cecum and ascending colon being used to augment the bladder, while 10 cm of terminal ileum with a reinforced ileocecal valve was used to create the catheterizable conduit and stoma at the umbilicus. Demographic data and baseline characteristics were recorded for patients in both groups. Bladder and bowel function and the patient's perception of their symptoms and quality of life were assessed by asking the patient to complete the two questionnaires mentioned earlier. One year after the operation, changes in the patients' symptoms, their quality of life and their perception of treatment outcome were reassessed. Perioperative and convalescence parameters for each patient in both groups were recorded including operative time (defined as the time from skin incision to final dressing as recorded by the anesthesia team), estimated intraoperative blood loss, hospital stay, postoperative oral intake time, and the time to meet the discharge criteria (three consecutive meals without developing nausea or vomiting) (Table 2).

The mean operative time for the open augmentation enterocystoplasty with catheterizable stoma formation was 278 minutes compared to 468 minutes for the laparoscopic series ($P < 0.001$). There was no significant difference between the two groups with regard to intraoperative blood loss. The mean estimated intraoperative blood loss in the laparoscopic series was 178 cc (range, 100–350) versus 248 cc for the open group (range, 100–500 cc) ($P = 0.4$). Both groups were significantly different in regard to the mean time to begin oral intake after the operation. Mean time to oral intake was significantly shorter after the laparoscopic approach (1.7 days) when compared with the open approach (5.2 days, $P < 0.0001$). The mean time necessary to meet the

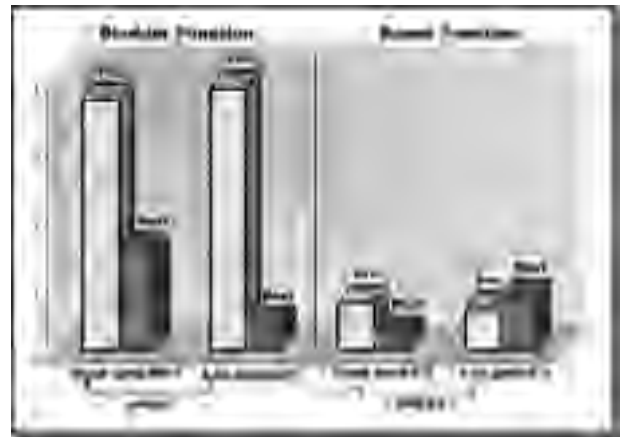
	Open cases	Laproscopic cases	*P* value
Number of patients	9	9	
Gender (male/ female)	1/8	1/8	
Mean age	45	36	<0.09
Mean operative time (min)	278	468	<0.001
Mean blood loss (mL)	248	178	<0.15
Mean time to oral intake (days)	5.2	1.7	<0.001
Mean hospital stay (days)	8.2	4.4	<0.001
Mean bladder scale	2.2	3.8	<0.07
Mean bowel scale	0.15	0.2	<0.63

FIGURE 8 ■ Comparison between the bladder and bowel scale after open and laparoscopic approaches.


discharge criteria (three consecutive meals without developing nausea, vomiting, or abdominal distension) was significantly shorter with laparoscopic approach (mean, 2.8 days) than with open approach (mean, 7.1 days, $P < 0.0001$). The mean hospital stay until the patient was discharged home was significantly shorter with laparoscopic cases (mean, 4.4 days; range, 3–6) than with open cases (average 8.2 days, range 5–11) ($P < 0.001$). There was significant improvement in the bladder function as demonstrated by the BLCS after both open and laparoscopic approaches. The mean improvement in bladder function after the laparoscopic approach and after the open approach was 3.8 and 2.2, respectively. Improvement in bladder function was better after the laparoscopic approach ($P = 0.07$); there was no adverse effect on the bowel function after both procedures (Fig. 8).

Laparoscopic Ileovesicostomy and Augmentation

In the past three decades, clean intermittent catheterization proposed by Lapides has been accepted by the urologic community as an excellent method of management of the neurogenic bladder that fails to empty (8). However, this option may not be applicable for some patients such as those without manual dexterity and without assistance from care givers. In these cases, options may include the use of chronic indwelling urethral or suprapubic catheter or urinary diversion. Chronic catheter placement is frequently associated with complications including stone formation, tissue erosion, frequent infection and malignancy; therefore, it is uncommonly used as first-line definitive management (9). Urinary diversion, which traditionally takes the form of an ileal conduit involving ureteral reimplantation, may lessen the risk for catheter-associated problems. However, a different set of problems such as urinary reflux and ureteral obstruction may arise (10).

Incontinent ileovesicostomy providing low-pressure urinary storage and drainage was first introduced in 1994 to address the problems associated with conventional incontinent urinary diversions (11). Without ureteral mobilization or reimplantation, it decreases the operative time and avoids the risk for ureteral complications. Preserving the ureterovesical junction, it maintains the antireflux mechanism and prevents pyocystis formation. Furthermore, it does not require the use of any catheter or foreign material, either intermittently or chronically. These advantages, together with excellent renal function preservation and the low rate of complications, have been confirmed by several recent reports with long-term follow-up. In fact, ileovesicostomy has been recommended as a better alternative to all other types of incontinent urinary diversion (12–14).

Prior to our publication in 2002, all ileovesicostomy procedures described were performed in the conventional, open manner. Similar to augmentation, the major surgical components of ileovesicostomy included the following: (i) bladder mobilization with cystotomy creation, (ii) harvesting of a well-vascularized bowel segment, (iii) establishment of bowel-to-bowel anastomosis with closure of the mesenteric window, and (iv) performance of full-thickness, mucosa-to-mucosa ileovesical anastomosis in a tension-free, watertight manner. Using the laparoscopic approach described below, we have been able to accomplish all these steps in four patients to date and use this technique as a primary approach to ileovesicostomy formation.

Surgical Technique

The patient is positioned in the dorsal lithotomy position and catheterized with a urethral catheter. After creation of a pneumoperitoneum, a five-port transperitoneal

laparoscopic approach is used. The bladder is distended with sterile saline solution and then mobilized anteriorly and laterally with standard laparoscopic techniques. An inverted U cystotomy is then made antero-superiorly with laparoscopic technique. The ileocecal junction and the distal 15 cm of ileum are laparoscopically identified. The distal margin of the ileal segment to be harvested is marked with a superficial electrocautery burn and then exteriorized through a 2-cm extension of the infraumbilical laparoscope port site. The pneumoperitoneum is then evacuated.

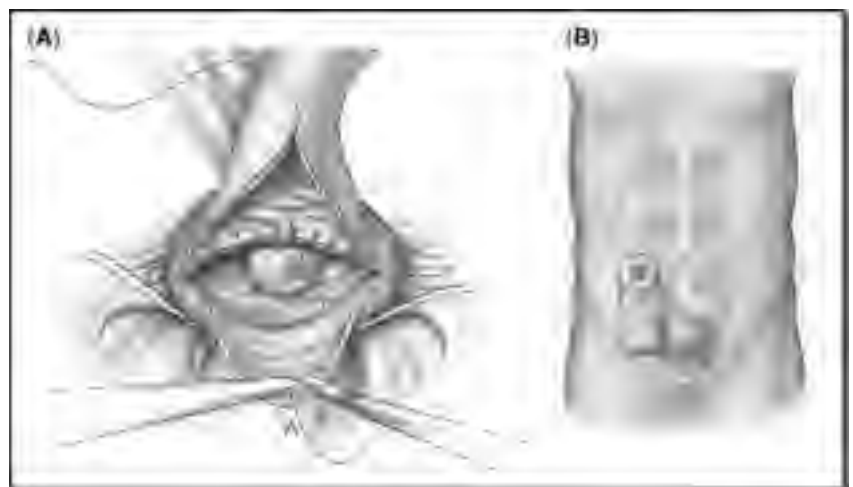
A 17-cm ileal segment proximal to the superficial electrocautery marking is harvested with conventional open techniques through the infraumbilical post site, with careful preservation of its vascular supply. Bowel-to-bowel continuity is restored in the side-to-side manner. The proximal end of the harvested ileal segment is opened with complete removal of the surgical staples. The segment is thoroughly irrigated with saline solution, and the proximal end of the bowel segment is spatulated for a distance of 3–4 cm along its antimesenteric surface. The bowel is then reintroduced into the abdominal cavity with the conduit caudal to the bowel anastomosis. The 2-cm extended infraumbilical incision is then closed and the pneumoperitoneum is re-established.

The mesenteric pedicle is first inspected carefully to prevent torsion. The spatulated proximal ileal end is oriented in relation to the cystotomy site. Single-layer ileovesical anastomosis with 2-0 absorbable sutures is then performed by laparoscopic free hand suturing and intracorporeal knot-tying techniques in a circumferential manner (Fig. 9). At the completion of the ileovesical anastomosis, the bladder is distended with saline solution via the urethral catheter to rule out leakage. The distal end of the ileal segment is brought to the skin level at the planned stoma site of the right 10-mm port site and a loop stoma or end stoma is created with open techniques. One suction drain is placed through the left 5 mm port site, with the rest of the port sites closed following evacuation of the pneumoperitoneum.

Isolation and reanastomosis of the exteriorized bowel through a 2-cm extension of an existing port site has been considered as an acceptable component of laparoscopic intestinal surgery (15). This approach provides several advantages including the ability to effectively evacuate residual fecal materials in the isolated bowel segment without significant intraperitoneal contamination, thereby minimizing abdomino-pelvic abscess formation.

RESULTS

Our results are comparable with the published surgical techniques utilizing an open approach. In the most recent report of traditional ileovesicostomy formation, the mean operative time was 4 hours (range, 2.8–6.6 hours), and the mean estimated blood loss was 403.8 cc (range, 50–2000 cc) (14). The laparoscopic operative time and blood loss presented here are well within the ranges of those in open surgery. Postoperatively, our patient resumed oral intake and physical activity quickly, had minimal narcotic requirements, and a short hospital stay. There are no detailed data on postoperative morbidity and convalescence in the recent literature for comparison. Our preliminary experience

FIGURE 9 ■ Laparoscopic ileovesicostomy formation: Anastomosis of the spatulated end of the proximal ileal loop end to the cystotomy site with intracoporeal suturing (A); maturation of the stoma to the laparoscopic port site (B). *Source*: Courtesy of the Cleveland Clinic Foundation.


appears to be promising. Further clinical experience and long-term follow-up will be necessary to confirm our findings and define the role of the laparascopic approach for this technique of bladder augmentation and urinary diversion.

SUMMARY

- Laparoscopic augmentation enterocystoplasty with or without urinary diversion is technically feasible and successfully emulates the established principles of using an open approach while minimizing operative morbidity and maximizing clinical effectiveness.
- Various bowel segments can be fashioned and anastomosed to the bladder laparoscopically.
- The increased costs associated with laparoscopy and with minimally invasive surgery in general have been a significant disadvantage; however, a previous report on the costs of laparoscopic procedures concluded that increased surgical experience reduces the surgical time and length of the hospital stay, thereby decreasing the overall costs.
- The increased use of reusable instruments results in considerable economic benefits. Implementation of appropriate time and cost saving strategies will ultimately result in decreased expenses associated with laparoscopy (16).
- Although laparascopic enterocystoplasty is currently a lengthy procedure lasting twice as long as open surgery, further technical modifications and increasing experience will continue to reduce the surgical time involved.
- Laparoscopic augmentation cystoplasty is an attractive option for patients with complex co-morbid illnesses who desire an improved quality of life similar to that associated the traditional open procedure.
- A clinically significant positive impact on patient postoperative QOL related to bladder control compared with the preoperative status can be achieved using a laparoscopic approach, which does not negatively impact the patient's bowel control.
- Our experience suggests that laparoscopic enterocystoplasty with or without urinary diversion is a viable alternative to open enterocystoplasty.

INTRODUCTION

Burch Colposuspension: The Evolution of a Procedure

In 1961, Burch (1) published the development of a new technique for colposuspension, based on a technique started in 1958. A paramedian incision was used to enter the abdomen and space of Retzius. He instilled 50 cc of milk in the bladder to identify possible perforations. The periurethral tissue was cleaned off and then three 2.0 chromic sutures were placed at the midurethra and the bladder neck. These sutures were fixed to Cooper's ligament. In 1968, Burch (2) reported a subjective cure rate of 92% in 143 patients with 10 to 60 months of follow-up.

Tanagho (3) suggested several refinements to increase the cure rate for Burch colposuspension (Table 1). Tanagho stressed that the importance of the surgical repair "is to preserve the initially intact sphincteric mechanism, to restore its proper position, and to provide it with adequate support." This was achieved by clearing off the overlying fat, while staying at least 2 cm lateral to the urethra and urethrovesical junction. Elevation of the anterior vaginal wall by the surgeon's hand enabled the dissection and correct placement of absorbable sutures at the midurethra and lateral to the urethrovesical junction. He stressed the formation of a "hammock" of support without compressing the urethra against the pubic bone, while elevating the vaginal wall to approximately 2 cm below Cooper's ligament. Many physicians consider the Burch–Tanagho colposuspension the "gold standard" for the treatment of primary genuine stress incontinence. We feel the laparoscopic colposuspension must include the Burch–Tanagho technique in order to be called a laparoscopic Burch colposuspension, and any variation on this technique in this chapter will be simply called a laparoscopic colposuspension.

Laparoscopic Colposuspensions

In 1991, Vancaillie and Schuessler (4) attempted the first laparoscopic retropubic repair, a Marshall–Marchetti–Krantz, and in 1992 (5) reported a series of laparoscopic Marshall–Marchetti–Krantz and Burch colposuspensions. Over the next few years, several others (6–8) reported larger series. Before widely recommending the laparoscopic procedure, cure rates better or comparable to open surgery need to be demonstrated.

SELECTION, EVALUATION, AND ANATOMY

Patient Selection

After the diagnosis of genuine stress incontinence is made, the physician and the patient determine the necessity of surgery, usually after a trial of more conservative treatment.

TABLE 1 ■ The Tanagho Principles for Burch Colposuspension

1. Remove paraurethral fat out to lateral sidewalls.
2. Keep dissection 2 cm from urethra and bladder neck.
3. Elevate paraurethral tissue with vaginal hand during dissection and suture placement.
4. Clean off Cooper's ligament.
5. Place a right and left suture through the paraurethral tissue 2 cm lateral to the midurethra and up through Cooper's ligament.
6. Keep paraurethral tissue elevated with vaginal hand while tying.
7. Repeat bilateral suture placement 2 cm lateral to the bladder neck and through Cooper's ligament.
8. Do not over-correct when tying the sutures, leaving 2 cm between pubic ramus and the urethra.

Relative contraindications for laparoscopy include history of severe abdominal or pelvic adhesions, prior incontinence procedures, intrinsic sphincter deficiency, or the necessity of other abdominal procedures requiring laparotomy.

The decision to perform the Burch procedure through an open or laparoscopic technique depends on the patient's history and the skill of the surgeon.

Relative contraindications for laparoscopy include history of severe abdominal or pelvic adhesions, prior incontinence procedures, intrinsic sphincter deficiency, or the necessity of other abdominal procedures requiring laparotomy.

Many physicians will only treat primary genuine stress incontinence, but the author (9,10) and others (11) have successfully treated recurrent genuine stress incontinence laparoscopically. Prior procedures such as anterior vaginal repair, needle suspensions, Marshall–Marchetti–Krantz, Burch, and bone anchor procedures are not absolute contraindications.

Laparoscopic Burch has been used to successfully to treat patients with low urethral closure pressure, low Valsalva leak point pressure, and urethral hypermobility. Laparoscopic Burch is not the surgery of choice with a frozen urethra.

Evaluation

In many clinics, a basic evaluation consists of history, physical exam, urine culture and sensitivity, 24-hour urolog, quality-of-life questionnaires, cystoscopy, bladder neck ultrasound, cough stress test, postvoid residual, and multichannel urodynamics.

When obtaining history, besides in-depth questions about urinary complaints and pelvic support problems, patients are questioned in detail about obstructive defecation and fecal incontinence. In our clinic, 23% of patients with severe genuine stress incontinence or pelvic organ prolapse have fecal incontinence, which is in agreement with others (12–15). Many have obstructive defecation associated with rectal prolapse, rectocele, and intussusception (16,17). When there is a history of fecal incontinence or obstructive defecation, we include anal manometry, anal ultrasound, and pudendal nerve terminal motor latency studies to aid in the treatment plan. A basic filling cystometrogram with Valsalva leak point pressure is essential if multichannel urodynamic testing is not available.

Surgical Anatomy

It is essential to understand the anatomy of the anterior wall and the pelvis to safely perform laparoscopy. There are several vessels and nerves that come into play with laparoscopic pelvic procedures. The first vessels at risk from trocar placement are the great vessels (aorta/vena cava) at the infraumbilical site. The umbilicus is at the L3–L4 level and, in women with thin to normal body habitus, the aortic bifurcation is at L4–L5. In obese women, the umbilicus is lower. In thin to normal-sized women, the infraumbilical trocar is placed at a 45 degree angle inclined toward the pelvis, while in an obese female, the trocar can be placed closer to a 90 degree angle. The left common iliac vein crosses over the lateral half of the lower lumbar vertebrae and can be inferior to the umbilicus, making it susceptible to injury at trocar insertion or when exposing the sacral promontory. The common iliac vessels course 5 to 6 cm lateral from the midline before bifurcating into the internal and external common iliac vessels.

The inferior epigastric artery, arising from the distal portion of the external iliac artery, crosses the medial border of the inguinal ligament and runs along the inferior lateral edge of the rectus muscle to anastomose with the superior epigastric artery, a branch of the internal mammary artery (Fig. 1). Two inferior epigastric veins accompany the artery. The superficial epigastric artery arises from the femoral artery 1 cm below the inguinal ligament and passes through the femoral sheath to supply the superficial area of the abdominal wall, up to the umbilicus. If the patient is thin, this vessel can be transilluminated.

The obturator artery is one of the terminal branches of the internal iliac artery and is found on the lateral pelvic sidewall, leaving the pelvis via the obturator canal along with the obturator nerve (Fig. 2). It gives off a pubic branch, which anastomoses with

FIGURE 1 ■ Abdominal wall vascular and neural structures at risk during laparoscopy and normal trocar sites. (A) Superficial circumflex artery, (B) femoral artery, (C) superficial inferior epigastric artery, (D) external iliac artery, (E) inferior epigastric artery, (F) iliohypogastric nerve, (G) ilioinguinal nerve, (H) 10-mm trocar sites, (I) 5-mm trocar sites.

the pubic branch of the inferior epigastric artery to supply the posterior surface of the symphysis. In 25% of patients, an accessory obturator artery arises from the inferior epigastric artery. In approximately 4% of patients, both an obturator and an accessory obturator branch are present. Care must be taken with these vessels, because they complete an anastamotic circle of vessels between the internal and external iliac arteries, referred to as the circle of death in many surgical texts. Damage to any vessel in this circle can result in significant hemorrhage.

Neuropathies can occur from nerve damage or entrapment during laparoscopic surgery. Lateral trocar placement can damage the iliohypogastric and ilioinguinal nerve, leading to sharp pain in the suprapubic or groin area (18) (Fig. 1). Obturator nerve damage can occur during dissection of the space of Retzius or with paravaginal repairs, causing sensory loss to the medial thigh and difficulty in ambulating (19).

SET-UP, INSTRUMENTATION, AND SURGICAL PROCEDURE
Set-Up
It is helpful to place a video monitor lateral to each thigh of the patient, if two monitors are available. If only one monitor is available, we find it helpful to position it between the patient's legs so we are turned toward the patient's pelvis as we operate. This helps in judging spatial relationships. The surgeon stands on the left and the assistant on the right, with the scrub nurse next to the surgeon beside the patient's left thigh. The patient is in a supine position and her legs are placed in low Allen™ [a] stirrups for easy maneuverability. A three-way 20-French Foley is placed in the bladder. Methylene blue is added to the saline and attached to the Foley.

Instrumentation
A "saddle bag pouch" is draped over the patient's right thigh to conveniently place frequently used instruments such as monopolar spatula, scissors, bipolar forceps, graspers, blunt-tipped dissectors, needle holders, and suction–irrigation device. We find the monopolar spatula, set at 50 to 90 W pure cut, to be a very useful tool to enter the space of Retzius. It is used for dissection on its thin side and as small vessels come into the operating field, it is turned to the broad side for coagulation. We use Talon 90-degree self-righting needle holders with spring handles[b]. A 0 polydioxone on a C-1 needle[c] is used for the four Burch sutures and the closure of the space of Retzius. If paravaginal sutures are needed, interrupted figure-of-eight 2.0 Prolene sutures are used. Four disposable trocars[d] are used: 10-mm infraumbilical, 10-mm left lateral, 5-mm right lateral, and 5-mm suprapubic. The Inlet Closure Device®[e] is used to close all 10-mm or greater trocar sites and any 5 mm site used for back loading needles. An open-ended knot pusher is used for extracorporeal knots.

Surgical Procedure
The patient's legs are placed in low Allen stirrups and a three-way Foley is put in the bladder.

FIGURE 2 ■ Obturator and Accessory Obturator Artery. (A) Normal Obturator artery, present 70 percent. The patient should be flat and not in Trendelenburg, which can bring the pelvic vessels closer to the abdominal wall.

The patient should be flat and not in Trendelenburg, which can bring the pelvic vessels closer to the abdominal wall.

The infraumbilical area is infiltrated with marcaine 25% (as are all of the trocar sites) and a stab incision is made. Preemptive anesthesia significantly decreases postoperative pain.

Veress needle or open Hasson technique is employed to achieve pneumoperitoneum (20). Once the abdominal pressure reaches 15 mmHg, the infraumbilical trocar is passed into the abdomen through the umbilical aponeurosis. The laparoscope, with video camera, is inserted. The left lateral port area is transilluminated to identify the superficial inferior epigastric vessels. A skin incision is made, and the 10-mm trocar, with a 5-mm reducer, is passed through the abdominal wall under direct vision. The same technique is used to place the right lateral and suprapubic 5-mm trocar. At this point, the patient can be placed in Trendelenburg in order to visualize the pelvis. After the initial abdominopelvic inspection is done, approximately 150 cc of methylene blue saline are instilled through the Foley catheter to delineate the borders of the bladder. The surgical landmarks for the initial peritoneal incision into the space of Retzius are the right and left obliterated umbilical arteries, slightly lateral and superior to the pubic tubercles. A transverse incision is made approximately 3 cm above the inferior aspect of the pubic bone from one obliterated vessel to the other. In the midline, care should be taken as the obliterated urachus, which can be vascular, is incised. It is important to remember that the patient is in Trendelenburg position and to not direct the dissection perpendicular to the pubic bone, but rather to dissect in an upward fashion. This will prevent inadvertent cystotomy. The pubic bone is identified under the retroperitoneal fat layer and can be followed into the space of Retzius. The correct plane is composed of fine areolar tissue and fat, which can be easily swept away with the spatula.

The Foley bulb is identified and care is taken to stay at least 2 cm lateral to the urethra. Adipose tissue is not removed from the anterior surface of the urethra. The surgeon's left hand is placed in the vagina to elevate the lateral paraurethral tissue, which greatly aids dissection. The rich venous plexus adherent to pubocervical fascia can be coagulated as necessary. On the sidewall, the arcus tendineus of fascia pelvis (arcus white line), along with the branching of the arcus tendineus of the levator ani, is identified. The obturator vessels and nerve are identified entering the obturator canal. The ischial spine is directly below the obturator canal. The Cooper's ligament is identified along the superior surface of the pelvic bone and cleaned off. The first absorbable 0 PDS suture[f] is placed 2 cm lateral to the midurethra as this tissue is elevated with the vaginal hand. A large purchase of tissue is taken. A figure-of-eight suture is not necessary, as demonstrated by Burch and Tanagho (1,3). The needle is passed up through the Cooper's ligament, and while the vaginal tissue is elevated, the suture is tied with an extracorporeal knot utilizing an open-ended knot pusher (Table 2).

The vaginal tissue should not be pulled all the way up to Cooper's ligament because this may result in overcorrection of the urethrovesical angle and possibly kink the ureter.

The vaginal tissue should not be pulled all the way up to Cooper's ligament because this may result in overcorrection of the urethrovesical angle and posibly kink the ureter.

We leave approximately 2 cm of space between the suture and Cooper's ligament and a similar space between the urethra and pubic arch. The second suture is placed 2 cm lateral to the bladder neck and tied. Sutures are placed on the opposite side in similar fashion. At completion, the four sutures elevate the pubocervical fascia to form "dog ears," creating a hammock under the midurethra and bladder neck (Fig. 3). As the last two sutures are being placed, indigo carmine is given intravenously.

The final step is cystoscopy. It is essential that dye is seen coming from both ureteral orifices and that no sutures have penetrated the bladder wall. If the dye is not seen, the sutures must be removed from that side and replaced. We know of no reports of the ureter actually being caught in a Burch suture. The cause of ureteral obstruction is due to overelevation of the trigone, which crimps the ureter, preventing flow (21). After cystoscopy, the space of Retzius is closed with a continuous 0 PDS suture.

The Burch is always done last if there are concomitant procedures. The urethrovesical angle can be affected by other repairs done after the Burch, secondary to changes in the pelvic axis. We usually do uterosacral vaginal colpopexies prior to the Burch to prevent prolapse in the posterior pelvic compartment in any patient demonstrating vaginal support weakness. The Burch has been combined with anterior and posterior support procedures, sacrocolpopexy (9), laparoscopic hysterectomy, external anal sphincteroplasty (12), and rectopexy.

ENTRY INTO THE SPACE OF RETZIUS

The space of Retzius can be reached by an intraperitoneal or an extraperitoneal approach. The suggested advantages of the extraperitoneal approach include not entering the intraperitoneal cavity, decreased risk of vascular and bowel injury, and bypassing intra-abdominal adhesions (23–24). Decreased blood loss reportedly is due to instillation of CO_2 gas at 20 mmHg into the extraperitoneal space, causing compression of capillaries (23). Some authors suggest the extraperitoneal dissection allows better vision and gives the added advantage of using regional anesthesia (22,23). It also allows lower placement of trocars, making it easier to reach the operative field. At one center (24), extraperitoneal laparoscopic Burch was cheaper than open Burch ($3100 vs. $6000).

In several experiences, this extraperitoneal dissection is reported as faster and cheaper than open or laparoscopic transperitoneal Burch, with comparable cure rates and high patient satisfaction (22,25–27).

Possible complications include higher rates of cystotomy, subcutaneous emphysema, inadvertent entry into the peritoneal cavity, conversion to open or intraperitoneal Burch, and exclusion of patients with prior abdominal surgery (22,24,26). Prior surgery is not a contraindication in some centers (27,28).

Extraperitoneal laparoscopy can result in greater degrees of carbon dioxide absorption than transperitoneal surgery, increasing the chance of pneumomediastinum and pneumothorax (26,29).

Extraperitoneal access can be achieved via balloon dissector, operating laparoscope, direct vision trocar, or regular trocar, or by the surgeon's finger. The technique is started by making a small incision in the abdominal midline that is opened down to the preperitoneal space. Then, either a balloon or a trocar is placed in this potential space and carbon dioxide is instilled, opening the space of Retzius. Two 5-mm ports are placed

> In several experiences, this extraperitoneal dissection is reported as faster and cheaper than open or laparoscopic transperitoneal Burch, with comparable cure rates and high patient satisfaction.

> Extraperitoneal laparoscopy can result in greater degrees of carbon dioxide absorption than transperitoneal surgery, increasing the chance of pneumomediastinum and pneumothorax.

FIGURE 3 ■ (A) Superior (laparoscopic) view of space of Retzius with four Burch sutures in place. (B) Parasagittal view of Burch sutures attached to Cooper's ligament.

It is uncommon to see a patient who requires only a Burch colposuspension; therefore, the intraperitoneal technique is the more common approach in many centers.

3 cm above the suprapubic bone and 2 cm lateral to midline, avoiding the inferior epigastric vessels. The remainder of the procedure is carried out similar to the transperitoneal Burch. Mesh and tacks are utilized more often than sutures in the extraperitoneal Burch literature. Cure rates reported for both techniques are comparable to that for open Burch.

It is uncommon to see a patient who requires only a Burch colposuspension; therefore, the intraperitoneal technique is the more common approach in many centers (10,30–32).

Most patients requiring pelvic reconstructive surgery need additional procedures including apical vault support, paravaginal repair, anterior and/or posterior vaginal repair, or other intra-abdominal procedures (33).

OUTCOMES, COMPARATIVE STUDIES, COMPLICATIONS, AND COSTS

Outcomes

When examining outcomes of Burch colposuspension procedures, a differentiation between procedures done with the true Burch–Tanagho technique and those utilizing multiple modifications in surgical techniques is important. The confusingly varied outcomes reported for the laparoscopic "Burch" result, in part, from a failure to make this differentiation between techniques.

When examining outcomes of Burch colposuspension procedures, a differentiation between procedures done with the true Burch–Tanagho technique and those utilizing multiple modifications in surgical techniques is important. The confusingly varied outcomes reported for the laparoscopic "Burch" result, in part, from a failure to make this differentiation between techniques.

We will delineate the outcomes from laparoscopic classical Burch technique verses "modified Burch" procedures. As stated earlier, the laparoscopic Burch will refer only to procedures utilizing the Burch–Tanagho technique and all other procedures will be called laparoscopic colposuspensions.

In their initial report, Vancaillie and Schuessler (4) duplicated the Marshall–Marchetti–Krantz laparoscopically. Subsequently, the same group (5) reported 10 laparoscopic Burch colposuspensions, utilizing one suture per side. Several series reported laparoscopic Burch success rates of 89% to 100% with one to two-year follow-up (Table 3) (6,7,8,32,34–38). Liu (6) reported on 107 cases with 97% subjective cure rate over a follow-up of 3 to 27 months. He had a 10% complication rate including four cystotomies and one kinked ureter. He reported high patient satisfaction.

Extracting data from six different studies (8,10,12,33,39,41), we demonstrated an objective cure rate of 91% at one year in 178 patients. The majority of these patients showed objective cure by multichannel urodynamic testing. In most of these studies, patients with detrusor instability and intrinsic sphincter deficiency were excluded. The de novo detrusor instability rate was less than 9% with one to two years of follow-up, which is lower than that reported in most open Burch colposuspension studies (42–45). On urodynamic testing, there was a significant increase in pressure transmission ratio, functional urethral length, and maximum bladder capacity. There was no significant change in maximal flow rate. Multiple laparoscopic procedures for total vaginal vault prolapse and genuine stress incontinence were performed (33), including the first reported laparoscopic paravaginal repair. With the laparoscopic Burch alone, 97% of the patients were discharged in less than 24 hours and 93% voided spontaneously prior to

discharge. When combined with multiple repairs including laparoscopic hysterectomy, posterior vaginal repair, apical vault repair, and sacrocolpopexy, 91% of the patients were discharged in less than 48 hours. The few patients who experienced delayed voiding had substantial posterior repairs or preoperative maximum flow rates of ≤15 cc per second. In the absence of these two factors, it was uncommon for a patient to not be able to void on the first postoperative day.

Cooper et al. (38) reported on 113 women in a retrospective study, with a mean follow-up of eight months. A combination of transperitoneal (94) and extraperitoneal (21) approaches were used. There was an 87% subjective cure rate. Fourteen percent of these patients had mixed incontinence. There were 10 cystotomies, one inferior epigastric vessel injury, one vaginal tear, one suture in the bladder, and one possible enterotomy. Papasakelariou and Papasakelariou (32) reported a subjective cure of 91% at two years. Flax (46) used gasless laparoscopy to perform Burch colposuspensions in 47 patients. A balloon was used to open the retropubic space and then a laparolift system was used for exposure in placing four Burch sutures. Forty-four of 47 patients—a 90% cure rate—needed no pads with a mean follow-up of 8.2 months. Persson and Wolner-Hanssen (47), in a randomized controlled study of 161 patients, demonstrated the importance of two sutures per side in the laparoscopic Burch colposuspension. One group of 78 had one double-bite and the other group of 83 had two single-bite sutures on each side. At one year, the objective cure rate was 58% and 83%, respectively ($p = 0.001$). These findings support the necessity of two sutures per side for optimum results and give a possible explanation for the high failure rate reported by many with a single suture per side. Persson stopped this study before he reached adequate numbers of patients required to power the study, because of poor outcomes in patients with one suture per side.

There are numerous reports of modified laparoscopic colposuspensions with varying results. The majority of these modifications are attempts to minimize intracorporeal laparoscopic suturing in order to simplify the procedure.

The staple-mesh technique was first reported in 1993 (48). After opening the space of Retzius and removing the fat from the paraurethral area, the vaginal hand elevates the tissue 2 cm lateral to the bladder neck and a one by three centimeter strip of Prolene hernia mesh is attached with two to three staples. With the tissue still elevated, the other end of the mesh is stapled to Cooper's ligament. All 40 patients, with a mean follow-up of six months, reported improved voiding and resolution or improvement of symptoms. At five years (49), 27 patients were seen in the office and seven returned questionnaires. The five-year success rate, defined as no recurrent leaking by history, was 88% (30 of 34 confirmed outcomes). These authors recommend this procedure for the advantages of a shorter learning curve and good outcome, as reported by others (50,51).

We performed a randomized controlled study comparing laparoscopic suture Burch (35 patients) and laparoscopic staple-mesh colposuspensions (34 patients). At one year, the objective cure rates were 91% and 94%, respectively.

In a work in progress, the five-year follow-up showed a significant difference, with an 84% cure for the suture group and 57% cure for the staple mesh ($p < 0.003$) (Ross, unpublished data). Reentry into the space of Retzius was extremely difficult in the staple-mesh group, secondary to extreme scarification. The mesh had pulled away from the pubocervical fascia in the several patients who had repeat surgery. We no longer use this technique due to our high long-term failure rate and the difficulty in additional surgery. Others (52,53) have reported similarly poor long-term outcomes.

McDougall (54) compared modified laparoscopic colposuspension to a Raz procedure, reporting similar one-year outcomes. In the laparoscopic colposuspension, two braided sutures were placed in the endopelvic fascia on each side and tied intracorporeally. The sutures were then passed through Cooper's ligament and secured with a polydioxanone clip. In a retrospective long-term review (54) (mean 45 months, range 17–71 months), only 15 of 50 patients with laparoscopic colposuspension and 10 of 29 patients who underwent Raz procedures were continent. In addition, there was a 28% rate of urge incontinence. The failure of delayed absorbable clips could possibly play a role in the early poor outcomes reported. Two more studies reporting poor long-term outcomes used different ways of suturing. At 36 months, laparoscopic colposuspensions done with bone screws had a 40% cure rate by patient questionnaires Das. Lobel and Davis (57) used a variety of suturing techniques utilizing curved needles, straight needles, and Stamey needles. Many of these patients had one suture per side and at 36 months, the cure rate was 69% and improved 11%. There are several reports utilizing different types of needle to incorporate transvaginal tissue, transfix Cooper's ligament, or to fix sutures to the abdominal wall with buttons to complete a laparoscopic

There are numerous reports of modified laparoscopic colposuspensions with varying results. The majority of these modifications are attempts to minimize intracorporeal laparoscopic suturing in order to simplify the procedure.

We performed a randomized controlled study comparing laparoscopic suture Burch (35 patients) and laparoscopic staple-mesh colposuspensions (34 patients). At one year, the objective cure rates were 91% and 94%, respectively.

colposuspension (58–61) Harewood, (62). It is difficult to compare these studies to studies utilizing the traditional Burch–Tanagho procedure.

Other variations in sutures include a staple-suture procedure (63), in which a hernia stapler is used to staple a Gore-Tex suture to the pubocervical fascia and then to Cooper's ligament. The free ends of the suture are then tied with an extracorporeal knot to help set the height of elevation. No outcome data for the 60 patients treated with this technique have been published. In the Nolan–Lyons procedure (64), the pubocervical tissue is pulled up through an endoloop, which is tightened down to hold the tissue. The endoloop is used to pull the tissue to the desired elevation and then stapled to Cooper's ligament. Lyons reported a 92% subjective cure rate at 12 months. No long-term data have been reported. Kiilholma et al. (65) performed a modified colposuspension on 17 patients by applying fibrin sealant glue to the urethrovesical junction on each side of the bladder neck. Then, placing the first and middle finger in the vagina, the urethrovesical junction was pressed to the retropubic periosteum and held there for five minutes. Twelve patients were followed for 12 months; 10 reported being completely dry and two were improved.

In 1999, we reported an 85% objective cure rate at five years in a prospective longitudinal study of 87 women who had undergone laparoscopic Burch (41). Objective cure was defined as no evidence of genuine stress incontinence, detrusor instability, or intrinsic sphincter deficiency on urodynamic testing or CST. In addition, bladder neck ultrasound at maximum cystometric capacity was used on many patients. The laparoscopic technique duplicated the open Burch–Tanagho except for the mode of entry into the space of Retzius. All patients voided spontaneously before discharge at 24 hours, or 48 hours if they had a concomitant laparoscopic hysterectomy. All patients were on oral pain medication in less than 12 hours. Treatment failures were greatest in the first year after surgery. There were no additional failures in the fourth year and only one in the fifth year. There was a positive correlation between failure and severity of pelvic organ prolapse at the time of repair.

Comparative Studies

Ideally, comparisons between surgical procedures should be based on the long-term results of direct, head-to-head studies in which cohorts of similar patients are prospectively randomized to undergo one of the different procedures to be studied, and follow-up evaluation is conducted by practitioners blinded as to which procedure the patients have undergone. Unfortunately, it is often difficult to get patients to agree to randomization after two different procedures have been described as successful, making randomized controlled studies rare. The following studies compare the clinical outcomes of laparoscopic Burch colposuspension with those of the open Burch colposuspension, laparoscopic colposuspension with mesh and staples, tension-free vaginal tape suburethral sling, and bone anchor suburethral slings. For comparison purposes, the laparoscopic Burch colposuspension is defined as the Burch–Tanagho colposuspension performed via laparoscopic access.

Laparoscopic vs. Open Burch Colposuspension

There are five prospective, randomized controlled studies comparing open and laparoscopic colposuspension in the literature. Three of these studies utilized the classic Burch–Tanagho technique, and two modified the technique by using one suture per side in most cases. All three studies utilizing the Burch–Tanagho technique have been reported in abstracts. Burton (66,67) reported a randomized controlled trial comparing open and laparoscopic Burch, utilizing absorbable suture. His study included 30 patients with moderate to severe genuine stress incontinence in each arm followed for three years postoperatively. Superior results, in terms of both subjective and objective cure, were noted in the open arm, both at one- and three-year follow-up. Objective cure, defined as no genuine stress incontinence on video cystourethrography at one year, was noted in 97% of the open cases and 73% of the laparoscopic cases. At three years, the open procedure maintained a 93% objective cure rate, while the laparoscopic cure rate had dropped to 60%. Burton has been criticized for having done only 10 laparoscopic procedures prior to the onset of the study. Subsequently, two multicenter studies demonstrated no significant differences in outcomes between the two procedures. Carey et al. (68), in a multicenter study involving 200 patients with proven genuine stress incontinence randomized to open or laparoscopic Burch colposuspension, showed six-month objective urodynamic cure rates of 80% and 69% for the two procedures, respectively, and subjective success of 95% and 100% between the two procedures, respectively. Neither difference was statistically significant. Summitt et al. (69), in a multicenter trial involving 28 laparoscopic procedures and 34 open procedures, demonstrated objective one-year success rates of 92.9% for the laparoscopic Burch and 88.2% for the open Burch.

Lavin et al. (70) had cure or improvement of 71% and 91% in a laparoscopic Burch group and 67% and 89% in a open Burch group at six months. At two years, cure and improvement had fallen to 58% and 77% in the laparoscopic group and 50% and 59% in the open group. Saidi et al. (22), in a retrospective study, compared 70 patients with laparoscopic Burch to 87 patients with open Burch and reported 91% and 92% objective cure at 12 months, respectively.

Prospective randomized studies in which one stitch per side was utilized have shown mixed results. Su et al. (71), utilizing two to three stitches per side for open colposuspensions but only one stitch per side on most of their laparoscopic colposuspensions, showed objective cure rates of 80.4% and 95.6% for laparoscopic and open colposuspensions, respectively. These patients had a minimum one-year follow-up and objective cure was defined as dry on urodynamic testing. Interestingly, on a one-hour extended pad test, the laparoscopic group showed a slightly greater improvement than the open group, although there was no statistically significant difference between the groups pre- or postoperatively with respect to this measure. As previously discussed, the difference between one stitch and two per side likely accounts for the difference in outcomes. In 2001, Fatthy et al. (72) published a study in which one suture per side was utilized for both the open and laparoscopic colposuspensions.

> Prospective randomized studies have shown no statistically significant difference in objective cure (by urodynamic testing), with cure reported in 87.9% of the laparoscopic cases and 85% of open cases after a follow-up of 18 months.

Prospective randomized studies have shown no statistically significant difference in objective cure (by urodynamic testing), with cure reported in 87.9% of the laparoscopic cases and 85% of open cases after a follow-up of 18 months.

There are three published retrospective cohort studies comparing open with laparoscopic Burch, utilizing the classic Burch–Tanagho technique. Ross (8) reported one-year objective cure rates of 94% and 93%, respectively, for the laparoscopic and open approaches in a cohort study involving 30 patients followed prospectively in the laparoscopic arm compared to a retrospective evaluation of 32 in the open arm. That same year, Polascik et al. (73) reported on a retrospective cohort study, showing a subjective cure rate of 83% using the laparoscopic approach with a mean follow-up of 20.8 months versus 70% via the abdominal route with a mean follow-up of 35.6 months. More recently, Huang and Yang (74), in a retrospective cohort study, reported one-year subjective cure rates of 84% and 89% for laparoscopic and open Burch colposuspensions, respectively. There were no statistically significant differences in cure rates between the two approaches in any of these three studies. Miannay et al. (75) also demonstrated no difference in subjective cure rates at one and two-year follow-up between open and laparoscopic colposuspension, even though only one suture per side was utilized in the laparoscopic cases.

> Overall, laparoscopic Burch colposuspension, when performed in an identical fashion to the open Burch, yields one-year results comparable with those of the open Burch and results in less post-operative pain, a shorter hospital stay, and a quicker return to normal activity. Long-term comparative data are still lacking.

Laparoscopic Burch studies report the following advantages: a shorter length of stay with the laparoscopic approach was noted in all but one study in which this parameter was studied (3,5–7,9,11,12,74). Likewise, significantly less postoperative pain (5–7,12) and a quicker return to normal activity were noted in the laparoscopic group (5,7,11,12). When reported, complications did not differ statistically. The data from these studies are, for the most part, consistent with prior noncomparative studies of laparoscopic Burch colposuspension.

Overall, laparoscopic Burch colposuspension, when performed in an identical fashion to the open Burch, yields one-year results comparable with those of the open Burch and results in less post-operative pain, a shorter hospital stay, and a quicker return to normal activity. Long-term comparative data are still lacking.

Laparoscopic Burch vs. Tension-Free Vaginal Tape Suburethral Sling

It has been almost a decade since Ulmsten et al. (76) described the tension-free vaginal tape suburethral sling procedure and reported on his early successes. The rapid rise in popularity of the tension-free vaginal tape procedure has coincided with the rise in popularity of the laparoscopic Burch colposuspension as minimally invasive procedures for the cure of genuine stress urinary incontinence. Both procedures have their cadre of proponents, with laparoscopic Burch colposuspension advocates noting the longer track record of the Burch procedure, the ability to visualize the surgical field, and the lack of concern over erosion, while tension-free vaginal tape advocates point to shorter duration of surgery, slightly shorter recovery, relative ease of the procedure, and perceived lower cost. To date, there have been two prospective, randomized controlled trials published comparing the two procedures and one large prospective randomized controlled trial comparing tension-free vaginal tape with the open Burch procedure.

Persson et al. (77) reported one-year follow-up data on their prospective randomized trial comparing tension-free vaginal tape with laparoscopic Burch colposuspension. Their study, assessing 31 patients in the laparoscopic arm and 37 patients in the

tension-free vaginal tape arm, demonstrated no significant difference in efficacy between the two procedures, with objective cure rates (defined as a negative short pad test) of 87% and 89%, respectively, for the laparoscopic Burch and tension-free vaginal tape. Interestingly, subjective cure rates were markedly lower in both groups, 52% and 57%, respectively. These findings were based on a strict questionnaire and there was no significant difference between the two. Ustun et al. (78) reported a study of 46 patients with genuine stress incontinence randomized to undergo laparoscopic Burch ($n = 23$) or tension-free vaginal tape ($n = 23$) who were followed for up to 24 months postoperatively. They showed an objective cure rate of 82.6% in both groups. The laparoscopic Burch group had a mean follow-up of 13.5 months, and the tension-free vaginal tape group with 11.3 months. Cure was defined as subjectively dry, negative stress test, and no leakage on urodynamic testing performed at three months.

Ward and Hilton (79) recently published two-year data on their ongoing prospective randomized controlled trial comparing tension-free vaginal tape with open Burch colposuspension. The two-year follow-up data for objective cure by negative pad test was not statistically different between the two procedures, with 81% of tension-free vaginal tape patients and 80% of open Burch patients cured. Sixty-two percent of the patients with the open Burch procedure and 60% of tension-free vaginal tape patients reported being dry in this study. These findings are in agreement with other studies comparing these procedures.

There are few studies with direct comparisons of complication rates, costs, length of stay, and perioperative convalescence between laparoscopic colposuspension and tension-free vaginal tape. In Persson and Wolner-Hanssen's study (47), the authors noted a statistically shorter operating time and fewer postoperative visits in the tension-free vaginal tape group. There was also a trend toward earlier discharge in the tension-free vaginal tape group. Ustun et al. (78) reported shorter operating room time and length of stay in the tension-free vaginal tape group. These data are, for the most part, consistent with noncomparative data on tension-free vaginal tape, which generally show operating time shorter than that reported in most studies for laparoscopic Burch. In general, the more experienced the laparoscopist, the smaller the difference in time between the two procedures. Despite the shorter operating room time, Persson and Wolner-Hanssen (47) found the total cost of tension-free vaginal tape to be higher than that of the laparoscopic Burch, because of the high cost of the tension-free vaginal tape set. Cost comparisons are notoriously difficult not only because of differences in surgery times among different surgeons but also because operating roomtime costs per minute differ among different locations. There are no studies with direct comparisons of intraoperative and postoperative complications.

In a prospective randomized study comparing immediate outcomes of tension-free vaginal tape and laparoscopic mesh colposuspension, Valpas et al. noted no major differences in intraoperative or postoperative complications. Likewise, Debodinance et al. (81), in a retrospective review of all 800 female anti-incontinence procedures performed at their hospital over 13 years, showed no major differences in intraoperative or immediate postoperative complications between tension-free vaginal tape and laparoscopic Burch colposuspension. He did note higher de novo voiding difficulties (18.5% vs. 0%) and de novo urgency (11% vs. 4.8%) in tension-free vaginal tape when compared to laparoscopic Burch colposuspension. Valpas et al. (80) demonstrated a shorter duration to complete bladder emptying and reduced pain medication consumption in the tension-free vaginal tape group.

Laparoscopic Burch vs. Bone-Anchored Sling

In addition to tension-free vaginal tape, transvaginal bone-anchored sling procedures have been introduced in an attempt to provide a minimally invasive sling for the treatment of female genuine stress incontinence. There are no long-term follow-up studies beyond 36 months for bone-anchored slings and no comparative studies. There is no prospective data or objective outcomes analysis.

Studies reporting on bone-anchored slings utilizing cadaveric fascia for the sling component demonstrate cure rates ranging from 37% to 78%, with mean follow-ups of 10.6 and 30 months (82–84). Suspected failure of the cadaveric material is the given for the poor results. The best results are a 78% subjective cure rate with a mean follow-up of 12.4 months, obtained utilizing Tutoplast cadaveric fascia lata. Complication rates were low, though de novo urge incontinence was noted in 58% of patients in one study (83).

Three studies utilized coated polyester for the sling component. Cure rates were 61.5% at a mean follow-up of 11.4 months (85) to 90% with a minimum follow-up of 24 months (86). The latter study excluded patients with ISD. Giberti and Rovida (87) reported

a 100% failure rate with four patients with intrinsic sphenteric deficiency. Erosion and impaired wound healing were a significant problem in two of these studies, affecting 16% (87) and 53.8% of patients (85). Rates of de novo urgency and/or voiding dysfunction ranged from 8.6% (85,86).

With the lack of comparative trials, evidence from the current literature on transvaginal bone-anchored sling would indicate that it offers no advantage over laparoscopic Burch, in terms of efficacy, and may produce inferior results. Additionally, the studies suggest a higher complication rate. Comparative studies are necessary to make any further clinical assessment of transvaginal bone-anchored sling procedures.

Complications

Few studies differentiate between major and minor complications. The complication rates range from 0% to greater than 20% (Table 4) (5,33,38,57). Major complications seen with laparoscopic Burch include bladder injury, ureteral damage or kinking, abscess or seroma formation in the space of Retzius, failed procedure requiring additional surgery, de novo detrusor instability, new onset intrinsic sphincter deficiency, urinary retention, voiding dysfunction, and a possible increase in posterior compartment prolapse (87).

Speights et al. (89) reported a 2.3% lower urinary tract injury rate in 171 patients. The four injuries were inadvertent cystotomies, two following prior Marshall–Marchetti–Krantz and staple-mesh procedures. All occurred in the dome of the bladder and were repaired laparoscopically intraoperatively. There were no ureteral injuries. The authors pointed out that this injury rate was lower than the 10% injury rate observed in an open Burch colposuspension series (90). A French center (91) reported a 3% injury rate in 104 laparoscopic Burch procedures, two cystotomies and one partial ureteral transaction. Ferland and Rosenblatt (21) reported ureteral obstruction in two postoperative patients. Cystoscopy revealed a transmural passage of suture anterior and lateral to the urethral orifice in one patient and puckering and lateral displacement of the right trigone, causing ureteral obstruction in the second patient. Both these injuries were on the patient's right side, similar to other reports (92,93). Ferland suggested that when the surgeon stands on the patient's left side, suture placement tends to be lateral-to-medial with the right-sided sutures, increasing the risk of entrapment of the right bladder wall and intramural ureter (Fig. 4). To prevent this complication which is not seen on the left side because the natural suture placement is medial-to-lateral away from the bladder for a right handed surgeon, he recommended passing the right sutures medial-to-lateral (Fig. 5).

Dwyer et al. (93) reported three cases of bladder sutures and three cases of ureteral obstructions by suture in 178 patients, with an overall lower urinary tract injury rate of 3.4%. Cooper et al. (38) reported on 10 cystotomies and 1 bladder suture in 113 patients, resulting in a 9.7% lower urinary tract injury rate. The overall laparoscopic injury rate for the lower urinary tract in all gynecologic cases ranges from 0.02% to 1.7%, which is not different from that seen with open gynecologic cases. The higher incidence of inadvertent cystotomies reported in some series were usually in patients with prior surgery in the space of Retzius and were bladder dome injuries easily recognized and repaired at the time of surgery. It is essential that intraopertive cystoscopy be performed to identify occult bladder and ureteral injuries in all major urogynecologic procedures.

Data on de novo detrusor instability are scant and not well reported in most studies. The range appears to be approximately 3% to 13% (31,38,72,95). Cardozo et al. (45) reported a rate of 18.5% de novo detrusor instability in open Burch, supported by others (43,96,97). Jarvis reported a 9.6% mean incidence of laparoscopic de novo detrusor instability in a meta-analysis, with a range of 4% to 18% (98). These reports suggest a slightly higher rate of de novo detrusor instability with the open procedure. It has been suggested that the less scarring in the laparoscopic procedure could minimize occurrence of

detrusor instability. This has not been clearly demonstrated. In over 300 cases, our de novo detrusor instability rate following laparoscopic Burch has been 8% (Ross, unpublished data, 2004).

Several published series report no significant voiding dysfunction with laparoscopic Burch (6,10,37,40). Lavin et al. (70) found significantly less subjective voiding dysfunction after two years in laparoscopic versus open Burch, 16% and 52%, respectively. Su et al. (71) reported 4.3% voiding dysfunction in both laparoscopic and open Burch. No long-term follow-up studies are available. We have as many as 20% of our patients report positional changes in order to empty their bladders in the first six months following laparoscopic Burch, usually with resolution by the end of the first year. Routine bladder ultrasounds in our clinic have not demonstrated significant problems with increased postvoid residue.

The majority of studies have found less blood loss with laparoscopic Burch (22,70,71,73). Earlier, spontaneous voiding compared to other procedures has been reported in several studies (22,71,99). Decreased length of stay in the hospital has been reported in almost all of the laparoscopic studies (73).

Abdominal wall vascular injury is usually secondary to lateral trocar placement, resulting in inferior epigastric vessel damage (8). The reported incidence is 0.5% and it is reported to be less frequent with cone-shaped or blunt trocars (0%) as compared to sharp-cutting ones (0.83%) (100). Major bleeding, requiring transfusion, has been reported after injury to abdominal wall vessels (101).

A major advantage of laparoscopic surgery is the significantly lower ventral hernia formation (100). Most hernias that develop at trocar sites are due to lack of closure and are entirely preventable. The majority of these hernias are extraumbilical and the contents are usually small bowel (Richter hernia) (84.2%) and, less often, colon and omentum (102). Margossian et al. (103) reported a preperitoneal herniation of the terminal ileum through the right lateral 10-mm port in which the fascia had been closed, but not the muscle and peritoneum (Fig. 6). We had a similar experience with a left 10-mm trocar site. To prevent this complication, it is necessary to close the peritoneum, muscle, and fascia at large trocar sites. Several companies have simple devices to use for this purpose[g] and it adds very little time to the operative procedure (Fig. 7).

A rare complication reported during laparoscopy is postoperative acute ischemic necrosis of the small bowel. Hasson et al. (104) reported a case of a 34-year-old woman who underwent extensive adhesiolysis and myolysis and was readmitted with an acute abdomen 48 hours after discharge. At laparotomy, the patient had acute peritonitis, extensive adhesions, and a 3-cm perforation in the small bowel. Tissue examination of the resected bowel showed ischemic necrosis. Seven of eight patients with this diagnosis died. None of these patient's surgeries took longer than 1.4 hours. These cases reported in this series were described as elective, routine, uneventful, or without apparent complications at the time of surgery. The possible pathophysiology could stem from

FIGURE 7 ■ It is important to close fascia, muscle, and peritoneum; especially at large trocar sites. *Source*: From Ref. 102.

CO_2 pneumoperitoneum, which can cause decreased cardiac output due to increased systemic resistance, decreased venous return, and elevated intrathoracic pressure. It can potentially cause reduction in splanchnic blood flow, resulting from mechanical compression of mesenteric veins, humoral vasoconstriction of mesenteric vessels, and increased portal venous pressure caused by absorption of CO_2 and increased release of vasopressin. These effects can lead to mesenteric thrombosis, resulting in infarction of small bowel. Atherosclerosis, dense adhesions, or congenital stenosis can trigger these mechanisms. Hasson et al. suggest prevention is better than treatment in handling this catastrophic complication and recommend not letting the intra-abdominal pressure exceed 15 mmHg and periodically decompressing the pneumoperitoneum. This reinforces the adage that a patient should typically get better each day following laparoscopic surgery, and even small setbacks require immediate action.

> Walter et al. report minimal differences in complications, blood loss, operative time, hemoglobin change, hospitalization, or hospital charges between open and laparoscopic Burch.

Costs

Walter et al. (105) report minimal differences in complications, blood loss, operative time, hemoglobin change, hospitalization, or hospital charges between open and laparoscopic Burch.

At Walter et al.'s (104) facility, charges were $9900 and $9400, respectively, for the laparoscopic and open procedure. The authors concluded that there were no benefits with laparoscopy when vaginal prolapse repairs were performed. Kohli et al. (99) found laparoscopic operative times to be significantly longer and laparosocopy was higher than laparotomy ($4960 vs. $4079). Mean length of stay was 1.3 days and 2.1 days with laparoscopy and open colposuspensions, respectively, with laparoscopic equipment usage and cost being greater. Kung et al. (106) extracted cost data from hospital charts and office records. Professional fees, investigations, drugs, capital equipment, disposable equipment, and length of stay were used to calculate costs. There was a significant difference between laparoscopy and open procedures ($2938 vs. $5692). The cost-effective ratios (cost/cure) were $3029 and $6324 for laparoscopy and open procedures, respectively.

PARAVAGINAL REPAIR

Paravaginal herniation is commonly associated with urinary incontinence. The defect is suspected on pelvic exam when, on the Valsalva maneuver, the lateral sulcus bulges out, causing a cystocele with prominent vaginal rugae. The diagnosis is confirmed if both lateral sulci are supported and, on maximal Valsalva, the cystocele is no longer present. The defect can be unilateral or bilateral (33,107). It is caused by the tearing away of the pubocervical fascia from the arcus white line. The defect can be complete from the ischial spine to the pubic bone or partial, usually starting in the proximal portion. To start the repair, the pelvic floor is elevated with the vaginal hand and the bladder is mobilized medially. Interrupted permanent sutures are placed through the torn edge of the pubocervical fascia and then through the arcus white line. The first suture is placed proximally just above the ischial spine with the obturator canal directly above. Interrupted sutures are continued distally until the defect is closed, usually requiring four to six sutures. The paravaginal repair is done before performing the Burch procedure.

SUMMARY

■ Laparoscopy has become an extremely useful tool in the surgical armamentarium of pelvic floor reconstruction over the past decade.

■ Centers utilizing the laparoscopic Burch–Tanagho technique have reported comparable results to the open technique. Long-term follow-up studies are awaited.

■ There is no reason to anticipate different outcomes between open and laparoscopic procedures because the only technical variation is mode of entry.

■ Proper laparoscopic suture technique is just as efficient as open knot tying. Many initial reports of poor outcomes may be secondary to the steep learning curve and the difficulty in becoming proficient in suturing with laparoscopy.

■ Due to increased experience, more exposure to advanced procedures, better instrumentation, and better criteria for patient selection, reported complication rates after laparoscopic procedures are decreasing.

■ The incidence of urinary incontinence in women is increasing, and because there is better dissemination of information, younger women are seeking minimally invasive treatment for urinary incontinence. Laparoscopic Burch, transvaginal tape, and now transobturator procedures are appealing options.

INTRODUCTION

Vesicovaginal fistula remains a challenge to surgeons and a nuisance to patients, more so if it is recurrent. Controversy still exists over the ideal approach and time to repair. Introduction and promulgation of videolaparoscopy by Nezhat (1) has revolutionized modern day surgery and has become the predominant means of performing many common surgical procedures (2–4). With recent advances in minimally invasive urogynecologic techniques, it is possible to repair some of these fistulas laparoscopically. Operative laparoscopy for segmental bladder resection, vesicovaginal fistula repair, ureteroureterostomy and ureteroneocystostomy with or without psoas hitch had been reported by Nezhat et al. in 1990s (5,6). The laparoscopic approach significantly reduces the access trauma of traditional laparotomy with additional advantages of magnified vision of pelvic organs and less traumatic tissue handling and enables the surgeon to treat concomitant intraperitoneal pathology at the same time. Shorter hospital stay and accelerated postoperative recovery are other benefits of laparoscopic approach.

> The primary etiology of vesicovaginal fistula in developed countries is surgical trauma associated with gynecologic procedures. Abdominal hysterectomy has been shown to be the most common cause, with vesicovaginal fistula occurring in approximately one of every 1800 hysterectomies.

ETIOLOGY

The primary etiology of vesicovaginal fistula in developed countries is surgical trauma associated with gynecologic procedures. Abdominal hysterectomy has been shown to be the most common cause, with vesicovaginal fistula occurring in approximately one of every 1800 hysterectomies (7). Secondary causes include complications of obstructed labor, and radiation therapy of urogynecologic cancers.

There is a paucity of data regarding the pathogenesis of posthysterectomy vesicovaginal fistula. It is generally believed that vesicovaginal fistula are caused by suture ligation or crush injuries to the bladder at the time of hysterectomy. However, Meeks et al. (8) studied the outcome of 2/0 polyglactin suture placed through the bladder and vaginal cuff at the time of hysterectomy in 21 rabbits. Despite the placement of a hemostatic stitch through the bladder and vaginal cuff, no vesicovaginal fistula was seen in any of the animals. They concluded that if bladder injury were the sole cause of vesicovaginal fistula, a much higher rate of vesicovaginal fistula would be expected. Recently, Cogan et al. (9) investigated the relationship between various types of laparoscopic

bladder injuries (bipolar injury without perforation vs. 2-0 polyglactin suture through the bladder wall vs. bladder laceration with monopolar cautery that was repaired with 2-0 polyglactin suture) and vesicovaginal fistula formation in an animal model. Vesicovaginal fistulas were detected only in the groups with monopolar cautery bladder injuries. It was concluded that an electrosurgically induced cystotomy and repair of the bladder during the performance of a laparoscopic hysterectomy was associated with the formation of postoperative vesicovaginal fistulas. Flynn and Amundsen (10) noted multiple cavities in the vaginal epithelium and pathologic evidence of chronic inflammation in an acute setting in a patient with recurrent vesicovaginal fistula. They suggest that vesicovaginal fistula formation is multifactorial and that additional factors besides bladder injury such as chronic infection and formation of small abscesses may also play a role in the formation of postoperative fistula. In addition abscess rupture may be a mechanism for fistula tract formation.

DIAGNOSIS

Postsurgical vesicovaginal fistulas usually present 7 to 21 days after surgery. Most patients have urinary incontinence or persistent vaginal discharge. If the fistula is very small, leakage may be intermittent, occurring only at maximum bladder capacity or with particular body position. Other signs and symptoms include unexplained fever; hematuria; recurrent cystitis or pyelonephritis; vaginal, suprapubic, or flank pain; and abnormal urinary stream (11).

> **Postsurgical vesicovaginal fistulas usually present 7 to 21 days after surgery.**

Office testing is often able to distinguish between fistulas involving the bladder or ureters. Instillation of methylene blue into the bladder stains vaginal swabs or tampons in the presence of vesicovaginal fistula. If this test is not diagnostic, a transurethral Foley catheter should be placed to prevent any staining of the distal tampon from the urethral meatus. Unstained but wet swabs may indicate a ureterovaginal fistula. If leakage is not demonstrated, the bladder is filled to maximum capacity and provocative maneuvers such as valsalva or manual pressure over the bladder used to reproduce and confirm patient's symptoms. Intravenous indigo carmine can be given to rule out ureterovaginal fistula. Further evaluations, such as cystoureteroscopy and intravenous urogram permit the physician to localize the fistula, determine adequacy of renal function, and exclude or identify other types of urinary tract injury.

SURGICAL TECHNIQUE

Vesicovaginal fistulas are treated with different surgical techniques, depending on their cause and location. Small vesicovaginal fistulas that are not responsive to nonsurgical management, are usually repaired easily (12). The edges of the fistula are removed, and the defect is closed. Latzko's technique is used commonly for fistulas that are surrounded by severe fibrosis and close to the bladder neck or urethral meatus. Lee et al. (13) recommend an abdominal approach for fistulas in the upper part of a narrow vagina, multiple fistulas, those associated with other pelvic abnormalities, and fistulas close to the ureter. A combined abdominal and vaginal approach is used in some instances (14). Laparoscopy can be an alternative to laparotomy for managing vesicovaginal fistulas (15). Proposed advantages include magnification during the procedure, hemostasis, and shorter hospital stay and postoperative recovery.

> **The basic principles for laparoscopic repair of vesicovaginal fistula include adequate exposure, excision of fibrous tissue from the edges of the fistula, approximation of the edges without tension, the use of suitable suture material, and efficient postoperative bladder drainage.**

The basic principles for laparoscopic repair of vesicovaginal fistula include adequate exposure, excision of fibrous tissue from the edges of the fistula, approximation of the edges without tension, the use of suitable suture material, and efficient postoperative bladder drainage.

After induction of general anesthesia and placement of patient in dorsal lithotomy position, a 10-mm intraumbilical incision is made for insertion of the operative laparoscope coupled with the CO_2 laser. Any other cutting modality such as scissors, or ultrasonic or radio frequency energy can be used. Three 5-mm trocars are inserted in the lower abdomen for the suction-irrigator probe, grasping forceps, and bipolar forceps (16). The abdominal and pelvic cavities are inspected for any coexisting pathology. A simultaneous cystoscopy is done, and both ureters are catheterized to aid in their identification and protection during excision and closure of the fistula. A urethral catheter is pulled through the fistula into the vagina to facilitate identification during excision.

A digital rectovaginal examination is carried out to exclude rectal involvement. The bladder is carefully dissected away from the vagina using laparoscopic scissors

and gentle countertraction. An opening is made into the vagina, avoiding the bladder and rectum, and an inflated glove in the vagina helps maintain pneumoperitoneum. The anterior vaginal wall is elevated with a grasping forceps, and the fistula is identified with the previously inserted catheter, which also delineates the posterior bladder wall. The bladder is filled with water, and a cystotomy is made above the fistula. The water is evacuated as the bladder is distended by pneumoperitoneum from the cystotomy. The fistula tract, vesicovaginal space, and ureters are observed laparoscopically (Fig. 1). The vesicovaginal space is further developed laparoscopically using sharp dissection. The bladder is freed posteriorly from the vaginal wall. The fistula is identified, held with a grasping forceps, and excised (Fig. 2). Adequate bladder dissection and mobilization are essential to eliminate tension upon suturing.

Initially, the vaginal wall opening of approximately 1.5 cm is closed with one layer of interrupted polyglactin (Vicryl) suture (Fig. 3). Then the vesical defect is repaired in one or two layers with interrupted 2-0 or 3-0 polyglactin sutures, using intra- or extracorporeal knotting. Defects in the vagina and bladder are closed separately. Hemostasis in the vesicovaginal space and fistula area is essential. A peritoneal flap is obtained superior and lateral to the bladder dome, close to the round ligament and diverted toward the bladder base. The flap is used to separate the vesicovaginal space. The omentum can also be mobilized and introduced between the bladder and vaginal wall. Using two interrupted sutures of 3-0 polyglactin, the peritoneal or omental flap is anchored to the anterior vaginal wall. The bladder is filled in a retrograde fashion with 300 mL of diluted indigo carmine to confirm the integrity of the vesical wall. No intraperitoneal drainage is used. A suprapubic or transurethral catheter is inserted and ureteral catheters are removed. Prophylactic antibiotic can be administered postoperatively. The bladder catheter is left in place for 10 to 20 days and then a, cystogram is performed to verify the bladder integrity.

FIGURE 1 ■ The fistula tract, vesicovaginal space and ureters are observed laproscopically.

FIGURE 2 ■ Vesicovaginal space is further developed laparoscopically.

FIGURE 3 ■ The fistula tract is excised using CO_2 laser.

PREVENTION

In operative laparoscopy, meticulous dissection of vesicovaginal space and good hemostasis are essential for prevention of vesicovaginal fistula.

In operative laparoscopy, meticulous dissection of vesicovaginal space and good hemostasis are essential for prevention of vesicovaginal fistula.

Based on a study on mongrel dogs by Cogan et al. (9), cystotomy induced by electrosurgery during laparoscopic hysterectomy, can be a risk factor for formation of vesicovaginal fistula. Caution should be exercised when using electrosurgery in the vicinity of the bladder. The benefit of electrosurgical burn margin excision or omental flap interposition remains unclear, but both are accomplished easily with little risk and may play a role in fistula prevention. In another study on mongrel dogs, Sokol et al. (17) concluded that double-layer bladder closure appeared to be superior to single-layer repair for prevention of vesicovaginal fistula after monopolar cystotomy. Meticulous suture placement and avoidance of tissue strangulation are also essential for prevention of vesicovaginal fistula. During operative laparoscopy performed to treat extensive endometriosis, intentional or unintentional bladder lacerations, or ureteral injury are recognized complications. Repair of a resected ureter or closure of the bladder can be effectively accomplished endoscopically by experienced laparoscopic surgeons. This will prevent the complication of vesicovaginal fistula that requires reoperation (18–20).

RESULTS

Laparoscopic vesicovaginal fistula repair was first reported by Nezhat in 1994 (15). A total of seven patients with laparoscopic vesicovaginal fistula repair have been reported in the literature (15,21–24). Despite minor differences in surgical techniques, fistula repair was successful in all seven cases three to six months postoperatively. All cases were treated by surgeons with extensive experience and interest in advanced operative laparoscopy.

SUMMARY

- Laparoscopy is a viable alternative to open surgical repair of vesicovaginal fistulas.
- Advantages of the laparoscopic approach include magnification during the procedure, and shorter hospital stay and postoperative recovery.
- The fistula is resected under direct visualization and a tension-free reconstruction is performed.
- Based on limited number of case reports on laparoscopic vesicovaginal fistulas repair, it appears to be a safe and effective approach for fistulas that cannot be repaired vaginally.
- Undoubtedly, operative laparoscopy will replace most laparotomies in gynecologic surgery, it is only a matter of time.

INTRODUCTION

Primary pathology of the seminal vesicle is quite rare. With current imaging modalities such as computed tomography and magnetic resonance imaging, the seminal vesicles are being visualized more frequently and with better precision. As a result, more men are being diagnosed with abnormalities of the seminal vesicle, such as cysts or stones. Even when recognized, most are incidental findings not requiring treatment.

When confronted with the infrequent man requiring a therapeutic excision of the seminal vesicle(s), the surgical approach can be abdominal (1), perineal (2), retrovesical (3), transvesical (4), transcoccygeal (5), or transurethral (6). However, with the increasing laparoscopic experience and expertise of many urologists, the seminal vesicles can safely and suitably be removed laparoscopically.

ANATOMY, EMBRYOLOGY, AND FUNCTION

The seminal vesicles are paired structures lying obliquely from inferomedial to superolateral at the posterior junction of the prostate and bladder. They contribute approximately 70% of the seminal fluid to the ejaculate (7). The right seminal vesicle is larger than the left in approximately one-third of men (8).

The blood supply enters at the tip of the seminal vesicle and is usually from the vesiculodeferential artery, a branch of the superior vesical artery (9). Occasionally, there may also be branches from the inferior vesical artery (1).

Among fertile men without urologic disease or symptoms, the seminal vesicles range in size from 1.9 to 4.1 cm in length and 0.4 to 1.4 cm in width (10). Owing to their common embryologic origin, abnormalities of the seminal vesicle are often associated with congenital anomalies of the kidney and ureter. Since the seminal vesicle develops from the distal mesonephric duct along with the kidney and ureter (11), it is common to have ipsilateral seminal vesicle, renal, and ureteral anomalies. The most common association is a congenital seminal vesicle cyst along with renal agenesis. Furthermore, ectopic ureters may enter directly into the seminal vesicle (11).

INDICATIONS

Most patients requiring laparoscopic excision of the seminal vesicle have cysts, obstructing stones, or an ectopic ureter draining into the seminal vesicle. Rarely, a seminal vesicle abscess or recalcitrant seminal vesiculitis may warrant surgery. The majority of men with seminal vesicle pathology present with pain, infections, hematuria, or hematospermia.

Cysts

Cystic disease of the seminal vesicles is recognized more frequently in the era of cross-sectional imaging and transrectal ultrasonography. Seminal vesicle cysts are composed of a cuboidal or flattened epithelium, fibrous wall, and contain whitish, thick fluid (12). When congenital, most men also have concomitant renal dysgenesis and ureteral ectopia (13). Acquired

seminal vesicle cysts usually follow urinary tract infections or ejaculatory duct lithiasis and only rarely occur bilaterally (14,15). Seminal vesicle cysts can grow quite large (up to 15 cm) and have been reported to cause rectal obstruction (16). While prenatal ultrasonographic identification of a seminal vesicle cyst has been reported (17), most are diagnosed postpuberty following an evaluation for pain, hematospermia, or infections (18,19).

Seminal vesicle cysts should be distinguished from mullerian duct cysts, which are found in the midline flanked on each side by a normal seminal vesicle. Since most seminal vesicle cysts are asymptomatic, no treatment is required.

When treatment is deemed necessary, cyst aspiration and transurethral resection of the ejaculatory duct are options but usually not effective (20,21). Surgical excision remains the definitive treatment.

Stones

Seminal vesicle calculi are typically brown in color and may comprise inspissated protein or contain a mucoepithelial core covered with stone forming components such as calcium carbonate, urates, and phosphate (Fig. 1) (22). Men typically present with hematospermia, hematuria, painful ejaculation (23), pain, or as an incidental finding (22). Reflux of urine into the seminal vesicle, obstruction, infection, or congential anomalies have all been described as predisposing factors. Intervention is only necessary if symptoms warrant it, the pain is lateralizing, and imaging with computed tomography or magnetic resonance imaging indicates a stone. If composed only of inspissated protein seminal vesicle stones will not be visible on a computed tomography scan, and a T2-weighted magnetic resonance imaging with coronal imaging is recommended (Fig. 2) (22).

Masses

Rarely, men are diagnosed with masses of the seminal vesicle. Pain, obstruction of adjacent organs, dysuria, hematuria, or hematospermia can occur (24). Since the masses are often indistinguishable from adjacent organs, serum prostate-specific antigen and carcinoembryonic antigen can be helpful in determining if there is a prostatic or colorectal origin (24). Alternatively, an elevated serum CA125 is strongly suggestive of a primary seminal vesicle carcinoma (25). Most masses of the seminal vesicle are benign, such as papillary adenomas, cystadenoma, fibromas, and leiomyomas. Seminal vesicle tumors with malignant potential are exceedingly rare. Primary malignancies of the seminal vesicle such as adenocarcinoma (24), sarcoma (26), schwannoma (27), and squamous cell carcinoma (28) can occur and are probably best managed by aggressive extirpative surgery via either radical prostatectomy or cystoprostatectomy. While surgical excision is the primary form of therapy, radiotherapy and hormones have been used as adjuvant treatment (29–32). Regardless of treatment, the prognosis is poor (24).

To date there have been no reports of laparoscopic excision of the seminal vesicle for a primary malignancy.

To date there have been no reports of laparoscopic excision of the seminal vesicle for a primary malignancy.

IMAGING

Antegrade vasography and seminal vesiculography were first described in 1913 (33). When used for the evaluation of the infertile man, seminal vesicle abnormalities may

FIGURE 1 ◼ Pathological specimen shows seminal vesicle with calculus (*arrow*). *Source*: From Ref. 22.

be identified. Owing to its invasive nature and risk of vasal fibrosis or scarring, its use for seminal vesicle surgery has largely been supplanted by ultrasound, computed tomography, and magnetic resonance imaging.

Imaging of the seminal vesicles with intravenous urography has been replaced by other modalities. Rarely, intravenous urography diagnoses a radio-opaque stone, an ectopic ureter draining directly into the seminal vesicle, or a mass effect from a cyst or neoplasm.

As prostate cancer screening has become more routine, the number of transrectal ultrasound procedures has increased. Along with obtaining prostate biopsies, the urologist is afforded a view of the seminal vesicles. In addition to quantifying seminal vesicle size, stones appear as highly echogenic structures and cysts as hypoechoic fluid-filled cavities. Solid masses can be appreciated disfiguring the normal contour of the seminal vesicle and are typically hyperechoic.

Computed tomography can often provide useful information regarding the seminal vesicle and any associated renal or ureteral abnormalities. Since the seminal vesicle enhances following contrast administration, inflammatory lesions, cysts, and masses can be identified and distinguished from the surrounding structures. Simple cystic lesions display Hounsfield units of 0–10. When filled with stones, debris, blood, or pus the Hounsfield units are higher. Even with modern computed tomography capabilities, masses of the seminal vesicle can sometimes be difficult to differentiate from the adjacent bladder, prostate, or rectum. Furthermore seminal vesicle stones may be composed of protein without any calcification making visualization on noncontrast computed tomography very difficult or impossible (22).

Magnetic resonance imaging has proven to be an accurate and useful imaging tool for the seminal vesicles. Since the seminal vesicles are of intermediate signal intensity on T1-weighted images they can reliably be distinguished from the adjacent fat, bladder, and rectum. On T2-weighted images, the seminal vesicles are of varying intensity, depending on the age and androgen status of the man (34). As the levels of circulating androgens increase, the intensity of the seminal vesicles does also. Therefore, the seminal vesicles of postpubertal men with normal androgen levels have high signal intensity whereas those of prepubertal boys, many elderly men, and men undergoing androgen ablation have low signal intensity. The use of endorectal coils, the advent of higher Tesla magnets, and fast spin-echo techniques have all enhanced, and will continue to improve MR imaging of the seminal vesicles. Seminal vesicle cysts typically show high T2 and low T1 signal intensity but can vary based on composition (proteinaceous, hemorrhagic, etc.) and concentration of the fluid. The signal intensity of an inflammatory lesion of the seminal vesicle depends on the chronicity of the disease and whether bleeding is present. Chronic seminal vesiculitis typically appears as low intensity signals on both T1 and T2-weighted images (35).

Proteinaceous seminal vesicle stones are seen as discrete, signal void structures on T2-weighted images making magnetic resonance imaging superior to computed tomography for imaging the seminal vesicles (Fig. 2) (22).

SURGICAL TECHNIQUE

Preoperative Considerations

Owing to their embryologic similarities, congenital seminal vesicle abnormalities often coexist with ureteral or renal anomalies (21,36). Because of this association, all patients with a congenital seminal vesicle cyst should be considered for imaging of their kidneys and ureter with a computed tomography scan or magnetic resonance imaging as well as cystoscopy to evaluate for ureteral ectopy or duplication.

The surgeon performing excision of a congenital seminal vesicle cyst should also be prepared to remove ureteral and renal remnants when necessary.

Prior to laparoscopic seminal vesicle surgery, the patient undergoes a mechanical bowel preparation with either magnesium citrate or Fleet's phosphosoda. Debulking the gastrointestinal tract affords the surgeon more working space in the abdominal cavity and also allows for a primary closure of bowel should an injury to the intestine occur. In men with a sterile urine culture, an intravenous first-generation cephalosporin is given one hour prior to surgery.

Patient Positioning

Following general anesthesia and gastric decompression, an 18 French urethral catheter is placed in the bladder. We prefer to use a catheter with a 30 cc balloon to aid in intraoperative identification of the trigone and bladder neck. The patient is positioned supine on spreader bars with both arms tucked alongside the body. Spreader bars allow

The sidebar notes (in gray boxes):

Proteinaceous seminal vesicle stones are seen as discrete, signal void structures on T2-weighted images making magnetic resonance imaging superior to computed tomography for imaging the seminal vesicles (Fig. 2).

The surgeon performing excision of a congenital seminal vesicle cyst should also be prepared to remove ureteral and renal remnants when necessary.

An exaggerated Trendelenburg position may lead to excessive facial edema and paresthesias.

FIGURE 3 ■ Depicted here are 10 mm (X) and 5 mm (x) port size locations for laparoscopic seminal vesicle excision.

The surgeon must carefully identify and stay away from the ureters. If there is any question as to their location or proximity to the seminal vesicles, an externalized ureteral stent can be placed via flexible cystoscopy to identify the ipsilateral ureter.

easy access to the rectum where an O'Conor drape is placed to allow digital prostatic mani-pulation during the procedure. The table is gently flexed to open up the pelvis and a moderate Trendelenburg position is used to allow gravity retraction of the bowels.

An exaggerated Trendelenburg position may lead to excessive facial edema and paresthesias.

Operative Technique

The laparoscopic surgical approach to the seminal vesicles was first described by Kavoussi and Clayman in 1993 as a method for freeing up the seminal vesicles at the time of laparoscopic pelvic lymph node dissection immediately prior to a perineal prostatectomy (37). This transabdominal laparoscopic approach has subsequently become one of the initial steps of laparoscopic radical prostatectomy (38).

Pneumoperitoneum is obtained with a Veress needle or via an open technique. Either a 10–12 mm umbilical port is placed. Kavoussi originally described a five-port fan configuration for trocar placement with a 12 mm trocar just below the umbilicus, two 10 mm trocars lateral to the rectus muscle just caudal to the umbilicus and two 10 mm trocars just lateral to the rectus muscle approximately 2 cm above the superior iliac crest (36). We have found four ports to be adequate for laparoscopic seminal vesicle surgery with a 10–12 mm port just below the umbilicus, two 5 mm ports just lateral to the rectus sheath 2–3 cm below the umbilicus and a 5 mm port in the left lower quadrant just above the level of the anterior superior iliac crest (Fig. 3) (22). Larger 10–12 mm ports always can be substituted for 5 mm ports should instrumentation such as stapling devices, clip appliers, ultrasound probes, hernia staplers, or large fan retractors be necessary. If necessary, an additional fifth port can be placed in the right lower quadrant just above the anterior superior iliac crest or in the midline midway between the umbilicus and symphysis pubis as the surgeon sees fit.

The surgeon typically stands on the patient's left side while the assistant guides the camera and provides retraction or suctioning from the patient's right side. An AESOP robot or a fixed camera holder can also be used, which typically is placed through the umbilical port.

A full visual inspection of the abdomen is performed prior to addressing the seminal vesicles. Often, the colon overlies the area of the seminal vesicles and may need to be mobilized and retracted with either a fan or Jarit retractor. Upon reflecting the bladder anteriorly, the ureters can be visualized alongside the posterior surface of the bladder. Immediately inferior to the ureters the vas deferens enters into the prostate (Fig. 4).

The surgeon must carefully identify and stay away from the ureters. If there is any question as to their location or proximity to the seminal vesicles, an externalized ureteral stent can be placed via flexible cystoscopy to identify the ipsilateral ureter.

The size of the seminal vesicles can vary widely. A large congenital cyst may completely fill the pelvis whereas a seminal vesicle with a stone may be difficult to identify.

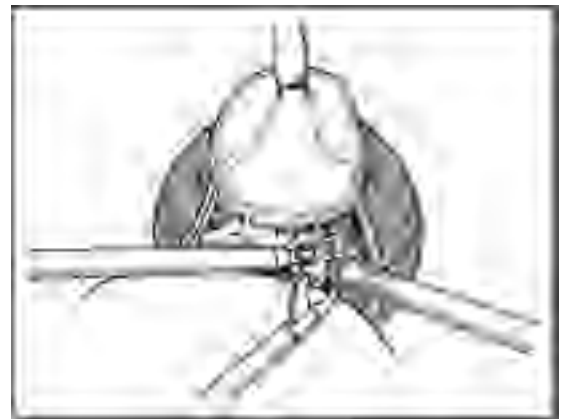
FIGURE 4 ■ The seminal vesicles seen there through the peritoneal reflection are the lowest ridge of tissue below the ureter and vas deferens.


FIGURE 5 ■ The surgeon typically stands on the patient's left side to dissect out the seminal vesicle, while the assistant who is on the right directs the suction device.

Following anterior retraction of the bladder, the peritoneum is incised transversely 2–3 cm above the rectovesical junction until the lateral border of the seminal vesicle is fully visualized. A longitudinal incision over the course of the seminal vesicle of interest is then made perpendicular to and crossing the previously made transverse incision. A combination of sharp and blunt dissection, clips, and cautious electrocautery is utilized to dissect the seminal vesicle caudally to its ampulla at the junction of the prostate (Fig. 5).

The neurovascular bundles responsible for erectile function travel lateral to the seminal vesicles (39). Sharp dissection rather than coagulation should be used in that area.

When identification of the seminal vesicle and its adjacent structures is challenging, injection of methylene blue or indigo carmine transperineally (13), transurethrally (19), or transvasal (13) helps to identify the seminal vesicle. To assist in identification of complex or large congenital seminal vesicle cysts Basillote advocates cannulating the ipsilateral ejaculatory duct with a 75cm three French ureteral catheter and injecting a mixture of contrast and indigo carmine so that additional fluoroscopic and laparoscopic guidance is available (19). We have additionally found intraoperative laparoscopic ultrasonography of the seminal vesicle to be helpful. It may be necessary to open Denonvillier's fascia in some cases to get as close to the prostate as possible when clipping and transecting the seminal vesicle. Depending on the extent of dilation, the seminal vesicle can be taken at its junction with the prostate using a Weck clip, titanium clip, or endo-GIA stapler. For patients with large congenital seminal vesicle cysts desiring to bear children the vas deferens needs to be carefully identified and dissected free from the cyst. The vas deferens can occasionally be difficult to separate from the cyst wall. Leaving a narrow strip of the cyst wall on each side along the vas deferens helps minimize the chances of vasal injury (17). Other groups advocate clipping and transecting the vas deferens to facilitate complete resection of the cyst (13,15,18).

After the seminal vesicle has been resected, it can be removed using an endo-catch bag. For large symptomatic congenital cysts, intracorporeal drainage with a needle can facilitate its safe removal. If the surgeon chooses to reapproximate the peritoneum a hernia or universal stapler can be employed. Oral nutrition is resumed the night of surgery and the urethral catheter is removed once the patient is ambulatory. Discharge from the hospital typically occurs the day following surgery.

> The neurovascular bundles responsible for erectile function travel lateral to the seminal vesicles. Sharp dissection rather than coagulation should be used in that area.

SUMMARY

- Primary pathology of the seminal vesicle is quite rare.
- Owing to their embryologic similarities, congenital seminal vesicle abnormalities often coexist with ureteral or renal anomalies. The surgeon performing excision of a congenital seminal vesicle cyst should also be prepared to remove ureteral and renal remnants when necessary.
- The neurovascular bundles responsible for erectile function travel lateral to the seminal vesicles (39). Sharp dissection rather than coagulation should be used in that area.
- To date there have been no reports of laparoscopic excision of the seminal vesicle for a primary malignancy.

INTRODUCTION

A varicocele is an abnormally dilated and tortuous pampiniform plexus, the venous complex that flows into the spermatic veins. Varicocele is present in 15% of the male population and not present prior to puberty (1–3). The majority of cases are thought to be due to absent or incompetent valves in the proximal internal spermatic vein with left-sided predominance linked to the higher venous pressures in the left internal spermatic venous system. The right spermatic vein enters the vena cava at an oblique angle, while the left spermatic vein enters the left renal vein at a right angle. The left venous insertion is also 8 to10 cm more cephalad than the insertion on the right. Both factors presumably increase the hydrostatic pressure within the left spermatic vein when compared with the right (1). Approximately 90% of unilateral varicoceles are left-sided, although bilateral varices may be found in 50% of patients (4, 25).

Varicocele is usually asymptomatic, but occasionally causes orchalgia. When symptomatic, varicocele causes a dull ache or heavy sensation in the testes that is typically worse at the end of the day or after prolonged standing or heavy exertion. Recumbency usually offers relief. Varicoceles are associated with impaired spermatogenesis and steroidogenesis (5–7). In a study conducted by the World Health Organization on 9043 men, the incidence was 25.4% in men with abnormal semen and 11.7% in men with normal semen (8). The majority of varicoceles are not associated with infertility. However, the prevalence of varicocele is increased in men presenting with male-factor subfertility—40% in men presenting with primary infertility and 80% in men presenting with secondary infertility suggesting a progressive decline in spermatogenesis and steroidogenesis over time if left untreated (9). Deleterious effects on the contralateral testis have also been noted (6,10). The exact mechanism of impaired fertility is unknown and probably multifactorial (11). Reversed venous blood flow in the spermatic veins disrupts the counter-current testicular temperature modulation. Zorgniotti and Macleod demonstrated increased testicular temperature associated with varies (12) and Wright et al. reported a decrease in testis temperature following varicocelectomy (13).

DIAGNOSIS

Varicocele presents due to male-factor subfertility, orchalgia, or as an incidental finding on routine physical examination. Varicocele is diagnosed primarily by physical

examination of the cooperative, relaxed, and warm patient in the upright position. To limit the effect of cremasteric retraction the testes are gently supported. Inspection and palpation of the scrotal contents is directed to a point just superior to the testes. Grade III (large) varicoceles are visibly thickened veins above the testis. Grade II (medium) varicoceles are palpable in the standing patient without a Valsalva's maneuver. Grade I (small) are palpable only with a Valsalva's maneuver. Ipsilateral testicular atrophy may also be present based on measurement or comparison to the contralateral testes. Isolated varico-cele on the right may be associated with renal tumors, retroperitoneal masses, or lymph-adenopathy and should be further evaluated for causes of proximal venous compression. Dilated veins can be distinguished from a cord lipoma because the lipoma will tend to slip from grasp when genltly pinched (14).

Additional diagnostic studies include ultrasound, thermography, venography, scintigraphy, and MRI but are not recommended in the routine evaluation of the infertile male unless the physical examination is equivocal. When faced with an inconclusive physical examination and a high index of suspicion, scrotal ultrasonography may provide evidence of subclinical varicocele based upon venous caliber and demonstration of reversed venous flow during Valsalva's maneuver. Furthermore, ultrasonography is noninvasive and can identify other pathologic processes in the testes, epididymis, and spermatic cord including objective measurement of testicular dimensions with greater accuracy than physical examination or orchidometer (15). A subclinical varicocele is found only on scrotal sonography and not on physical examination. According to Jarrow et al., only palpable varicoceles are clearly linked to male subfertility (16).

INDICATIONS FOR TREATMENT

Varix ligation is indicated in patients with a palpable varix and at least one of the following: (i) pain that is not attributable to other intrascrotal pathology (17); (ii) adolescent ipsilateral testis volume loss of 2 ml or greater than 20% of volume (18–21); or (iii) infertility attributable to the male partner based upon abnormal semen analysis or abnormal results of sperm function tests associated with a female partner who is fertile or suffers a treatable cause of subfertility (16). Treatment of varicocele is not indicated for infertility if the male partner has normal semen quality or a subclinical varicocele (16). Men with palpable varicoceles and abnormal semen quality who are not currently attempting conception but are interested in preservation of fertility may wish to undergo varix ligation when informed of the progressive deterioration of semen quality associated with varicocele (5,7,9). Varix ligation is cost-effective in comparison to alternate treatments, which might include assisted reproductive techniques such as in vitro fertilization with or without intracytoplasmic sperm injection (22,23). Young men with asymptomatic varicoceles and normal semen parameters should be followed with semen analyses and physical examination every one to two years. Adolescents with an asymptomatic varicocele and normal ipsilateral testicular size should be offered annual examination and measurement of testicular size. Repair should be offered at the first sign of testicular or semen abnormality (16). Varix ligation is not recommended for a subclinical varicocele or for prophylaxis in the asymptomatic adolescent (2,24).

TREATMENT OPTIONS

Nonoperative Therapy
Varicoceles can currently be treated by both operative and nonoperative techniques. Nonoperative treatment is typically performed by interventional radiology and includes transvenous embolization with coils or balloons or injection of sclerosing agents (boiling-hot contrast or absolute ethanol) to induce varix thrombosis. Both embolization and sclerosis are performed under local anesthesia with supplementary intravenous sedation at a cost of one-fourth to one-fifth that of surgery (25). Rates of success vary but generally do not approach those reported for operative varix ligation especially with right-sided varicoceles (24,25).

Other nonoperative treatments have not gained acceptance due to equivocal outcomes. Attempts to decrease testicular temperature by means of a scrotal cooling were cumbersome and lacking in durable improvements in semen analysis (12). Empiric medical therapy (clomiphen citrate, tamoxifen) showed no benefit (26).

Operative Therapy

Surgical treatment options are derivatives of either the inguinal approach of Ivanissevich (27) or the retroperitoneal approach of Palomo (28). Microsurgical techniques in the inguinal and subinguinal exposures require careful dissection in order to protect the spermatic artery and preserve lymphatic channels; maginification (e.g., loupes in the inguinal approach and microscope in the subinguinal approach) is mandatory (16,29). The inguinal approach identifies the spermatic vessels as they course through the inguinal canal where spermatic cord structures incorporate the cremasteric vein that may contribute to the varix pathophysiology. The spermatic and cremasteric veins are isolated and ligated while protecting the vas and spermatic artery. The inguinal approach is associated with increased postoperative pain and delay in return to full activity when compared with the subinquinal or laparoscopic techniques (30,31).

The subinguinal approach requires magnification and ligation of a greater number of venous tributaries that are intimately associated with the testicular artery (32). Furthermore, multiple spermatic arteries may course through the spermatic cord at the subinguinal level making dissection more demanding (33). Doppler ultrasound can facilitate detection of number and location of spermatic arteries.

The Palomo approach, e.g., ligation of the spermatic veins above the internal ring, can be performed by open or laparoscopic technique. The retroperitoneal approach permits ligation of spermatic veins without the attendant risk of injuring arterial collaterals, specifically the cremasteric and deferential arteries, which join the spermatic cord at or below the internal ring. One disadvantage of this approach is the lack of access to the cremasteric vein, which, according to Enquist and Stein, will contribute to a higher recurrence rate when compared with the subinguinal approach (32,34).

Advantages of laparoscopic varix ligation

■ Access to right and left varices with the same number of access ports (25, 35);
■ Improved visualization of the vessels via a transperitoneal approach especially in the obese patient;
■ Decreased number of veins to ligate (and fewer arteries to spare in the cephalad spermatic vascular bundle if one so chooses);
■ Magnification of vascular structures and a panoramic view of the retroperitoneal structures, which permits identification and ablation of aberrant collateral veins arising from the kidney, iliac vein, or sigmoid colon;
■ Minimal postoperative pain and a very short convalescence with reduction in lost productivity and early return to work;
■ Avoidance of injury to the vas and collateral arterial flow as may occur with the inguinal or subinguinal approaches;
■ An option in the presence of a failed inguinal/subinguinal or percutaneous embolization approach or in patients who have had previous inguinal hernia repair (36).

CONTRAINDICATIONS TO LAPAROSCOPIC VARIX LIGATION

Laparoscopic varicocelectomy is contraindicated in patients with recurrent or persistent varix following a retroperitoneal varix ligation.

The site of laparoscopic transperitoneal and open retroperitoneal varix ligation is the same. Patients with persistent varix following retroperitoneal ligation should be treated by alternate methods: either transvenous spermatic vein sclerosis or spermatic vein ligation via the inguinal or subinguinal approach (36,37). We have, however, successfully performed salvage laparoscopic varicocelectomy in patients who have undergone failed transvenous or inguinal varix ligation. Previous abdominal surgery is a relative contraindication and risk to intraperitoneal structures but can be minimized with use of the Hasson cannula or the Endopath Optiview®[a]. Successful laparoscopic varix ligation utilizing the Hasson cannula has been performed in patients who previously have undergone appendectomy, hernia repair, omphalocele, and pyloromyotomy without complication (38,39).

SURGICAL TECHNIQUE

Patient Preparation

The patient should be advised of the risks and benefits to varix ligation and of the available approaches with discussion of the advantages and disadvantages to each (40). Special emphasis is paid to the risks peculiar to laparoscopy and to the possibility need to convert to open technique and possible laparotomy to repair injury to intestine or blood

Laproscopic varicocelectomy is contraindicated in patients with recurrent or persistent with recurrent or persistent varix following a retroperitonealvarix ligation.

---

[a]Ethicon, Cincinnati, OH.

vessel. In our series to date, all varix ligations have been completed laparoscop-ically. Each patient should be aware that successful varix ligation results in improvement in semen parameters and/or reduction in pain in most but not all patients. In fact, there is a nominal risk of testicular atrophy due to compromise of testicular arterial blood flow. In a recent study laparoscopic varix ligation for painful varicocele resulted in complete resolution of pain in 84.5% at a median follow-up of six months (41).

Laparoscopy is typically performed under general anesthesia. Although this procedure has been done under both epidural and local anesthesia, we feel that laparoscopy with pneumoperitoneum is best tolerated under general anesthesia. There is a report of laparoscopic varix ligation using local anesthesia but no attempt to pre-serve the testicular artery was made (42). Preservation of the spermatic artery is delicate and time-consuming and hampered by patient movement. Proponents of the retroperi-toneal approach to varix ligation debate the utility of sparing the spermatic artery. Several reports have found no difference in testis volume after laparoscopic clipping of the entire retroperitoneal spermatic vascular bundles without arterial sparing (43–45). Several authors report increased rates of varix recurrence and hydrocele formation when the spermatic artery is spared (43,46,47). Conversely, many surgeons have excellent success with arterial sparing techniques (29,48).

We do not currently require a bowel preparation prior to laparoscopic varix ligation. Routine antibiotic prophylaxis consists of a cephalosporin one hour before surgery. After induction of anesthesia, an oral gastric tube is placed and the stomach evacuated. The surgical field includes the external genitalia and the entire abdomen. Gentle retrac-tion of the testes and spermatic cord can aid in identifying the spermatic vessels and collateral veins traversing the internal ring. We typically pass a straight catheter to drain the bladder before proceeding with insertion of the Veress needle.

Instrumentation

We have used both the Veress needle and the open Hasson technique to gain initial pneumo-peritoneum. Currently, we use the Veress needle and feel this is safe when appropriate precautions are taken. The principle instruments we use are curved scis-sors, a curved dissector, and a right-angle dissector. For intracorporeal ties we add two laparoscopic needle drivers. Five millimeter clip appliers can be used to clip-ligate smaller vessels. A 5-mm 45° laparoscopic lens is used. We no longer routinely use a 5 mm laparoscopic Doppler probe to assist in the identification of the spermatic artery or arteries because several investigators have shown no benefit from sparing the internal spermatic artery (43–45). We use 5-mm ports, which decrease morbidity when compared with 10mm ports. Small veins can be ligated with use of the 5-mm clip applier. Larger veins or bundles of veins that exceed the capacity of the 5-mm clip can be ligated with 2-0 silk ligature using intracorporeal tying techniques thus avoid-ing the need to separate the venous branches into several small bundles. An instru-ment tie can be accomplished using two needle drivers or two curved dissectors. Alternatively, one may ligate by performing extracorporeal ties using a 5-mm knot pusher. If choosing not to preserve the testicular artery, mass ligation of the entire vascular bundle can be accomplished with extracorporeal ligation or a two-port technique using the harmonic scalpel.

Operation

Patient Position and Port Placement

We place the patient in supine position with arms adducted. Skin preparation includes the abdomen and genitalia. After infiltrating with 0.25% marcaine, a 5 mm skin incision is made just above the umbilicus. The Veress needle is passed through this incision and into the peritoneal cavity. Proper positioning of the Veress needle is confirmed using appropriate tests and insufflation proceeds to reach intraperitoneal pressure of 20 mmHg. Once proper pneumoperitoneum is achieved, a 5 mm trocar is advanced into the peritoneal cavity and a 45° camera is inserted. We inspect the peri-toneal contents, giving special attention to viscera deep to the site of the Veress nee-dle and first trocar insertion. Next, we place two 5 mm ports. In the case of a left varicocele, one port is placed lateral to the rectus muscle just below the umbilicus and the other is placed in the midline midway between the umbilicus and pubis. For bilat-eral varicoceles, both ports are placed lateral to the left and right rectus muscle just below the level of the umbilicus. Once the ports are in place the patient is placed in the Trendelenburg position.

Dissection and Ligation

If the sigmoid colon is fixed over the spermatic veins cephalad to the left internal ring (the proposed site of surgery), the colon is mobilized to expose the spermatic vascular bundle incising along the lateral peritoneal reflection. Once the internal ring is exposed, the spermatic vessels are identified deep to the peritoneal membrane passing cephalad over the psoas muscle. The vas is seen curving medially over the external iliac vein and artery.

Using curved scissors, a 3- to 5-cm incision through the peritoneum is made parallel and lateral to the spermatic vessels with the caudal limit 3 cm above the internal ring. This minimizes injury to the vas deferens and scrotal insufflation. The medial flap of the peritoneum is grasped and the underlying spermatic vessels are gently and bluntly swept from the underside of this flap. From the midpoint of the first incision a perpendicular incision is made through the medial peritoneal flap to the lateral aspect of the iliac artery. This resulting T incision provides ample exposure. External traction on the testis/spermatic cord helps to identify all veins that may contribute to the varicocele.

The entire spermatic vascular bundle is mobilized from the underlying psoas muscle using both blunt and sharp dissection. Deep dissection is avoided to spare the underlying genitofemoral nerve crossing anterior to the psoas muscle. Loose adventitial tissue is stripped from the spermatic vessels. The vascular bundle is separated into medial and lateral bundles. Typically there are three to eight spermatic veins and a single spermatic artery located posterior and medial to the veins. The spermatic artery is not specifically identified and intracorporeal knotting techniques are used to ligate and divide each vascular bundle, which are then divided between ligatures. The procedure may be performed on the contralateral side as needed.

Completion of the Operation

An orderly and systematic departure from the abdomen is recommended to ensure hemostasis and rule out inadvertent injury. The operative site(s) is inspected with intraperitoneal pressure reduced to <8 mmHg and active bleeding sites are identified and cauterized. Each trocar site is inspected at the time of removal to ensure no active bleeding from the anterior abdominal wall. Scrotal emphysema from extravasation of CO_2 through the internal ring can be massive and this can expressed back into the peritoneal cavity and vented through an open trocar site. The patient is returned to the horizontal position; we aspirate any blood or irrigant that may have collected in the pelvis. The subcutaneous tissues are reapproximated and the skin is closed with a subcuticular 3-0 Vicryl Rapide[®][b] or Dermabond[®][c]. Virtually all procedures are performed in the outpatient setting. The patient is advised to return to full activity as tolerated. Semen analyses are performed every three months for one year or until pregnancy is achieved (16).

RESULTS

Fertility

Varicocele repair has been proven to improve semen parameters in 50% to 80% of men and surgical methods successfully eliminate >90% of the varicoceles (16,34,35,43). Pregnancy rates following laparoscopic varix ligation (26–46%) are similar to those reported following open repair (49,50). The american urological association's Best Practice Guidelines identified only two well-designed, randomized, prospective controlled studies of men with palpable varicoceles, abnormal semen quality, and normal spouses (16). In one study there was a significant increase in testicular volume and semen quality but no increase in pregnancy rates after repair was demonstrated (51). The other study showed a 60% conception rate following varicocele repair compared to a 10% conception rate in the untreated group (52). American urological association's Best Practice Guidelines considers varicocele repair for infertile men with palpable varicoceles an appropriate option because of the proven improvement in semen parameters, low operative risks, and the possibility of increased fertility (16).

---

[b]Ethicon, Cincinnati, OH.
[c]Johnson & Johnson, Somerville, NJ.

Pain

Pain attributable to varicocele resolves in 50% to 86% of patients presenting with orchalgia (41,53). Cadeddu et al. report significant pain reduction following laparoscopic testicular denervation (gonadal vessels divided cephalad to the vas deferens) in men with chronic orchalgia refractory to medical management and not attributable to varicocele (54).

Complications

Complications include hydrocele and recurrent varicocele. Incidence of either is reportedly less when the internal spermatic artery is not preserved (29,43,46–48). Other complications are rare and include the following: (i) bleeding either from inferior epigastric vessel secondary to trocar placement or delayed bleeding from the spermatic vessel due to incomplete ligation or thermal injury and (ii) visceral injury due to trocar or instrument mishap. Very few surgeons report conversion to open approach. Conversion is usually due to bowel adhesions. The operating microscope is not readily available to many urologists and for surgeons skilled at laparoscopy, the effectiveness and low complication rate of laparoscopic varicocelectomy supports its use in urologic practice.

INTRODUCTION

Chronic renal failure and end-stage renal disease are increasingly significant public health problems both medically and economically. Approximately 3 million persons in the United States have chronic renal failure, as defined by a glomerular filtration rate of less than 60 mL/min/1.73 m. Many of these patients progress to end-stage renal disease, the prevalence of which in the United States was almost 1400 per million, or a total of 406,081 patients in 2001, with an average age of 57.8 years. The prevalence of end-stage renal disease has increased every year since 1980, although the rate of increase has slowed to 2.4% per year (1).

The etiology of this persistent increase in end-stage renal disease is multifactorial. The four most common causes of end-stage renal disease in the United States are diabetes mellitus (138,483 total cases and 41,312 new cases in 2001), hypertension (91,636 total cases and 24,942 new cases in 2001), glomerulonephritis (60,888 total cases and 7687 new cases in 2001), and cystic kidney diseases (17,112 total cases and 2143 new cases in 2001) (1). The incidence of diabetic nephropathy, which is the leading cause of end-stage renal disease in adults, continues to increase. Another factor is the improved survival of patients with severe cardiovascular disease and diabetes, who are at high risk for end-stage renal disease, and our increasing acceptance of the placement of persons with severe comorbid illnesses on treatment for end-stage renal disease. Also, end-stage renal disease has increased dramatically in the elderly population and this has coincided with the increasing age of the U.S. population.

The annual cost of the end-stage renal disease treatment program consumes an ever-increasing portion of the Medicare budget—22.8 billion dollars in 2001, amounting to 6.4% of the annual Medicare budget (1). Treatment options for end-stage renal disease include hemodialysis, peritoneal dialysis, which may be continuous ambulatory peritoneal dialysis or continuous cycling peritoneal dialysis, cadaveric renal transplantation, or living donated renal transplantation.

The 2003 annual data report from the U.S. Renal Data System listed 86,289 patients initiated on hemodialysis and 6991 initiated on peritoneal dialysis for the preceding calendar year. From 1997 to 2001, the incident rates for initiation of peritoneal dialysis dropped by 4%, whereas the incident rates for hemodialysis increased 3.3% and the incident rate for renal transplant as the initial end-stage renal disease treatment modality increased 8.9%. The prevalent end-stage renal disease population currently includes 264,710 patients treated with hemodialysis and 24,268 treated with peritoneal dialysis; 113,866 patients have a functioning renal transplant. Thus 65% of prevalent end-stage renal disease patients are treated with hemodialysis, 28% are treated with a functioning renal transplant, and 7% are treated with peritoneal dialysis (1).

The incidence of peritoneal dialysis indicates that approximately 7000 new peritoneal dialysis catheters are placed each year in the United States and that approximately 24,000 must be properly maintained. Many different renal replacement therapies are available for the treatment of end-stage renal disease patients. The most commonly utilized renal replacement therapies are hemodialysis, peritoneal dialysis, and renal transplantation. Outcome comparisons suggest that renal transplantation is the best overall treatment for end-stage renal disease patients. Specific patient characteristics supporting the use of one modality over another have previously been described. Renal replacement therapy is preserved longer on peritoneal dialysis than on hemodialysis (2).

Continuous ambulatory peritoneal dialysis is an established and effective method for end-stage renal failure patients. Open surgical insertion is often associated with significant morbidity. Percutaneous and laparoscopic catheter placement has been used increasingly in recent years (3).

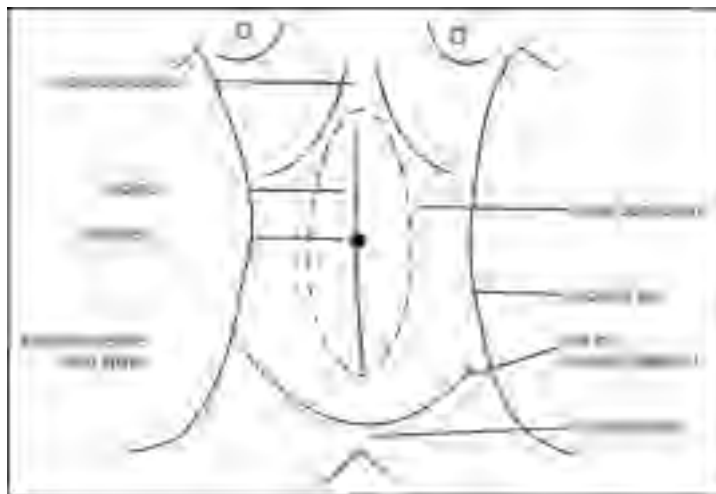
ANATOMY OF THE ABDOMINAL WALL AND PERITONEUM

The abdominal wall (Fig. 1) extends from the osteocartilaginous thoracic cage to the pelvis. It is helpful for descriptive purposes to subdivide it into anterior abdominal wall, right and left abdominal walls (loin and flanks), and posterior abdominal wall. The combined term "anterolateral wall" is used because some structures (the external oblique muscle and cutaneous nerves) are located in the anterior and lateral walls (4–6).

Innervation and Lymphatic Drainage

The abdominal wall is composed of nine layers. From outward in they are: (i) skin, (ii) subcutaneous tissue, (iii) superficial fascia (Scarpa's fascia), (iv) external abdominal oblique muscle, (v) internal abdominal oblique muscle, (vi) transversus abdominis muscle, (vii) transversalis fascia, (viii) extraperitoneal adipose tissue, and (ix) peritoneum.

The muscular abdominal wall is composed of three flat muscles (external oblique muscle, internal oblique, and transversus abdominis) and one strap-like muscle (rectus

FIGURE 1 ■ The anterior abdominal wall.


abdominis muscle). The parietal peritoneum is the innermost layer of the abdominal wall. It is a thin layer of dense, irregular connective tissue and is covered on the inside by a layer of simple squamous mesothelium. The peritoneum provides little strength in wound closure, but it affords remarkable protection from infection if it remains uninvolved.

The rectus muscles are each contained within a facial sheath, which is derived from the aponeurosis of the three flat abdominal muscles. Below the semicircular line, which is the point at which the inferior epigastric artery enters the rectus sheath, the posterior rectus sheath is lacking because the fascia of flat muscles pass anterior to the rectus muscle. A thin layer of the transversalis fascia covers the muscle, below the semicircular line, posteriorly, which is usually transparent when viewed from the inside at operation (3–5).

The Peritoneum

The peritoneum is composed of two portions (4,6,7). The parietal peritoneum lines the inner abdominal wall and is supplied by somatic nerves. The visceral peritoneum lines the visceral organs and is supplied by the visceral nerves. The epithelial lining of the peritoneum is mesoepithelium and produces a small volume of peritoneal fluid for lubrication of the visceral organs. The peritoneal space between the parietal and visceral peritoneum is the peritoneal cavity. The peritoneal membrane covers the inner surface of the abdominal wall and passes along the mesenteric vessels to form the mesentery

Physiology of the Peritoneum

The peritoneal membrane lined by mesoepithelium provides a frictionless environment for visceral organs and produces visceral fluid of about 100 cc daily. Its characteristic is clear straw colored (6,7). The peritoneal membrane can absorb fluid and solute, which is controlled by the concentration of fluid and solutes. The peritoneum can absorb normal saline solution approximately 35 mL/hr after initial equilibrium 300 to 500 mL/hr in hypertonic normal saline.

> The peritoneal circulation plays a major role in the exchange of fluid and solutes draining peritoneal dialysis.

The peritoneal circulation plays a major role in the exchange of fluid and solutes draining peritoneal dialysis. The parietal peritoneum is supplied by the vessels from the abdominal wall and the visceral peritoneum. The splanchnic vasculature contains about one-third of total blood volume and a blood flow rate that exceeds 1200 mL/min, with mesenteric blood flow representing about 10% of cardiac output. There are many factors that influence the peritoneal circulation, such as age, cardiac output, exercise, and hormonal substances (such as angiotensin and epinephrine) (6,7).

FACTORS AFFECTING PERITONEAL DIALYSIS EFFICIENCY

Surface Area

The estimated surface area of the peritoneal cavity is about 1 to 2 m^2. Factors that may limit surface area include previous abdominal surgery, episodes of peritonitis, chronic inflammation, cellular metabolic alterations, condition of hydration of the mesothelium—all of which can affect the efficiency of the peritoneal membrane (8–11).

THE INDICATION FOR DIALYSIS

There are two modalities of dialysis: hemodialysis and peritoneal dialysis. The indication for dialysis includes end-stage renal disease, acute renal failure, drug and chemical poisoning, acute hyperkalemia, metabolic disorder, and volume overload from congestive heart failure or lung diseases. In the case of renal failure, dialysis therapy is initiated when approximately 90% of normal renal function has been lost.

The absolute contraindications for all forms of dialysis are irreversible dementia or coma, hepatorenal syndrome, and advance malignancy. Both forms of dialysis are effective with proper patient selection. hemodialysis has the advantage of rapid clearance. It is useful in hyperkalemia, volume overload, and drug overdose. Continuous ambulatory peritoneal dialysis has been utilized during the last five years with increasing frequency in the treatment of patients with chronic renal failure. Peritoneal dialysis is preferred in patients who cannot tolerate the hypotensive state or the heparinization required for hemodialysis. Other advantages include portability, safety, fewer medications, no routine anticoagulation, and little change in hematocrit. Severe peritoneal fibrosis or pleuroperitoneal fistula are the absolute contraindications in peritoneal dialysis.

PERITONEAL ACCESS DEVICES

The optimal access device must transfer large volumes of dialysate into and out of the peritoneal cavity in a minimal amount of time, as well as maintain normal anatomy, bacteriology, and physiology of the surrounding tissues. There are two types of peritoneal catheters (8,9,11).

Acute Peritoneal Dialysis Catheter

These catheters are designed to be used for up to three days. Acute peritoneal dialysis catheters are made of polyurethane or nylon, appear like a straight tube, are relatively rigid, and have numerous 1-mm diameter side holes for drainage. *There is no cuff.* If it is necessary to perform dialysis for more than three days, the placement of a chronic catheter at the start of dialysis therapy should be considered.

Chronic Peritoneal Dialysis Catheter

Chronic peritoneal dialysis catheter are designed to be used on a long-term basis, are made from biocompatible material such as silicone or polyurethane, and usually contain numerous 1-mm diameter side holes; however, at least one type of chronic peritoneal catheter that has linear grooves or slots rather than side holes is available on the market. All of the chronic peritoneal dialysis catheters have one or two extraperitoneal Dacron® cuffs that promote local inflammatory response and cause a fibrous plug to fix the catheter in position, which prevents fluid leakage and inhibits organism migration from outside the peritoneal cavity.

There are four common types of peritoneal dialysis catheters:

1. Straight Tenckhoff, with 8 cm portion containing 1 mm diameter side holes
2. Straight Tenckhoff, with perpendicular disc
3. Curled Tenckhoff, with 16 cm portion containing 1-mm diameter side holes
4. T-fluted catheter, with grooved limbs positioned against the parietal peritoneum

The various intraperitoneal designs are created to diminish outflow obstruction. Besides intraperitoneal geometry, there are many designs of chronic peritoneal catheter, which alter the shapes of the subcutaneous portion between the muscle wall and the skin opening. The shapes all provide a lateral or downward direction to decrease the risk of the infection.

The cuff of continuous ambulatory peritoneal dialysis catheters also has many designs: single cuff, double cuffs, and disc-bell deep cuffs. The material used to manufacture chronic peritoneal catheters are soft, such as silicone rubber or polyurethane. The polyurethane catheters form a weak bond with the Dacron cuff and loosening of this bond can create pericatheter leakage. The diameter of the catheters can vary but the outer diameter is approximately 5 mm, with the internal diameter ranging from 2.6 to 3.5 mm.

CONTRAINDICATIONS TO PERITONEAL DIALYSIS CATHETER PLACEMENT

There are relatively few contraindications to the placement of peritoneal dialysis catheters. The most important consideration is whether or not the abdominal cavity has previously been violated. Previous pelvic surgery that may lead to adhesions, colostomy, ileostomy, or urinary diversion would be a relative contraindication. Absolute contraindications include aortic vascular graft within three months, presence of ventriculoperitoneal shunt, ascites, and peritonitis. Previous retroperitoneal/ extraperitoneal surgical procedures such as hysterectomy, caesarean section, and nephrectomy (retroperitoneally) are not considered contraindications.

SURGICAL TECHNIQUES

In the case of chronic renal failure, a soft catheter providing a lower risk of erosion to visceral organs is preferred. Besides the type of the catheter, the placement technique influences the longevity of the catheter, hospital stay, and infection rates. These "complications" will be discussed later in this chapter. There are four common methods of implantation:

1. Dissecting technique (open surgery)
2. Blind puncture

3. Peritoneoscopy-assisted percutaneous method
4. Laparoscopy-assisted techniques

Dissecting Technique (Open Surgery)

The dissecting technique is commonly utilized by general surgeons and involves placing the catheter by minilaparotomy under general anesthesia (11). The layers of the abdominal wall are dissected under direct vision. The parietal peritoneum is identified and incised. The catheter is advanced into the peritoneal cavity by feel until the deep cuff is within the rectus muscle. The cuff is then secured in the rectus muscle by sutures placed at the peritoneal entry site and at the outer rectus sheath.

Blind or "Seldinger" Technique

In the blind or modified Seldinger technique, a needle is inserted into the abdomen, a guidewire placed, a tract dilated, and the catheter inserted through a split-sheath; all maneuvers are performed without visualization of the peritoneal cavity (11). The deep cuff usually remains outside the outer rectus sheath after implantation. The blind technique is not widely used in the United States. The bedside blind insertion technique is associated with a significant risk of visceral damage and high rate (31%) of subsequent migration leading to failed dialysis (12). The other disadvantage is that final catheter placement cannot be controlled, and it is not suitable for the placement of "complex" catheters.

Peritoneoscopic Technique

Peritoneoscopic insertion, which is now, most often, performed by nonsurgeons, employs a small (2.2 mm diameter) optical peritoneoscope (Y-Tec® Scope[a]) for direct inspection of the peritoneal cavity and identification of a suitable site for the intraperitoneal portion of the catheter (11,13–21). Hence, of the three techniques described so far, only the latter allows for the direct visualization of the intraperitoneal structures. This technique is most commonly used by nephrologists and its use is rapidly expanding.

Peritoneoscopic placement varies from laparoscopic techniques, which will be elaborated on below (22,23), because it employs a much smaller scope and puncture size, only one peritoneal puncture site, a device to advance the cuff into the musculature, air in the peritoneum rather than CO_2, and local anesthesia rather than general anesthesia.

For peritoneoscopic insertion, the entire abdomen is prepped and draped in sterile fashion. A small skin incision (2–3 cm) is made over the desired location under local anesthesia (11). Dissection is carried down only to the subcutaneous tissue. The anterior rectus sheath is identified but not incised. A preassembled cannula with trocar and a spiral sheath is then inserted into the abdominal cavity through the rectus muscle (Fig. 2). Either medial or lateral border of the rectus could be used to gain access to the peritoneal cavity. The trocar is then removed and replaced by the peritoneoscope to confirm the intra-abdominal position of the cannula. Approximately 600 to 1000 cc of air is then infused to create a pneumoperitoneum and separate visceral and parietal peritoneal surfaces. At this point, peritoneoscopy is performed (Fig. 3). Bowel loops, the dome of the bladder, and the presence or absence of intra-abdominal adhesions are identified. The cannula with the spiral sheath wrapped around it is then advanced to an identified location (usually in the pelvis). The cannula and the peritoneoscope are then removed, leaving the spiral sheath in place. The spiral sheath is dilated to 6 mm diameter and the catheter is advanced into the desired location through the spiral sheath using an internal stylette. The deep cuff is implanted into the rectus muscle using an implanter tool without dissection of the anterior rectus sheath or the muscle. Some secure the deep cuff into the rectus muscle by using a purse-string suture at the anterior rectus sheath. The superficial cuff is implanted into the subcutaneous tissue and a tunnel and an exit site are created (Fig. 4). The tunnel and exit site are routinely directed inferiorly. The subcutaneous tissue is sutured using absorbable material while the skin is closed with nylon. No sutures are placed on the external rectus sheath or at the skin exit site.

The ability to directly visualize intraperitoneal structures is advantageous to the catheter placement (15,16,18). With this approach, the surgeon can avoid bowel loops, adhesions, and the omentum and determine the most suitable site for catheter placement. In this technique, neither the rectus sheath/muscle nor the parietal peritoneum

_____

[a]Medigroup, Naperville, IL.

Peritoneoscopic placement varies from laparoscopic techniques, which will be elaborated on below because it employs a much smaller scope and puncture size, only one peritoneal puncture site, a device to advance the cuff into the musculature, air in the peritoneum rather than CO_2, and local anesthesia rather than general anesthesia.

FIGURE 2 ■ During peritoneoscopic insertion of a peritoneal dialysis catheter, a trocar and cannula, with its wrapped spiral sheath, is being inserted through the rectus muscle under local anesthesia.

FIGURE 3 ■ A peritoneoscope (*single arrow*) has been introduced into the abdominal cavity through the cannula and the fibro-optic light (*double arrow*) source is being connected to the scope.

is incised, and the initial puncture is only about 3 mm in diameter. Thus, the layers of the anterior abdominal wall remain intact and tightly opposed to the catheter and cuff after placement.

The preference of one technique over another must take into account the incidence of complications (pericatheter leakage, exit site and tunnel infection), long-term catheter survival associated with each technique, costs, ease and timely insertion of the catheter, and factors contributing to mortality risk (general anesthesia).

Peritoneoscopic placement of peritoneal dialysis catheters by nephrologists has been rigorously compared with the surgical and the blind technique (Table 1). Both randomized and nonrandomized studies have documented the superiority of the peritoneoscopic technique in terms of incidence of catheter complications (infection, outflow failure, and pericatheter leak) and catheter survival (13,15,21–40). Recently, Gadallah et al. (15) reported the results of a randomized trial comparing the peritoneoscopic and the surgical technique. Early peritonitis episodes (occurring within two weeks of the catheter placement) occurred in 9 of 72 patients (12.5%) in the surgical group as compared to 2 of 76 patients (2.6%) in the peritoneoscopic group ($p = 0.02$). A higher incidence of exit site leaks was also found in the surgical group (11.1%) than in the peritoneoscopic cohort (1.3%) ($p = 0.002$). Finally, the study clearly demonstrated prolonged catheter survival with peritoneoscopic placement at 12, 24, and 36 months [77.5% vs. 62.5% ($p = 0.02$); 63% vs. 41.5% ($p = 0.01$); 51.3% vs. 36% ($p = 0.04$), respectively]. In addition, the overall catheter failure rate was higher in the surgical group than in the peritoneoscopic group (55.2% vs. 32.8%; $p = 0.003$). Pastan et al. (21) found similar results in a separate randomized study. The avoidance

of various complications by peritoneoscopic placement may relate to the decreased tissue dissection required with this technique. Extensive dissection (incising/splitting the rectus sheath/muscle as well as incising the parietal peritoneum) in the surgical technique may lead to loose attachment of the catheter to the abdominal wall increasing, thereby, the incidence of pericatheter leaks, subsequent tunnel infection and peritonitis, and catheter loss.

Laparoscopic management for obstructed catheter was first described in 1985 (41). Since then, a number of authors have reported their success in using laparoscopy to assist the placement or the salvage of obstructed catheters (42–46).

Peritoneal dialysis catheters have been successfully placed via the open surgical technique, the percutaneous (blind puncture) method, and the peritoneoscopy-assisted percutaneous methods. The latter two techniques were associated with lower complication rates, quicker use of the catheter, and longer functional survival, but also carried the risk of vascular and visceral injury during blind entry with a Veress needle or other penetrating instrumentation. Newer techniques that reduce the incidence of iatrogenic complications and provide greater visualization of the peritoneal cavity have been described. Laparoscopy-assisted placement allows for the visualization and positioning of the catheter under adequate pneumoperitoneum status with the ability to manipulate and not just visualize intra-abdominal structures. On comparing to other techniques, many reported series have shown better outcomes of laparoscopy-assisted technique as regards reduced risk of visceral organ injury or vascular injury, incidence of catheter flow dysfunction, peritoneal leakage, abdominal wall hernia, pain, hospital stay, and early start of peritoneal dialysis (45,47–57). Laparoscopic implantation procedures are also a cost-effective means

> Laparoscopic management for obstructed catheter was first described in 1985. Since then, a number of authors have reported their success in using laparoscopy to assist the placement or the salvage of obstructed catheters.

of establishing peritoneal dialysis access as compared with the open dissection technique (22,58).

LAPAROSCOPIC IMPLANTATION OF CONTINUOUS AMBULATORY PERITONEAL DIALYSIS CATHETER

There are several laparoscopic variations in the placement of continuous ambulatory peritoneal dialysis catheters (3,59). The "different techniques" are similar but one may offer slight advantages over the other; thus they are described in some detail below.

Patient Preparation

Before the patients undergo placement of continuous ambulatory peritoneal dialysis catheter, the position of the exit catheter should be chosen due to the characteristic of abdominal wall, and the exit hole should be created at least 2 cm above or below the belt line. With this caveat, the position of the patient's body and manipulation will not put pressure on the tunnel catheter

Instrumentation

- High-flow carbon dioxide insufflator
- CCD camera and at least one monitor
- 30° laparoscope
- One 5- to 10-mm port (trocars/cannulas) and two 3- to 5-mm ports (trocars/cannulas)
- Laparoscopic tissue forceps
- Laparoscopic grasping forceps

Technique

Under general anesthetic with muscle paralysis and assisted ventilation, the patient is put in a supine position with the head tilted downward at a 30° angle. The urinary bladder is emptied and a nasogastric tube is inserted. Pneumoperitoneum is performed by inserting a needle (Veress needle) into the abdomen. The position of the needle should be checked by aspirating and infusing 5 mL of saline (i.e., the "water drop test"). Intra-abdominal pressure must be carefully observed to ensure that it is below 12 mmHg during insufflation.

Previous abdominal surgery is a relative contraindication to blind needle insertion and consequently a Hasson cut-down technique can be used instead for the first port, especially, if there has been extensive previous abdominal surgery of peritonitis. A Tenckhoff catheter is placed in the peritoneal cavity, and an adequate pneumoperitoneum is created. A subumbilical transverse incision, 0.5- to 1.0-cm long, is made dissecting through to the subcutaneous layer. After opening the anterior rectus sheath, a blunt dissection is made of the rectus muscle to posterior sheath and peritoneum. A 5- or 10-mm trocar is inserted and fixed. The formation of the pneumoperitoneum is made via this trocar. An operative laparoscope facilitates ideal visualization and distal catheter placement. A small separate incision is created for catheter exit (Figs. 5 and 6) (47).

The initial exploratory laparoscopy is conducted with a 30° videolaparoscope. Two 3- to 5-mm trocar ports are inserted lateral to the rectus sheath under direct vision and one 3- to 5-mm port is used as the exit site of the catheter. Fixing the omentum to the parietal peritoneum at two points on the lateral abdominal wall level with the umbilicus, using 3-0 prolene, can be done and creates an omental wrapping that is effective in averting mechanical problems. The continuous ambulatory peritoneal dialysis catheter is then inserted through the umbilical trocar deep into the true pelvis by stiffening the stylet. This method allows for adjustment of the position of the catheter in the true pelvis by grasping the forceps under vision and fixing the catheter tip to the posterior wall of the urinary bladder in males and uterus in females. Implementing this method lowers the risk of migration of the catheter and prevents subsequent catheter migration, leading to failed dialysis of the kidney. The sutures encircle the catheter rather than pass through it, so that the catheter can be easily removed later if necessary (60). The cuff is then placed between the posterior rectus sheath and the rectus muscle fiber and the fascia is sewn tightly. The portion of the peritoneal catheter at the subcutaneous layer is grasped by a hemostat clamp, creating a subcutaneous tunnel from the exit port (5-mm port wound). It is necessary to check the distal catheter to make certain it is in the right position, as well as treat any bleeding at the closure of the incisional wound. The subcutaneous tunnel path and catheter exit are best evaluated with the abdomen in a

FIGURE 5 ■ Laparoscopy-assisted implantation of continuous ambulatory peritoneal dialysis catheter.

FIGURE 6 ■ Diagram shows cross section of continuous ambulatory peritoneal dialysis catheter in the abdominal wall.

normal position, without the bulging of pneumoperitoneum. A catheter without a preformed bend is laid out over the skin to assist in marking the exit site. The tunnel is shaped in an arched fashion so that the catheter makes a gentle bend in the subcutaneous tract and exits the skin in a downward direction with the superficial cuff no closer than 2 cm from the skin exit site. Proper alignment of the catheter is maintained with the assistance of the radio-opaque stripe as the catheter is passed through the subcutaneous tunnel. Care is taken not to alter the catheter position in the transabdominal wall tract during the subcutaneous tunneling process (61).

VIDEOLAPAROSCOPY-ASSISTED IMPLANTATION OF CONTINUOUS AMBULATORY PERITONEAL DIALYSIS CATHETER (51,62)

Historically, this procedure has been performed under general anesthetic because a pneumoperitoneum with CO_2 gas is not well tolerated by patients. Subsequently, this procedure has been modified by Giannattasio et al. and Crabtree and Fishman and can now be performed under local anesthesia with nitrous oxide gas and intravenous sedation. Currently videolaparoscopy is used more due to many benefits such as lower risk of trauma, short recovery time, short hospital stay, and small surgical scar (51).

Technique

Under a general anesthesia with muscle paralysis and assisted ventilation, the patient is put in a supine position with the head tilted downward. Pneumoperitoneum is performed by inserting the pneumoperitoneum needle (Veress needle) off the midline lateral to the rectus sheath at the umbilical level. The pneumoperitoneum needle is then replaced by the port sleeve of the scope and the gas insufflation tubing is transferred to this port. A 5-mm laparoscope is recommended. A small vertical incision is made on the opposite side of the abdominal wall at the umbilical level. An additional port (surgeon preference) is inserted through the rectus muscle along the incision with the patient in a Trendelenburg position and at an angle of 45° in the caudal direction, making the peritoneum entry 2 to 3 cm below the umbilical level. The point of penetration through the anterior rectus sheath is more cranial than the penetration point of the posterior rectus sheath. The caudally angulated passage through the abdominal wall encourages the peritoneal dialysis catheter to remain oriented in a pelvic direction. Insertion of the continuous ambulatory peritoneal dialysis catheter into this port allows adjustments to the distal cuff above the peritoneal layer under laparoscopic control.

MINILAPAROSCOPIC PLACEMENT OF PERITONEAL DIALYSIS CATHETER

Some surgeons have evaluated a new technique for continuous ambulatory peritoneal dialysis catheter placement, which requires only a single 2-mm port (49,56).

Minilaparoscopic placement of peritoneal dialysis catheter has been described by Varela et al. and Al-Dohayan et al. This procedure uses a single 2-mm port under direct visualization with a 2-mm scope and a modified Seldinger technique.

Technique

Under a general anesthesia with muscle paralysis and assisted ventilation, the patient is put on the supine position with the head tilted down. A 2-mm supraumbilical incision is made and the pneumoperitoneum is performed by inserting a Veress needle, creating a 2-mm portal. After establishing pneumoperitoneum (CO_2) with Trendelenburg positioning, an 18-gauge needle is introduced into the right and left lower quadrants. A guidewire is inserted through the 18-gauge needle and advanced to the true pelvic cavity. The dilator and sheath are advanced over the guidewire. Then, a continuous ambulatory peritoneal dialysis catheter is advanced through the sheath, over the right lower quadrant toward the pelvis. The sheath and guidewire are removed. A 5 cm subcutaneous tunnel is made by blunt dissection through the exit wound above the belt line. The catheter position is verified by direct visualization. A second 2-mm trocar may be placed to guide the catheter toward the pelvis. The catheter is flushed with heparinized saline. Local anesthesia is administered and the skin incisions are closed. Placement of the catheter can be performed under local anesthesia. This method has been described utilizing helium or nitrous gas, which is less irritating to the peritoneum than carbon dioxide.

BURYING THE PERITONEAL DIALYSIS CATHETER

Traditional surgical implantation of Tenckhoff catheters involves immediate exteriorization of the external segment through the skin, so that the catheter can be used for supportive peritoneal dialysis or for intermittent infusions during the "break-in" period. To prevent blockage and to confirm function, the catheter is flushed weekly with saline or dialysate; each exchange carries the same risk of peritonitis as in continuous ambulatory peritoneal dialysis therapy to avoid bacterial contamination of the exit site. The catheter must also be bandaged and the skin exit site must be kept clean in the weeks after placement. The patient must, therefore, be trained in some techniques of catheter care. It has always been difficult to decide when to place a peritoneal dialysis catheter in a patient with chronic renal insufficiency. If the catheter is placed too early, the patient may spend weeks to months caring for a catheter that is not used for dialysis. If the catheter is placed after the patient becomes uremic, it is often used for peritoneal dialysis therapy without a "break-in" period.

Moncrief et al. devised a placement technique in which the entire peritoneal catheter can be buried under the skin some weeks to months before it is used (63). The catheter-burying technique was first described for the placement of a modified Tenckhoff catheter with a 2.5 cm-long superficial cuff, but the technique has been adopted for standard dual-cuff Tenckhoff catheters (64–66). In the original technique, the external portion of the catheter was brought through a 2 to 3 cm skin exit site (much larger than the usual 0.5 cm incision). The catheter was then tied off with silk suture then coiled and placed into a "pouch" created under the skin. The skin exit site was then closed. Weeks to months later, the original skin exit site was opened, and the free end of the catheter was brought through the original skin large exit site (63,64).

The goal of burying the peritoneal dialysis catheter was to allow ingrowth of tissue into the cuffs of the catheter to prevent bacterial colonization and to allow ingrowth and anchoring of the deep and subcutaneous cuffs. Burying the catheter effectively eliminated early peri-catheter leaks and decreased the incidence of peritonitis rate. In 66 months of follow-up, patients with the buried Tenckhoff catheter had peritonitis infection rates of 0.017 to 0.37 infections per year, versus 1.3 to 1.9 infections per year in control patients (63). In a study of 26 buried Tenckhoff catheters, incidence of infectious complications during peritoneal dialysis was 0.8 infections per year and catheter-related peritonitis was only 0.036 per patient-year (64). A retrospective study confirmed a significantly lower catheter infection and peritonitis rate in patients having had buried catheters and a significantly longer catheter life (67,68), although the procedure was not effective when used for single-cuff catheters.

Exit site infections were not decreased in catheters that were buried, but this is understandable, because a large exit site was created when the catheter was buried, and a similarly large site was recreated when the catheter was exteriorized. Creating the "pouch" under the skin requires a considerable amount of dissection and trauma near the exit site. The size of the pocket limits the length of catheter that can be coiled and

buried under the skin, limiting the external length of the catheter after exteriorization. The exit site must be opened widely to remove the catheter, because the coil rests in a position distant from the skin exit site. Subcutaneous adhesions to the silk suture around the catheter further restrict removal. Increased trauma near the exit site during placement and exteriorization of the catheter may have caused an increased incidence of early exit infection with this technique. In one study of "embedded" catheters in 26 adult patients (with mean subcutaneous residence of 79.5 days), 2 patients developed local seromas and 12 developed subcutaneous hematomas (5 of which were revised surgically) (69). At catheter "activation," there were a number of flow problems: nine patients developed fibrin thrombi (two requiring operative clearance) and four patients had omental catheter obstruction (four requiring omentectomy). When burying the Tenckhoff catheter by standard techniques, there were a total of 27 complications in 26 catheter placements, with 13 of these complications requiring corrective surgery.

When catheters are placed by the Y-Tec procedure, the quill and cannula of the system can be reassembled and used to bury the external portions of dual-cuff Tenckhoff and Advantage catheters (12). The catheter exit site is made slightly larger than the standard exit site. The quill and cannula are inserted through this exit site to create a long, straight tunnel for the external end of the catheter. The catheter is blocked with an internal plug, rather than an external silk suture. This technique has been used to bury and then remove over 40 Tenckhoff and Advantage catheters. There have been few early complications of insignificant hematoma (3%), seroma (0%), exit infection (3%), or outflow failure (0%) and all catheters have functioned after exteriorization (12). Nephrologists can bury and exteriorize peritoneal dialysis catheters with greater ease and lesser trauma than surgical procedures and obtain results and benefits that are at least as positive.

POSTOPERATIVE CARE

Postoperative care after minimally invasive placement is very convenient because of shortened recuperation time and rapid wound healing. If there is an urgent indication to perform dialysis, minimally invasive placement of catheters allows rapid initiation of dialysis without leakage (54).

COMPLICATIONS OF LAPAROSCOPIC PLACEMENT OF CHRONIC PERITONEAL DIALYSIS CATHETER

Continuous ambulatory peritoneal dialysis is now an established technique for renal dialysis. In chronic peritoneal dialysis, operative laparoscopy is minimally invasive and is associated with the low morbidity and rapid return to normal activity. Reported series have shown feasibility and safety of the laparoscopic technique, which is also more effective than the open procedure or blind technique (61,70–72); however, the laparoscopic placement of the chronic peritoneal dialysis catheter can still have complications, both acute and chronic.

Acute Complications

Peritoneal Access
Complication from Veress needle or trocar placement can occur as with any laparoscopic procedure. Injuries to the abdominal wall vasculature or visceral organ injury can occur. If perforation occurs, the needle should be immediately removed and discarded. Because of the small size of Veress needle, the majority of the injuries do not require operative intervention (70). The Veress needle may injure the omental or mesenteric blood vessels or may cause major abdominal or pelvic vessel vascular injury. Their management depends on the amount of bleeding.

The incidence of serious hemorrhage from trocar injury requiring transfusion is approximately 0.4% (71). The introduction of a trocar into the abdominal cavity is likely responsible for bowel injury when a peritoneal dialysis catheter is inserted using the peritoneoscopic technique (16) or laparoscopic techniques. Bowel injuries due to the introduction of insufflation needles, trocars, and rigid catheters and colonoscopic examinations have been reported (73–76). A majority of these perforations are usually small and seal spontaneously (77,78). These "miniperforations" close spontaneously within 24 to 48 hours, most likely secondary to omental adherence (77,78). Simkin and Wright (79) provided direct evidence of the self-sealing nature of bowel perforations sustained during peritoneal dialysis catheter insertion.

During surgical exploration, they observed sealed bowel perforations that were sustained during peritoneal dialysis catheter insertion 12 to 16 hours earlier. A majority of small perforations are self-sealing and do not require surgical intervention (76–78,80–82).

Pneumoperitoneum

Pneumoperitoneal pressure greater than 10 to 15 mmHg, especially in children, for prolonged time can result in barotrauma. High gas pressure can cause decreased venous return due to caval compression and can result in decreased cardiac output, leading to hypotension (70). Hydrothorax occurs in less than 1% of patients and is manifested by very poor drainage of dialysate, dyspnea, and abnormal chest radiographic findings (pleural effusion) (72).

Late Complications

Exit Wound and Tunnel Infection

Erythema around the skin exit site may be part of the normal wound-healing process. Evidence of pain or extrusion of pus should elicit concern about catheter infection. Empiric treatment with antibiotics is advised to try to salvage the catheter and is appropriate as long as there are no sign of peritonitis, fasciitis, or sepsis. *Staphylococcus aureus* is the prominent organism for both exit site and tunnel infection and peritonitis. The incidence of *S. aureus* is greatest in the first year and decreases over time on dialysis (61). The cuff of the catheter is a strong barrier against penetration of infection into the abdominal cavity via subcutaneous tunnel (83).

Catheter Obstruction

In the late phase, the causes of catheter obstruction are the translocation of the catheter and bowel or fibrin clot formation and are resolved by laxatives and/or addition of heparin 500 U/L to dialysis solution.

Pericatheter Leak

Pericatheter leaks are more likely with midline catheter incision than with rectus muscle insertion. The late leakage and acute leakage are not managed differently but the late leakage usually requires surgical correction.

Peritonitis

The peritoneal segment of the catheter is a foreign body in the abdominal cavity and may be a source of colonization by bacteria that have migrated around the catheter. The deep cuff may cause recurrent peritonitis because bacteria can form microabscess around the deep cuff. Exit site and tunnel infection by *S. aureus* and related peritonitis led to catheter loss in 85% of cases in a recent series (61).

Peritoneal Dialysis Catheter Migration

This complication occurs more frequently in open rather than minimally invasive techniques. The proper placement of the catheter in the deep pelvis and fixation of the catheter tip to the posterior wall of the urinary bladder in males and uterus in females has been suggested to lower the risk of catheter migration (21,60). peritoneal dialysis catheter migration to the upper abdomen is not an uncommon problem (15–35%) and usually leads to outflow problems and catheter failure. The condition is suspected by encountering flow problems and is confirmed by plain abdominal X-ray. A variety of techniques have been used to combat migration with long-term success rates of 27% to 48%. Recently, the success of Fogarty catheter manipulation for the migrated peritoneal dialysis catheter was evaluated prospectively in 232 patients by nephrologists. In this study, a Fogarty catheter was advanced into the peritoneal dialysis catheter to a premarked point at which the end of the Fogarty catheter was near the end of the intraperitoneal portion of the peritoneal dialysis catheter. The Fogarty catheter was then inflated with 0.5 cc of sterile saline and manipulation was performed by tugging movement until the proper positioning of the catheter into the pelvis was suspected. Four to five attempts were made. Catheter patency was evaluated by checking dialysis inflow and outflow and the position of the catheter was confirmed by abdominal X-ray. In this study, the incidence of migration was found to be 15%. The results indicated a long-term (>90 days) success rate of 71% without any procedure-related complications. In contrast, at our center, Fogarty catheter manipulation corrected only 1/10 (10%) migrated catheters. Despite our inability to reposition these catheters, we were able to reinsert a new catheter during the same procedure, avoiding transfer to hemodialysis, placement of a tunneled hemodialysis catheter, and interruption of peritoneal dialysis.

FIGURE 7 ■ Peritoneal dialysis catheter removal. The catheter (*straight arrow*) has been exposed by dissection of the subcutaneous tunnel (*double arrow*). Note the catheter emerging at the exit site (*arrow head*).

PERITONEAL DIALYSIS CATHETER REMOVAL

Peritoneal dialysis catheter removal can also be safely performed without significant discomfort under local anesthesia. Here too, an operating room is not needed because the procedure can be performed in a procedure room using standard precautions for infection control. Briefly, the local anesthetic is infiltrated at the site of the primary incision and the subcutaneous tissue. Dissection is then carried down to the subcutaneous tissue and the subcutaneous tunnel harboring the catheter is identified. Using blunt dissection, a portion of the tunnel is separated from the surrounding tissue. The tunnel is then lifted by applying a hemostat under it. Using toothed forceps and Metzenbaum scissors, the tunnel layers are cut in a longitudinal direction and the catheter is exposed (Fig. 7). The catheter is clamped with hemostats and a nylon suture is applied through the catheter just outside the hemostats as a tag. At this point, the catheter is cut just outside the hemostat (remaining inside the nylon tag suture). Using Metzenbaum scissors, dissection is performed exposing tissue in the direction of the deep cuff. At this point, local anesthetic is infiltrated around the deep cuff. For catheters that have been in place for less than a month, blunt dissection using hemostats is all that is required to free the superficial and the deep cuff. For catheters in place for more than a month, sharp dissection using Metzenbaum scissors and a scalpel is needed. Exposure of the deep cuff and the anterior rectus sheath is required. Once the deep cuff is separated from the surrounding tissue, the intraperitoneal portion of the catheter is gently withdrawn from the peritoneal cavity. The defect created at the entry point (anterior rectus sheath) of the catheter is then closed with a purse-string suture using an absorbable material. The nylon tag is then pulled to expose the cut surface of the outer catheter segment and dissection is performed in the direction of the superficial cuff. Once the superficial cuff is free, this portion of the catheter can be easily removed through the primary incision site or the exit site. Absorbable suture material such as Vicryl is used to close the subcutaneous tissue while nylon is used to close the skin. The exit site is not sutured. The procedure should be performed only with sterile technique, good lighting, and antiseptic skin preparation.

SUMMARY

- Continuous peritoneal dialysis is an effective treatment for patients with renal failure.
- The open technique placement of continuous ambulatory peritoneal dialysis catheter is still the standard procedure.
- Current results of continuous ambulatory peritoneal dialysis catheter placement under direct peritoneoscopic or laparoscopic vision are encouraging
- The peritoneoscopy-assisted technique is very similar to laparoscopy-assisted technique and can be performed by nonsurgeon physicians (nephrologists).
- Laparoscopy-assisted technique allows the surgeon to fix the catheter to the abdominal wall to prevent catheter migration.
- Laparoscopy is also increasingly used as a technique for salvage of the malpositioned or blocked catheter. It is also associated with decreased infection, more rapid onset of use, decreased complication, and improved patient comfort.

LAPAROSCOPIC SURGERY FOR CHYLURIA

N. P. Gupta
Department of Urology, All India Institute of Medical Sciences, New Delhi, India

M. S. Ansari
Department of Urology and Renal Transplantation, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India

INTRODUCTION

> The most common cause of chyluria is parasitic infection secondary to filariasis caused by *Wuchereria bancrofti*.

Chyluria, the passage of chyle into the urine giving it a typical milky appearance, is due to a communication between lymphatic and urinary system. Chyluria is rare except in the areas of the world where filariasis is endemic specially India, Japan, Southeast Asia, and parts of Africa, Australia, and South America (1). The most common cause of chyluria is parasitic infection secondary to filariasis caused by *Wuchereria bancrofti.*

In 1878, Bancroft discovered adult worm in an abscess cavity; in 1929 it was named as *Wuchereria bancrofti* (2–4). Wood demonstrated pyelolymphatic reflux during retrograde pyelography in 1929 (5). In 1968, Wucherer described microfilaria in the urine of a patient with hematochyluria. Kinmoth (1955) introduced the technique of lymphangiography, and Kittredge described the lymphaticourinary communication (6).

> Chyluria can occur anywhere in urinary tract, but the chyluria of renal origin is the most common and usually represents the chronic stage of the filarial disease. Chyle consists of lymphatic elements: albumin, fat (triglycerides), and fibrin due to a formation of coagulum if a urine is left standing for a long time.

Chyluria can occur anywhere in urinary tract, but the chyluria of renal origin is the most common and usually represents the chronic stage of the filarial disease. Chyle consists of lymphatic elements: albumin, fat (triglycerides), and fibrin due to formation of a coagulum if a urine sample is left standing for a long time.

The quantity of lipids depends on the size of the fistula and the amount and composition of dietary fat. There are other pathologic conditions, which may clinically mimic chyluria and need differentiation (Table 1).

ETIOPATHOGENESIS

Chyluria may be classified as parasitic or nonparasitic (Table 2). Various theories have been suggested to explain the cause of chyluria. Prout postulated the theory of secretion of fat from blood through the kidney (9). Mollenbroch (1670) suggested abnormal connection between lymphatic and urinary system (10). Ackerman (1863) gave the "obstructive theory" and suggested that the obstruction of lymphatics anywhere between intestinal lacteals and the thoracic duct may give rise to chyluria (3). The theory of lymphatic obstruction appears to be most convincing and is well supported by the existing literature (11–13).

> The theory of lymphatic obstruction appears to be most convincing and is well supported by the existing literature.

The lymph vessels of the kidneys form three plexi, one of them lies within the renal parenchyma, second beneath the capsule, and the third in the perinephric fat (Fig. 1). The second and third groups communicate freely with each other. The vessels emerging from the renal substance converge to form four to seven trunks. At the

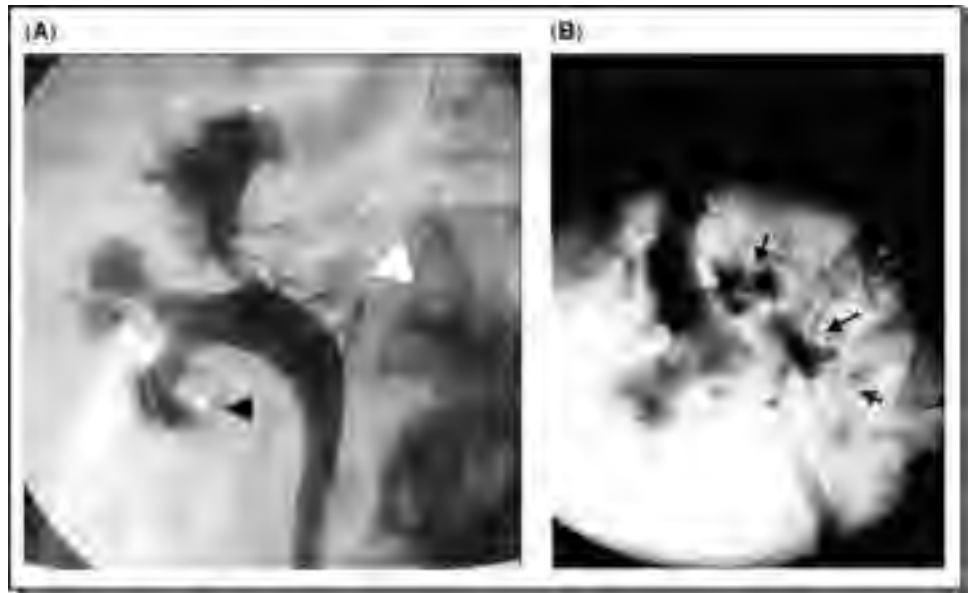
> Chyluria occurs after the lymphatic vessel ruptures into the renal tubules. This is secondary to the obstruction in the draining lymphatic, which is usually due to an acquired cause. The obstruction in tropical countries is most commonly caused by filariasis, i.e., *W. bancrofti* infection. The dying worm provokes lymphangiolar dilatation and finally obstruction. The obstruction leads to high intralymphatic pressure and rupture of lymphatic in to urinary system.

hilum, these lymphatics join capsular and perinephric groups and traverse along the renal vessels to lateral aortic nodes. The perinephric group also drains in to the lateral aortic nodes. The renal pelvis and upper ureter lymphatics are connected to lymphatics around the renal vessels or lateral aortic nodes. Lymphatics from lower ureter pass to common iliac nodes. Lymphatics from the bladder originate in three sets: vessels from trigone, superior surface, and inferolateral surface all drain in to external iliac group (14).

Chyluria occurs after the lymphatic vessel ruptures into the renal tubules. This is secondary to the obstruction in the draining lymphatic, which is usually due to an acquired cause. The obstruction in tropical countries is most commonly caused by filariasis, i.e., *W. bancrofti* infection. The dying worm provokes lymphangiolar dilatation and finally obstruction. The obstruction leads to high intralymphatic pressure and rupture of lymphatic in to urinary system (3).

The reported incidence of chyluria is up to 2% in cases of filariasis, and in endemic areas about 10% of the population may be infected (15).

FIGURE 1 ■ Diagrammatic display of lymphatic system of kidney, ureter, and bladder.

FIGURE 2 ■ Retrograde ureteropyelograms (two different patients) showing dilated lymphatic channels (*arrow heads*) of right kidney (**A**) and upper ureter and fistulous communication with retroperitoneal lymphatics (**B**).


CLINICAL PRESENTATION AND EVALUATION

Chyluria has an unpredictable course associated with remission and exacerbation. The disease usually affects young adults presenting with complaints of passage of whitish urine, white clots, or hematuria (hematochyluria). Sometimes chylous clots can lead to obstruction in the urinary tract, leading to clot colic (flank pain), retention of urine, or even anuria. Although not life threatening, the disease can be debilitating.

Chyluria can lead to considerable weakness and weight loss secondary to loss of proteins, cholesterol, and triglycerides (11,12,16).

Patient, usually come from an endemic area and give a long history of the disease. Urinary chemistry reveals proteiuria and lipiduria with high triglycerides along with a layer of chylomicrons. Serum proteins may be low in cases of intractable chyluria. Renal functions are usually normal. Intravenous urography is usually not helpful in delineating the pyelolymphatic leak but is required to know the function and anatomy of upper tracts. Cystoscopy may show the chylous efflux from the ureteral orifice from one or both the sides. In cases of clear efflux, ureters should be catheterized, and selective sampling should be tested for the chyle to know the exact side of the involved renoureteral unit.

Retrograde ureteropyelogram helps in establishing the connection between the lymphatics and urinary system. It is useful not only to identify the affected side but also to assess the severity of the pyelolymphatic communications (Fig. 2).

Ultrasonography or computed tomography of the abdomen may be required in cases of nonfilarial etiology, e.g., malignant tumors (7).

CONSERVATIVE TREATMENT

Conservative treatment of chyluria includes bed rest, low-fat diet (omission of long-chain triglycerides), and encouraging the use of medium-chain triglycerides (coconut oil) and high-protein diet (8). Medium-chain triglycerides (less than 12 C atoms) are transported directly from the gut to the liver via the portal system and not through the lymphatic channels, as are long-chain fatty acids. Multiple courses of antifilarial drugs are required. Other modalities of treatment include retrograde pyelography and instillation of sclerosing agents such as 10% to 25% bromide, normal saline, 0.2% povidone iodine, 50% glucose saline, or 1% to 2% silver nitrate in to the renal pelvis (12,17–19). Silver nitrate induces an inflammatory reaction in the lymphatics, resulting in chemical lymphangitis and edema of the lymph channels. Finally, fibrosis ensues causing blockage leading to immediate relief.

Retrograde pyelography and sclerotherapy have been used with a success rate varying from 55% to 68% with a recurrence rate above 50% on long-term basis (12,16,19).

A simple algorithm to treat chyluria is given in Figure 3.

Sidebar notes (left margin):

PATIENT SELECTION FOR LAPAROSCOPIC LYMPHATIC DISCONNECTION

Patients having persistent chyluria, clot colic, retention of urine, and weight loss despite conservative management and sclerotherapy need surgical intervention (7,12).

The various methods of surgical management tried are surgical disconnection of lymphorenal channels, renal capsulotomy, lymphaticovenous microsurgical anastomosis, renal autotransplantation, and nephrectomy (2,3,11,12,20–23). The success rate after open surgical management has been reported up to 93% at follow-up of one to four years (24,25). With the advent of laparoscopy, these cases are now efficiently managed by this minimally invasive approach. The procedure can be done via transperitoneal or retro(extra)peritoneal approaches.

TECHNIQUE OF RETROPERITONEOSCOPIC LAPAROSCOPIC LYMPHATIC DISCONNECTION

After induction of general anesthesia, the patient is catheterized and placed in kidney position. A 2-cm incision is given below and posterior to the tip of 12th rib. The incision is deepened down to the retroperitoneal space through dorsolumbar fascia. Through this wound, finger dissection is performed to create more retroperitoneal space. A homemade balloon (made from two finger stalks of a 7-1/2 glove, sleeved one over the other and tied over a 16 French red rubber catheter) or commercially available balloon is placed in the retroperitoneal space. The balloon is inflated for five minutes each time with instillation of about 500 mL of saline once directed cranially and then caudally to help create adequate retroperitoneal space. Hasson canula is put through this wound in to the retroperitoneal space, and two stay sutures are taken at the port site through the skin, subcutaneous tissue, muscles, and dorsolumbar fascia and tied around the canula in order to prevent surgical emphysema. Carbon dioxide pneumoretroperitoneum is created to a pressure of 15 mmHg, and laparoscope is introduced. Under laparoscopic vision,

> Patients having persistent chyluria, clot colic, retention of urine, and weight loss despite conservative management and sclerotherapy need surgical intervention.

FIGURE 4 ■ Schematic diagram for the port placement for right-side lymphatic disconnection.

FIGURE 5 ■ Opening of Gerota's fascia posteriorly to dissect out the kidney.

a second port (10 mm) is inserted in the same line 2 cm above the iliac crest. A third (10/5 mm) canula is inserted in midaxillary line, 2 cm below the costal margin (Fig. 4). The procedure of laparoscopic lymphatic disconnection includes five important steps (2,7,11–13):

1. Nephrolympholysis
2. Stripping of hilar vessels
3. Ureterolympholysis
4. Fasciectomy
5. Nephropexy

Nephrolympholysis

The kidney and adrenal gland are surrounded by perinephric or perirenal fat these together are enclosed by perirenal fascia or Gerota's fascia. Nephrolympholysis is the dissection of kidney from its surrounding perirenal fascia. Gerota's fascia is opened, and the kidney is dissected gradually out of the perirenal fascia (Fig. 5). The dissection is started posteriorly followed by dissection of the upper pole, lower pole, and finally the anterior surface. Once the kidney is mobilized all around, the dissection of the renal vessels is started posteriorly.

Stripping of Hilar Vessels

The vascular dissection is to be done with utmost care. The dilated perirenal and peri-hilar lymphatics are individually clipped and divided (Fig. 6).

The renal vessels are laid bare of perivascular tissue. The dilated lymphatics are diligently searched for and taken care under laparoscopic magnification. Once the posterior dissection is completed, the anterior surface of the vessels is cleared of loose areolar tissue and lymphatics.

> The vascular dissection is to be done with utmost care. The dilated perirenal and perihilar lymphatics are individually clipped and divided.

Ureterolympholysis

Ureterolympholysis includes circumferential mobilization of ureter down to common iliac vessels (Fig. 7). All lymphatics are individually ligated/clipped and divided. Transverse sweeping movements downwards help in clearing ureter out of the loose fatty tissue.

Fasciectomy (Excision of Perinephric Fat and Fascia Gerota)

The kidney is bared of its coverings. As much of perirenal fat as possible is removed. This maneuver removes the perinephric group of lymphatics, which freely communicate with subcapsular group of lymphatics and drain in to the lateral aortic nodes.

FIGURE 6 ■ Stripping of hilar vessels.

FIGURE 7 ■ Dissection of ureter all around with transverse sweeping movements.

Nephropexy

If the kidney thus freed is hypermobile in the retroperitoneal space, the renal capsule is fixed to the posterior abdominal wall using three sutures at upper, middle, and lower poles of the kidney. This is done to avoid tension on renal vessels. Finally, the retroperitoneal space is irrigated with saline, inspected for hemostasis, and a drain is placed. After desufflation, the port sites are closed with muscles and skin sutures.

TECHNICAL TIPS TO AID LAPAROSCOPIC LYMPHATIC DISCONNECTION

- Acquaintance to the variations in number and course of renal vessels helps in avoiding vascular catastrophe. During hilar stripping, one should carefully look for the posterior segmental branch of renal artery, which is the most constant division and makes its way out of the renal artery before it enters the renal hilum and proceeds posterior to the renal pelvis to supply a large posterior segment of the kidney. It may be mistaken for a dilated lymphatic vessel and get inadvertently clipped (12).
- Occasionally, the right renal artery may arch anterior to the inferior vena cava. In that way it will be located more anteriorly to the right renal vein. In retroperitoneoscopic approach, such anteriorly located right renal artery may be best approached through the plane created between the anterior surface of the kidney and peritoneal reflection medially. In such a situation, conversion of retroperitoneal to transperitoneal approach may be a more judicious step.
- During ureterolympholysis, staying in proper dissection plane, i.e., outside the ureteral adventitia that contains the plexus of ureteral blood supply that courses longitudinally along the ureter, helps in preserving the ureteral blood supply.
- To ensure complete lymphatic dissection, a few drops of methylene blue can be applied to the renal hilum via a specially designed laparoscopic syringe to aid in the visualization of the remaining lymphatic vessels (Fig. 8) (11).

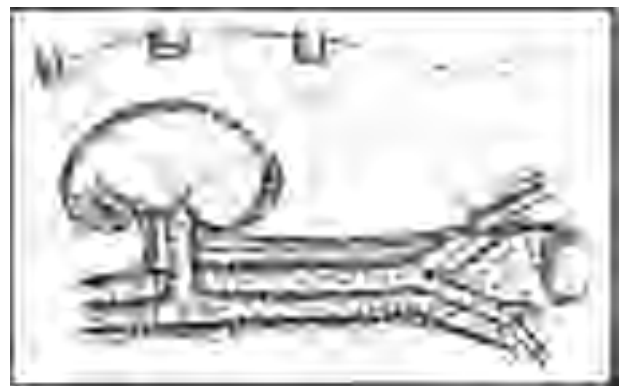
FIGURE 8 ■ Diagrammatic representation after completion of nephrolympholysis, stripping of hilar vessels, and ureterolympholysis.


TABLE 3 ■ Causes of Failure after Laparoscopic Lymphatic Disconnection

Early failure	Late failure
Incomplete stripping	Recanalization of lymphatic

Fistula in the lower part of the ureter and bladder	
Collateral release of chyle due to increased lymphatic pressure	

Source: From Refs. 19 and 22.

POSTOPERATIVE CARE AND FOLLOW-UP

Usually the patient is allowed oral food by evening on the day of surgery itself. The Foley catheter is removed next morning. Follow-up includes subjective and objective evaluation of the patient. Urine examination for chyle, lipids (triglycerides and cholesterol), and proteins should be checked in the postoperative period and then every six months. In spite of surgical intervention, chyluria may persist, which needs reevaluation, and some of the causes are discussed below (Table 3).

ADVANTAGES OF LAPAROSCOPY

Laparoscopy provides optical magnification that facilitates the identification of small lymphatics easily, thus increasing the chances of success with lesser blood loss and operative time.

As the open surgical procedure requires extensive mobilization within the retroperitoneum over a large area, it necessitates a large flank or midline incision. The objectives of open surgery can be easily met with minimally invasive technique of laparoscopy (Table 4) (11–13).

Laparoscopy provides optical magnification that facilitates the identification of small lymphatics easily, thus increasing the chances of success with lesser blood loss and operative time.

Postoperative recovery is rapid and hospital stay is short (11–13).

RETROPERITONEAL VS. TRANSPERITONEAL LYMPHOLYSIS

Retroperitoneal laparoscopic lympholysis has an obvious advantage, because the peritoneum is not transgressed at any level thus avoiding the potential complications such as bowel injury and prolonged ileus.

Leaving the initial report of transperitoneal approach (2), mostly the procedure of lympholysis has been performed retroperitoneally (11–13). Retroperitoneal laparoscopic lympholysis has the obvious advantage, because the peritoneum is not transgressed at any level, thus avoiding the potential complications such as bowel injury and prolonged ileus (4). It offers minimal invasion with lesser postoperative pain, lower morbidity, short hospital stay, and rapid recovery (4,8,11,12). Table 4 summarizes the various reported series on laparoscopic management of chyluria.

SUMMARY

- The severe or intractable chyluria does not respond to conservative measures such as dietary modifications or sclerotherapy and usually requires surgical intervention.
- The results of laparoscopic lymphatic disconnection are excellent, and the objectives of open surgery are effectively achieved by this minimally invasive approach.
- Laparoscopic lymphatic disconnection is safe, effective, and gives durable results in patients with intractable filarial chyluria; hence, it should be the procedure of choice.
- Laparoscopic lymphatic disconnection not only considerably reduces the incision-related morbidity without compromising the principles of open surgery, but also offers a quick recovery with a shorter hospital stay.

LAPAROSCOPIC INGUINAL HERNIA SURGERY

Bipan Chand and Jeffrey Ponsky

Department of Minimally Invasive Surgery, Cleveland Clinic Foundation,
Cleveland, Ohio, U.S.A.

INTRODUCTION

The first laparoscopic hernia repair was performed prior to laparoscopic cholecystectomy, yet has not supplanted open hernia repair, as has laparoscopic cholecystectomy for gallbladder disease. Reasons may include a steeper learning curve, an assumed increased operative cost, and the excellent alternative in open hernia repair. Ger in 1982 reported on 13 patients undergoing hernia repair, using a stapling device; the 13th patient underwent a laparoscopic repair (1). This early technique used a stapling device to close the neck of the hernia as the sole repair. Since then various techniques have been devised for laparoscopic herniorrhaphy. The initial approach consisting of simple ring closure had a high failure, because the deeper tissues were not approximated. This evolved to the necessity of a prosthetic biomaterial to reinforce the defect. Bogojavalensky first introduced hernia repair using a biomaterial in 1989 (2). At that time, a rolled piece of polyprolene mesh was placed into the indirect space of the hernia. Preliminary reports of this technique were promising, but long-term follow-up revealed a recurrence rate of 15% to 20%, leading to abandonment of such technique. Subsequently, the plug-and-patch and then the development of the intraperitoneal onlay mesh followed.

The intraperitoneal onlay mesh technique consisted of a large piece of biomaterial placed intra-abdominally to cover the peritoneum with a fixation device (3,4). This technique involved no dissection and was simple to perform, but led to a high failure rate for a number of reasons. The mesh would slip into the hernia defect, leading to adhesions with the bowel and also potential erosion into the bowel. Therefore, proper fixation of the mesh to the fascia of the transversalis muscle was deemed necessary to prevent this high failure rate and led to the development of the current transabdominal preperitoneal repair. Schultz et al. were the first to report on this technique, which involves dissection of the preperitoneal space and then fixation of a mesh to reinforce the defect (5). A later modification of this technique consisted of totally extraperitoneal approach, which involves balloon dissection into the preperitoneal space and avoids entering the abdomen (6). The totally extraperitoneal repair also incorporates a biomaterial mesh to repair the hernia with and sometimes without a fixation device.

Transabdominal preperitoneal and totally extraperitoneal approaches are the current modalities used in laparoscopic herniorrhaphy.

INDICATIONS AND CONTRAINDICATIONS

Contraindications to the laparoscopic approach are similar to those to open hernia repair (Table 1). The most important consideration is the surgeon's experience in performing a laparoscopic repair.

The learning curve for a transabdominal preperitoneal or totally extraperitoneal repair has been documented to be around 50 cases (7).

The laparoscopic transabdominal preperitoneal approach requires general anesthesia for adequate abdominal relaxation and insufflation. Although there have

> Transabdominal preperitoneal and totally extraperitoneal approaches are the current modalities used in laparoscopic herniorrhaphy.

> The learning curve for a transabdominal preperitoneal or totally extraperitoneal repair has been documented to be around 50 cases.

been reports of patients undergoing a laparoscopic operation (mostly totally extraperitoneal approach) using a spinal and even at times a local anesthetic, these types of regional anesthesia may not give adequate abdominal relaxation or afford good pain control. Other contraindications are related to abdominal insufflation and subsequent cardiopulmonary compromise. Patients with significant pulmonary obstructive disease or significant cardiac dysfunction may not tolerate the increased abdominal pressure or deep sedation of general anesthetic. These patients would benefit from open herniorrhaphy using a regional or local anesthetic. Laparoscopic hernia repair may be contraindicated in male patients with elevated prostate specific antigen, and indication for prostatectomy as dissection in the preperitoneal space after laparoscopic hernia repair is difficult.

Incarcerated hernias can be approached through a laparoscopic approach, but can be a challenge for the inexperienced laparoscopic surgeon. The manipulation of contents within the hernia sac and acute nature of incarceration (with possible bowel obstruction) may be difficult to reduce. In selected cases, general anesthetic and pneumoperitoneum will allow for adequate abdominal wall relaxation with subsequent spontaneous reduction of the hernia. If spontaneous reduction does not occur, then the surgeon must be meticulous in reducing the bowel from within the hernia sac. Occasionally, opening the hernia sac and widening the neck of the defect will allow the surgeon to safely reduce its contents.

Patients with chronic incarceration without mechanical bowel obstruction may be more amenable to the laparoscopic approach, given that less bowel dilation is encountered.

Other factors that may make operating on an acute obstruction unsafe include difficult abdominal entry, inadequate space for pneumoperitoneum, and difficult handling of dilated bowel. Signs and symptoms of peritonitis may alert the surgeon of possible strangulation and bowel ischemia requiring bowel resection, which may be approached laparoscopically. Again, the difficulty is obtaining a safe pneumoperitoneum and handling dilated and possibly ischemic bowel. Newer instruments and stapling devices have allowed for complete intracorporeal bowel anastomosis. Mesh infection is the primary concern in these contaminated fields, and appropriate biomaterial choice is important.

Gigantic scrotal hernias are difficult to approach laparoscopically. The difficulty is reducing the contents into the abdominal cavity while maintaining pneumoperitoneum. Repairing the large floor defect of the inguinal canal may also pose a problem. These hernias may require a laparotomy as well as an inguinal incision for reduction of the contents and then adequate floor repair.

ANATOMY

Laparoscopic herniorrhaphy requires detailed knowledge of pelvic anatomy. In fact the operation requires the surgeon to start from the deeper structures and work toward the more superficial layers. This unfamiliarity with internal inguinal anatomy may be one of the reasons that surgeons are uncomfortable with learning laparoscopic herniorrhaphy.

The initial landmarks for the transabdominal preperitoneal repair include (i) the medial umbilical ligament, which contains the obliterated umbilical arteries and (ii) the lateral umbilical ligament, which contains the inferior epigastric arteries. The direct space is seen medial to the epigastric vessels and the indirect space lateral to the vessels and adjacent to the cord structures within the internal inguinal ring.

Once the peritoneum is opened, key anatomical structures for the transabdominal preperitoneal repair and, initially, in the totally extraperitoneal repair include:
◾ Pubic tubercle
◾ Cooper's ligament
◾ Direct and indirect space
◾ Iliopubic tract

Once these key structures are identified, the hernia sac can be reduced, and mesh repair undertaken. Knowledge of the regional nerves is critical to avoid the neuralgias that had complicated the early laparoscopic repairs.

Important anatomic triangles have also been identified in laparoscopic hernia repairs. The "triangle of doom" is bounded by the medial aspect of the ductus deferens and laterally by the spermatic vessels and houses the iliac vessels and femoral nerve. The "triangle of pain" is made up of the iliopubic tract and the spermatic vessels and contains the lateral femoral cutaneous nerve and the genitofemoral nerve. These two regions should be avoided during fixation of the mesh to the transversalis fascia.

SURGICAL TECHNIQUES

The current two most common laparoscopic approaches to inguinal hernia repair include the transabdominal preperitoneal and the totally extraperitoneal repair.

Both the totally extraperitoneal and the transabdominal preperitoneal approach rely on the same concept introduced by Stoppa in the late 1980s (8). A prosthetic mesh is placed in the preperitoneal space covering and reinforcing the direct and indirect space of the inguinal floor. The only difference in these approaches involves the access into the preperitoneal space. The transabdominal preperitoneal approach requires entry into the abdominal cavity and incision of the peritoneum with creation of a flap, allowing access to the preperitoneal space. The totally extraperitoneal repair does not enter the abdominal cavity and allows for dissection only in the preperitoneal space.

Transabdominal Preperitoneal Hernia Repair

Transabdominal preperitoneal approach requires entry into the abdominal cavity. The patient is asked to empty the bladder prior to operation, and general anesthesia is administered. A Foley catheter is not routinely used in either laparoscopic approach. The patient is placed supine, and the monitors placed at the foot of the table. The surgeon stands on the opposite side of the inguinal hernia, and the abdomen is prepped from xiphoid to inguinal region, including the hernia. The initial trocar is placed using an open technique at the level of the umbilicus. We prefer to use a 10-mm trocar at this site allowing for a 10 mm 30° laparoscope.

Angled scopes are mandatory when performing laparoscopic transabdominal preperitoneal.

The 10-mm port allows for easy introduction of prosthetic mesh into the abdominal cavity. The patient is placed in Trendelenburg position, and diagnostic laparoscopy performed. The defect is identified and characterized as to either a direct or indirect hernia. The opposite side is also evaluated to rule out a double hernia. Two additional 5-mm trocars are then placed below the level of the camera and lateral to the rectus muscle. The use of a 20-gauge needle attached to a 10-cc syringe with local anesthetic allows for excellent visualization of each trocar site and for instillation of anesthetic into the peritoneum for postoperative pain control. Trocar placement lateral to the rectus muscle prevents injury to the epigastric vessels.

Familiarity with pelvic anatomy is crucial to performing a successful operation. The medial umbilical ligament contains the obliterated umbilical arteries and the lateral umbilical ligament contains the inferior epigastric vessels. A direct hernia defect is identified medial to the epigastric vessels and an indirect defect is lateral to the vessels and follows the cord structures through the internal ring.

Incising the peritoneum medially from the medial umbilical ligament to the anterior iliac spine laterally begins the operation. This peritoneal flap is further developed by bluntly pushing the fat and epigastric vessels toward the "ceiling." A wide pocket is required for adequate mesh placement. A large piece of mesh is required to provide adequate defect coverage and reduce the chance of recurrence. Dissection is then continued medially toward the pubic tubercle and Cooper's ligament. These structures are exposed using careful blunt dissection because numerous small crossing veins may be encountered and easily injured. The tubercle lies in the midline and can be felt with the instruments. Dissection is then continued laterally to expose the iliopubic tract and internal ring. Direct defects do not require manipulation of cord structures because the defect is only of the inguinal floor. When exposing this defect, the surgeon must reduce the hernia sac into the abdominal cavity. This is accomplished by retracting inferiorly on the peritoneal flap until the pseudosac of the floor, a white line that runs parallel to the inguinal floor, can be identified. The principle is to completely reduce the inverted peritoneum into the abdominal cavity and allows for complete coverage of the defect by prosthetic mesh. The indirect hernia courses along the cord structures through the internal ring. The reduction of an indirect hernia requires careful identification of the ductus deferens, which runs over Copper's ligament from medial to lateral, and other cord structures. Exposure of the direct space is also achieved when repairing indirect hernias. Blunt atraumatic graspers are used to carefully separate and reduce the indirect hernia away from the cord structures.

The fat surrounding the cord structures, known as cord lipomas, should be identified and removed. If this is not accomplished, patients may feel a recurrence has occurred.

Once the hernia has been reduced, a prosthetic mesh is placed into the abdominal cavity through the umbilical trocar. A large piece of polyprolene mesh that measures 10×15 cm is preferred. The mesh is orientated so there is complete coverage of

the direct and indirect space, and, most importantly, to cover the pubic tubercle where most recurrences occur. There have been no studies showing a benefit to creating a "slit" in the mesh to encircle the cord structures, and some authors feel that this may lead to cord ischemia. The mesh is then in place using a spiral tacker. The first tack is medially placed on the pubic tubercle and then along Cooper's ligament laterally. Next, the mesh is fixed to the "ceiling" of the inguinal floor along the posterior aspect of the transversalis fascia and then laterally above the iliopubic tract. The peritoneal flap is then reapproximated and tacked in place. The trocars are removed and fascia closed at the umbilical site.

Totally Extraperitoneal Hernia Repair

Patient and operating room are prepared in a similar fashion to the transabdominal preperitoneal repair. After an infraumbilical vertical incision is made, the anterior rectus fascia is incised, and the rectus muscle lifted upward and laterally, exposing the posterior sheath. The surgeon's finger is then used to gently separate the rectus muscle from the posterior sheath. The dissecting balloon is placed into this plane and directed toward the pubic tubercle. A 10-mm laparoscope is then placed into the balloon and the balloon slowly inflated under direct visualization. The balloon is then left inflated for a short time to tamponade any small vessels. The inferior epigastric vessels should be directed anteriorly during this step. The balloon is then removed, and a Hasson type trocar placed and the cavity insufflated to 12 mmHg. Two 5-mm trocars are then placed in the midline between the pubic tubercle and the umbilical trocar under direct visualization.

The pelvic anatomy is then delineated with identification of the pubic tubercle, Cooper's ligament, and the epigastric vessels. The lateral space is then bluntly developed toward the anterior iliac spine. For an indirect hernia, the sac is dissected perpendicular to the cord structures. The sac is then completely invaginated if at all possible to allow for placement of the mesh. A 10×15 cm mesh is placed into this space and tacked in a similar fashion as described in the transabdominal preperitoneal repair. Insufflation and trocars are removed and the skin closed. No fascial defect needs to be closed in the totally extraperitoneal repair.

Recent studies have shown the decreased necessity of fixation of the mesh in the totally extraperitoneal repair. This may lead to decreased postoperative neuralgia and decreased cost of surgery while not incur any an increase incidence of hernia recurrence (9).

> Recent studies have shown the decreased necessity of fixation of the mesh in the totally extraperitoneal repair. This may lead to decreased postoperative neuralgia and decreased cost of surgery while not incur any an increase incidence of hernia recurrence.

POSTOPERATIVE CARE

Patients are observed for a short time in the outpatient area and routinely discharged the same day of surgery. An intravenous nonsteroid, such as ketorolac, is given to patients at the time of emergence from anesthesia for pain control. Patients are ambulated in the recovery area, asked to void prior to release, and given a mild narcotic for postoperative pain control for the next several days. Routine activities, including showering, can be initiated the day after surgery. Patients are to refrain from driving while on narcotics and whether substantial pain still exists. Table 2 lists the most common postoperative complications.

TECHNICAL PEARLS

Bleeding

Significant bleeding may occur from various sources, including the epigastric vessels, the crossing veins over Cooper's ligament, and the iliac vessels. Proper trocar placement and dissection in the correct plane prevents injury to such vessels.

The use of a small gauge needle and syringe filled with anesthetic at the time of initial trocar placement during the transabdominal preperitoneal repair will allow for direct placement of trocars lateral to the epigastric vessels. During initial dissecting balloon placement in the totally extraperitoneal repair, it is important to visualize balloon expansion of the cavity and the correct anterior displacement of the epigastric vessels. If it becomes apparent that the epigastric vessels are being displaced incorrectly, insufflation should be stopped and the remainder of the dissection done under direct visualization. If the vessels become torn in either operation, they can be directly ligated using a suture passer and absorbable suture or clipped. Confidence with anatomy and location of the external iliac vessels and the constant

> Significant bleeding may occur from various sources, including the epigastric vessels, the crossing veins over Cooper's ligament, and the iliac vessels. Proper trocar placement and dissection in the correct plane prevents injury to such vessels.

crossing vein over Cooper's ligament will help the surgeon in avoiding these structures during the dissection.

Nerve Injury

Pain and paresthesias in the inguinal region were not uncommon after the early reports of laparoscopic hernia repair because of the initial unfamiliarity of the course of these nerves and the greater number of tacks to fixate the mesh (10). Careful attention to the anatomy of these nerves and reduction in the number of tacks used to fix the mesh to the transversalis fascia have decreased the incidence of these nerve injuries.

Avoidance of tack placement below the iliopubic tract and constant palpation of the tacker against the abdominal wall will ensure correct placement of tacks. However, if nerve entrapment occurs in the immediate postoperative period, the patient should be brought back to the operating room for tack removal.

Table 3 shows the nerves involved in hernia repair and the potential postoperative symptoms of nerve injury.

Visceral Injury

The transabdominal preperitoneal repair has the potential of injuring bowel and vascular structures during initial trocar placement as well as during hernia repair. It is imperative that appropriate patient selection be used when choosing a laparoscopic repair. Patients with multiple prior laparotomies or previous pelvic surgery may be better served through open repair. During totally extraperitoneal repair, there is also the potential for bladder injury with initial balloon dissection. A bowel obstruction can occur if the peritoneum is opened during a totally extraperitoneal repair and not recognized, and the bowel herniates into the preperitoneal space during desufflation.

> ■ If the bowel is injured during laparoscopic hernia repair, the bowel should be repaired and mesh placed using an open approach to prevent mesh infection.
> ■ Bladder injury may be avoided carefully directing the balloon above the pubic tubercle with an empty bladder.
> ■ Patients with previous retropubic surgery should not be offered a totally extraperitoneal repair.
> ■ Bowel herniates into the preperitoneal space during desufflation is prevented by closing all peritoneal openings with an endoloop and desufflating under careful visualization.

During transabdominal preperitoneal repair, it is also important to completely close the peritoneum to prevent exposure of the mesh to bowel. Polyprolene mesh exposed to bowel can lead to erosion of the biomaterial into bowel. If the peritoneum does not cover the mesh in its entirety, then an alternative biomaterial must be used to decrease the risk of adhesion and fistula formation.

Although both transabdominal preperitoneal and totally extraperitoneal repairs offer excellent results in regard to hernia repairs, there appears to be a trend toward more surgeons performing the totally extraperitoneal repair. This may be related to the decreased risk of bowel and vascular injury seen during totally extraperitoneal surgery (11). However, the incidence of complications is directly related to the surgeon's experience with the type of laparoscopic repair and therefore should the surgery.

Sidebar: Avoidance of tack placement below the iliopubic tract and constant palpation of the tacker against the abdominal wall will ensure correct placement of tacks. However, if nerve entrapment occurs in the immediate postoperative period, the patient should be brought back to the operating room for tack removal.

Nonrepair related:	Urinary retention MI, UTI, DVT, etc.
Repairs related:	Seroma Hematoma
Neuralgias:	Nerve entrapment Nerve injury
Groin pain:	Early (transient) Late (chronic)
Testicular symptoms:	Pain Ischemia
Trocar site problems:	
	Bleeding, Hernia, Infection
	Wound infection
Mesh complications:	Infection Late rejection

Abbreviations: MI, myocardial Infection; UTI, urinary tract infection; DVT, deep venous thrombosis.

TABLE 3 ■ Inguinal Nerves

Nerve	Function	Preventing injury
Ileohypogastric	Sensation along inguinal crease	Avoid deep tack placement, important to provide bimanual palpation
Ileoinguinal	Sensation over the base of the penis	As for ileohypogastric
Lateral femoral cutaneous	Sensation for entire lateral thigh	Avoid tacks below the ileopubic tract lateral to iliac vessels (triangle of "pain")
Genitofemoral	Genital branch is sensation of scrotum and adjacent thigh; Femoral branch innervates proximal anterior thigh	As for lateral femoral cutaneous
Femoral	Muscular innervation of leg	Avoid dissecting deep to the femoral vessels (triangle of "doom")

The most common causes of hernia recurrence are incomplete dissection and inadequate size of the mesh coverage.

Numerous studies have demonstrated that at least 2 to 3 cm of defect overlap is required, as well as the size of prosthesis being greater than 10×14 cm to prevent this type of failure.

Recurrences

Hernia recurrence remains the most reported and widely scrutinized aspect of herniorrhaphy. There are numerous causes of recurrences during laparoscopic hernia repair, with the majority being technical failures (Table 4).

The most common causes of hernia recurrence are incomplete dissection and inadequate size of the mesh coverage (12,13).

When performing a laparoscopic hernia repairs, it is imperative that all potential defect sites as well as cord lipomas be investigated. Failure to identify and remove a cord lipoma may let the patient believe a hernia still exists (14). A large piece of mesh is required to cover all potential sites including the direct, indirect, and femoral space.

Numerous studies have demonstrated that at least 2 to 3 cm of defect overlap is required, as well as the size of prosthesis being greater than 10×14 cm to prevent this type of failure (9,11,15).

Other causes of recurrences include mesh migration, shrinkage, and poor fixation (10). Fixation of the mesh is currently debatable. Two studies have shown no difference in recurrence rates when a large piece of mesh is used to cover the defect without fixation tacks (9,16). The most important finding in both studies is that a large piece of mesh was required for the repair.

SUMMARY

- The last decade has witnessed multiple studies comparing the laparoscopic hernia repair to the open approach.
- Over 70-randomized controlled trials, four meta-analyses, and two systematic reviews looking at inguinal hernia repairs have been published. These studies have demonstrated the safety and comparable recurrence rates of laparoscopic herniorrhaphy to the open technique (Table 5).
- The majority of studies show decreased postoperative pain and a faster return to preoperative activity with the laparoscopic repair (17–19).
- The operative time and overall cost has been shown to be higher in the laparoscopic repair. However, the majority of studies look at direct costs, such as operative equipment and operative time and not overall costs, such as time lost from work and increased pain medication requirements.
- Choosing reusable equipment, less fixation devices, and simple biomaterial meshes may decrease overall costs and allow for an increase in laparoscopic herniorrhaphy.

LAPAROSCOPIC
UROLOGIC ONCOLOGY

LAPAROSCOPIC ADRENALECTOMY FOR MALIGNANCY

Alireza Moinzadeh

Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

With improved radiographic imaging, adrenal masses are more frequently detected following a treated primary malignancy or noted incidentally as part of an unrelated work-up. Along with improvements in diagnostic techniques, laparoscopy has emerged as a formidable option for various urologic malignancies.

Currently, laparoscopic adrenalectomy is the gold standard for benign medical adrenal masses (1,2). However, the role of laparoscopy for malignant adrenal disease including primary adrenocortical carcinoma and metastatic lesions is more controversial.

> Currently, laparoscopic adrenalectomy is the gold standard for benign medical adrenal masses. However, the role of laparoscopy for malignant adrenal disease including primary adrenocortical carcinoma (adrenocortical carcinoma) and metastatic lesions is more controversial.

ADRENALECTOMY FOR SOLITARY METASTASIS

Metastases to the adrenal gland are more common than primary adrenocortical carcinoma. Such metastases tend to originate from pulmonary, renal, mammary, and gastrointestinal carcinomas (3). Adrenal metastasis has been noted in 10% to 27% of autopsies of patients with known malignancy (4,5). Patients with metastasis to the adrenal gland commonly have disseminated cancer. Rarely does the clinician diagnose a patient suspected of harboring an isolated adrenal metastasis. The management of such a patient presents a challenging dilemma. Having already undergone definitive treatment for the primary malignancy, the physician is faced with counseling the patient on the best treatment strategy for the presumed metastasis. Unfortunately, the treatment of such lesions is controversial. Although some reports support the surgical treatment of isolated adrenal metastases with long-term survivors, identifying the most suitable surgical candidate is less clear. The ideal study would involve a prospective comparison of patients with adrenal metastasis randomized to receive surgical treatment or observation or another form of treatment (chemotherapy/radiation). However, the accrual period of such a study would be extraordinarily long given the rare subset of patients in question. As such, clinical decisions must rely on larger retrospective studies, addressing a heterogeneous group of patients with a wide array of primary malignancies that have metastasized to the adrenal gland.

Several studies supporting the role of adrenalectomy for isolated adrenal metastasis have been reported. Several case reports have highlighted survival for solitary adrenal metastasis from colorectal cancers in carefully selected patients (6–8). These case reports consist of patients with solitary adrenal metastasis noted after primary colorectal resection. With intermediate follow-up, a survival advantage has been noted in patients with solitary adrenal metastasis of primary colorectal surgery undergoing adrenalectomy. Interestingly, the serum carcinoembryonic antigen was found to be elevated in patients with colorectal recurrence in the adrenal gland, although this elevation has not been noted in all reports (9).

Patients with metastatic lung cancer typically have a poor prognosis. Only 7% of patients present with solitary metastasis (10). Although still controversial, a survival advantage has been noted in patients with solitary adrenal metastasis from a non–small cell lung malignancy, whether synchronous or metachronous (11–15). These published series, with relatively small numbers and intermediate follow-up, have reported survival in this very select subset of patients. Luketich and Burt (11) compared the median survival of eight patients with isolated adrenal metastases from lung cancer who underwent adrenalectomy and chemotherapy with six patients who underwent chemotherapy alone. The median survival in the surgical group was found to be significantly increased (31 months) versus the chemotherapy alone group (8.5 months, $p = 0.03$). In another study, survival was noted in a multicenter trial of 43 patients with isolated adrenal metastases (32 synchronous, 11 metachronous) for patients with primary non–small cell lung cancer who underwent adrenalectomy (12). Median overall survival was 11 months, with three patients surviving over five years.

The survival of patients with metastatic renal cell carcinoma and multiple metastatic sites is poor. Although the overall number of patients is limited, those with solitary metastatic sites have been shown to possibly benefit from resection of the metastatic site, in particular, solitary metastasis to the lung (16–20). Lau et al. reported the largest series of 11 patients at Mayo Clinic with contralateral adrenal metastasis from renal call carcnone who underwent adrenalectomy. In this series, 2 of 11 patients (18%) were alive at last follow-up. Seven patients died at a mean of 3.9 years after adrenalectomy. Their review of the literature reveals that of 56 patients treated surgically for adrenal metastasis from RCC, 27 (48%) patients showed no evidence of disease on last follow-up. The median follow-up time is unfortunately not provided.

ADRENALECTOMY FOR ADRENOCORTICAL CARCINOMA

Adrenocortical carcinoma is a rare disease with estimated 75 to 115 new cases a year in the United States (21). The staging system commonly used for adrenocortical carcinoma is shown in Table 1 (22). In this staging system, stages I and II include tumors localized to the adrenal gland, while stages, III and IV include tumors with local or distant spread, respectively. In a review of 602 patients from seven institutions, Ng and Libertino (23) found five-year survival based on stage as: stage I, 30% to 45%; stage II, 12.5% to 57%; stage III, 5% to 18%; and stage IV, 0%. Median survival was shorter in patients with unresectable tumors (3–9 months) as compared to those with complete surgical resection (13–28 months).

Stage appears to be one of the best prognostic indicators of survival. Specifically, those with localized disease (stage I or II) tend to have the best outcome after surgical resection (24,25).

The primary therapy for adrenocortical carcinoma is surgical en bloc removal of the tumor. However, even with complete resection, local recurrence is seen in 35% to 85% of reported cases (23).

> The primary therapy for adrenocortical carcinoma is surgical en bloc removal of the tumor. However, even with complete resection, local recurrence is seen in 35% to 85% of reported cases.

CONTROVERSY ABOUT THE ROLE OF LAPAROSCOPY FOR MALIGNANCY

Although the role of laparoscopy for benign adrenal disease is currently defined, laparoscopic excision of malignant renal tumors of the adrenal gland remains controversial.

The concern about laparoscopy for adrenal malignancy stems from seven individual case reports published in the last several years (Table 2) (26–32). These single case reports challenge the adequacy of adrenal resection for adrenal glands with a primary adrenal malignancy or solitary metastatic site. In each case report, the authors describe local recurrence or peritoneal carcinomatosis shortly after (4–14 months) routine laparoscopic adrenalectomy. Two of the case reports consist of metastatic lung cancer to the adrenal gland. The other five case reports describe an initial adrenal mass thought to be benign after initial histopathologic analysis and only later diagnosed as malignancy when clinical recurrence was noted.

It is believed that laparoscopy may have been responsible for intraperitoneal tumor spread or local recurrence. However, definitive proof for this concern is not provided. More importantly, the innate aggressive nature of these cancers and the techniques involved in their removal are not addressed.

These case reports raise two broad concerns about laparoscopic excision of malignant organs, namely, (i) port-site metastasis, and (ii) local recurrence/carcinomatosis. As regards port-site metastasis, Tsivian and Sidi reported the relatively rare occurrence in 11 cases (0.6%) in over 2000 urologic laparoscopic cases reviewed (34).

> Although the role of laparoscopy for benign adrenal disease is currently defined, laparoscopic excision of malignant renal tumors of the adrenal gland remains controversial.

> It is believed that laparoscopy may have been responsible for intraperitoneal tumor spread or local recurrence. However, definitive proof for this concern is not provided. More importantly, the innate aggressive nature of these cancers and the techniques involved in their removal are not addressed.

The most significant risk factors in terms of port-site metastasis included the biological aggressive nature of the tumor, non-placement of the tumor in a specimen bag, violation of the tumor boundary, and ascites.

Port-site metastatic potential has been addressed in animal models as well. It is hypothesized that the escape of potential tumor filled pneumoperitoneum gas around loose fitted trocars may produce a "chimney effect" leading ultimately to port-site metastasis. Tseng et al. demonstrated the increased tumor growth rate in the rat model at port sites where there was a leak of pneumoperitoneum (478 mg of tumor) versus a control group (153 mg, $p = 0.01$) (35). However, such occurrence has not been clinically validated. Ikramuddin et al. used a saline trap to capture the effluent gas of 35 patients who underwent elective laparoscopic procedures (36). Although 15 patients had malignancies, only two were found to have malignant cells in the effluent. Both of these patients had carcinomatosis detected at the beginning of the case. As such, the authors concluded the unlikely nature of cell aerosolization as a significant contributor to port-site metastasis. The various animal models used thus far must be called into question (37). It may not be valid to extrapolate from such studies founded on the use of foreign malignancies remote from the usual primary site, which are introduced into the abdominal cavity.

With regard to carcinomatosis, two hypothetical concerns specific to the laparoscopic approach have been expressed including the dispersion of the malignant cells by the peritoneal CO_2 gas and the possibility of the immunosuppressive effects of pneumoperitoneum (38).

There are a limited number of basic science manuscripts using animal models that specifically attempt to address these concerns. In one such study using a rat model, a suspension of adenocarcinoma cells was placed in the abdomen with or without insufflation and compared to a third group with laparotomy (39). The animals were sacrificed six days post-tumor implantation. The abdomen was divided in six quadrants and gross examination was performed to score tumor density in each quadrant. The group with CO_2 insufflation had more disseminated cancer spread when compared to the gasless group or the laparotomy group. However, validation of these results has been mixed. Using a murine model, Allendorf et al. demonstrated an increased number ($p = 0.04$) and two times larger sized ($p < 0.01$) tumor carcinomatosis at peritoneal sites in the laparotomy group when compared to the insufflation group. The same authors have further defined the seeming protective effects of pneumoperitoneum in preventing carcinomatosis. They propose that a relative increased T-cell function associated with insufflation may lead to protection against cancer spread. This advantage may be lost with conventional laparotomy (40).

LAPAROSCOPY FOR MALIGNANT ADRENAL LESIONS

To date, there have only been a limited number of series dealing with adrenalectomy for malignancy (Table 3) (33,41–47). These series, from experienced laparoscopic surgeons from around the world, present small numbers of patients with relatively short follow-up. Nonetheless, certain inferences regarding the safety of laparoscopy for malignant lesions may be drawn. As stated previously, carcinomatosis and port-site metastasis are major concerns leading to reservations about laparoscopy for adrenal malignancies. In this group of 98 patients, only one case of carcinomatosis (one case in the authors' series) was documented. In addition, no cases of port-site metastases were noted in any of the series.

Our review of 31 patients (33 procedures) with malignant adrenal lesions is the largest published experience to date (33). The cohort comprised metastatic cancer ($n = 26$) and primary adrenal malignancy ($n = 7$). Mean adrenal tumor size was 5 cm (range, 1–10 cm). Mean operative time was three hours with estimated blood loss 258 cc and a mean hospital stay of 2.1 days. Of the 33 procedures, one was electively converted to open surgery. There was no operative mortality. The metastatic group consisted most commonly of RCC ($n = 13$), colonic malignancy ($n = 6$), and lung cancer ($n = 5$). With a median follow-up of 26 months, 17 (55%) were alive, of whom 15 (48%) had no evidence of disease. Five-year actuarial survival was 40%. Seven (23%) patients had local recurrence with no cases of port-site metastasis. Local recurrence was associated with an inferior survival when compared to no local recurrence ($p = 0.016$). Survival did not correlate to a patient's age, gender, tumor size, tumor side, or surgical approach. Unlike prior reports where a disease-free interval of more than six months was associated with overall improved survival (46,48), similar analysis of data in our series did not reveal a survival benefit.

The reader may note the variance in outcome when comparing Table 2 (case reports) to Table 3 (contemporary series supporting laparoscopy for adrenal malignancy). This

TABLE 3 ■ Literature Review: Series of Laparoscopic Adrenalectomy for Cancer [a]

Study (Ref.)	No. of patients	Follow-up (mo)	Comments
Heniford et al., 1999 (41)	11	8.3 (mean)	10 of 11 patients (91%) disease free
Valeri et al., 2001 (42)	6	8.6 (mean)	3 of 6 patients (50%) disease free
Henry et al., 2002 (43)	6	27.5 median	All patients with ACC, 5 of 6 patients (93%) disease free
Kebebew et al., 2002 (44)	18	39.6 (mean)	9/13 (69%) patients with metastatic disease to the adrenal gland disease free; 2/5 patients with primary ACC (40%) disease free
Lombardi et al., 2003 (45)	9	17 (mean)	9 of 11 patients (82%) disease free; 1 died of unrelated cause
Sarela et al., 2003 (46)	11	21 (median)	~60% survival. Comparison of 11 laparoscopic adrenalectomy with 20 open radical adrenalectomies. No difference noted in terms of overall survival
Feliciotti et al., 2003 (47)	6	19.5 (mean) for 2 patients died; 7 (mean) for 4 patients alive	4 of 6 patients (67%) disease free
Moinzadeh and Gill	31	26 (median)	13 of 31 patients (42%) disease free

[a]Only series with 5 or more cases are included.

discrepancy may be attributed to several factors. Solitary metastases of the adrenal gland cover a broad range of primary malignancies. Each specified cancer may have its own unique natural history and innate aggressiveness. With an adrenal metastasis, all the cancers in question have demonstrated the ability to metastasize; therefore, placing them in a more aggressive category. An overall limited survival with loco-regional recurrence should, therefore, not be surprising. The overall survival outcomes in Table 3 appear to compare favorably to the open series of adrenalectomy for malignancy presented earlier in this chapter.

With regard to adrenocortical carcinoma, the overall five-year survival after open surgery has been reported to be 25% (49). Furthermore, in a series of 179 patients having undergone open adrenalectomies, Bellantone et al. documented 52 patients (37%) with local recurrence (50). These data appear to compare favorably to available laparoscopic series, albeit small numbers of cases with the latter. Henry et al. (43) presented five of six patients with ACC having undergone laparoscopic excision with no evidence of disease at a median follow-up of 27.5 months. In our series, of the six patients with adrenocortical carcinoma, three (50%) were alive at a median follow-up of 21 months. Two patients had no evidence of disease, and one was undergoing chemotherapy.

GENERAL GUIDELINES FOR SURGERY

The technique of laparoscopic adrenalectomy has previously been outlined. Additional technical caveats are worth highlighting.

LAPAROSCOPIC ADRENALECTOMY FOR MALIGNANCY: CAVEATS

- All patients should have preoperative workup to rule out the possibility of multiple metastatic sites.
- Currently, the most important preoperative decision for successful postoperative outcome is patient selection.
- Our current contraindications for a laparoscopic approach include peri-adrenal tumor infiltration seen on preoperative computed tomography scan or a known renal vein/inferior vena cava tumor thrombus.
- Although size per se is not an absolute contraindication, tumor size >10 cm leading to a decreased working space, is probably best handled with an open approach.
- As en bloc radical excision should be the standard for potential surgical cure, the threshold for open conversion should be low. This philosophy ensures that basic principles of oncologic surgery are not compromised for the sake of performing the procedure laparoscopically.
- Technical expertise for multiple laparoscopic approaches (transperitoneal, retroperitoneal, and transthoracic) affords the surgeon additional options of access in patients with prior abdominal or retroperitoneal surgery (51).

SUMMARY

- With the increasing publications in support of laparoscopic adrenalectomy for malignancy, the controversy may ultimately end.
- Initial laparoscopic results indicate equivalent survival data with open surgical series.
- Patient selection, sound surgical judgment and technique are paramount for acceptable oncologic results.
- Concerns about laparoscopic excision of malignant organs, e.g., laparoscopic adrenalectomy includes (i) port-site metastasis and (ii) local recurrence/carcinomatosis.
- Further follow-up and additional experience is required prior to definitive conclusions regarding this topic.

LAPAROSCOPIC RADICAL NEPHRECTOMY: TRANSPERITONEAL APPROACH

Michael Grasso III

Department of Urology, St. Vincent's Catholic Medical Center,
New York, New York, U.S.A.

INTRODUCTION

Since the first description of laparoscopic nephrectomy performed by Clayman et al. in 1990, there has been great enthusiasm for employing endoscopic techniques to treat renal disease processes (1). The natural progression from treating benign disease states to more complex malignancies has followed. In fact, in 2004, the majority of renal tumors are treated laparoscopically. The transperitoneal approach was the first and, by many accounts, the traditional approach in addressing renal tumors. Where there was debate in the past on whether an adequate cancer result could be obtained with laparoscopic technique, long-term follow-up has shown that laparoscopic intervention produces reproducible and acceptable results with regard to cancer control (2–7). Laparoscopic nephrectomy also results in decreased postoperative pain, a reduction in analgesic requirement, a decline in hospital stay, and a quicker overall recovery (2,6,8–10). The indications for performing a radical nephrectomy have also been refined. Many smaller lesions today are treated with laparoscopic partial nephrectomy with excellent long-term disease-free survival rather than proceeding with complete organ removal (11–14).

The indications for performing a laparoscopic radical nephrectomy include solid and complex cystic renal tumors that are not amenable to partial nephrectomy by size criteria, location, or multifocality. Larger lesions and those involving the main renal vessels represent technical challenges with a higher conversion rate to open surgery.

In the early published series of laparoscopic radical nephrectomy, a tumor size of 8 cm was a relative cutoff. In reality, larger lesions and, in fact, many complex and bulky lesions can be addressed laparoscopically (15).

There are many attractive aspects of laparoscopic nephrectomy in the setting of renal cell carcinoma. The majority of patients who present with this disease state are elderly with comorbidities including pulmonary and cardiovascular disease. With the absence of a large flank or abdominal incision, patients tend to recuperate faster and frequently there is less postoperative exacerbation of underlying diseases such as chronic obstructive pulmonary disease due to decreased postoperative requirement of narcotics.

In adults, there is no age limit for laparoscopic radical nephrectomy. It has become a standard therapy for the elderly and even the oldest patients presenting with an indication for surgical intervention being treated in this fashion.

INDICATIONS FOR SURGICAL INTERVENTION USING A TRANSPERITONEAL LAPAROSCOPIC APPROACH

There are two major techniques that are employed to remove a cancerous kidney laparoscopically. Firstly, the more traditional transperitoneal approach, where the retroperitoneum is exposed and opened, and the kidney and the contents of Gerota's

> In the early published series of laparoscopic radical nephrectomy, a tumor size of 8 cm was a relative cutoff. In reality, larger lesions and, in fact, many complex and bulky lesions can be addressed laparoscopically.

fascia are brought into the peritoneal cavity during the surgical intervention. The other technique, which has gained increasing popularity, is a purely retroperitoneal dissection. There are certain relative contraindications and clinical presentations that lend themselves more to a retroperitoneal approach versus a transperitoneal approach.

In patients requiring prompt addressing of the renal hilum during dissection and in those patients with large anterior tumors where the transperitoneal dissection may be complicated by a tumor mass blocking the renal hilum, the retroperitoneal approach is superior. In addition, the retroperitoneal approach may be preferred in patients who have undergone prior intra-abdominal surgery, abdominal radiation therapy, or suffered from an intraperitoneal inflammatory state such as peritonitis.

The transperitoneal approach is preferential in patients with large renal tumors or renal lesions in an ectopic or horseshoe kidney.

Renal tumors, like other malignancies, can involve adjacent organs. Although a relatively uncommon occurrence, the surgeon must be aware of such a possibility and employ preoperative imaging to direct surgical intervention. If adjacent organs are involved, and specifically if the tumor appears to invade into the bowel or adjacent solid organs, and the surgeon feels that to obtain an adequate surgical margin adjacent organs may require resection, then a transperitoneal laparoscopic approach rather than a retroperitoneal endoscopic dissection is preferred. On the right side, the right colon and/or liver may be involved. On the left side, the spleen, the left colon, and the tail of the pancreas can also be involved. In all these settings, laparoscopic dissection via a transperitoneal approach is preferential.

CONTRAINDICATIONS TO LAPAROSCOPIC RADICAL NEPHRECTOMY

There are general contraindications for performing surgical intervention, and specific clinical states which would prohibit a transperitoneal laparoscopic radical nephrectomy. General contraindications include those patients who cannot tolerate a general anesthetic, those who present with an uncorrectable bleeding diathesis, or patients with underlying severe cardiovascular or pulmonary disease, who are thus not ideal surgical candidates. Relative contraindications to transperitoneal laparoscopic surgery include abdominal wall infection or suspected carcinomatosis and malignant ascites. Other specific and relative contraindications to a transperitoneal laparoscopic nephrectomy include multiple prior intra-abdominal procedures with severe adhesions, a history of severe peritonitis, or a diaphragmatic hernia. Patients with a history of cirrhosis with portal hypertension reflect another relative contraindication to transperitoneal laparoscopic radical nephrectomy. A retroperitoneal approach can be safely performed and is preferred in many of such patients.

In patients whose preoperative imaging suggests severe hilar adenopathy or encasement of the renal vasculature with tumor, there is a relative contraindication to laparoscopic nephrectomy. Finally, the presence of a renal vein or vena cava thrombus is a relative contraindication to laparoscopic surgical intervention. Although resection of a renal tumor with laparoscopic control of the renal vein distal to a tumor thrombus has been reported with a successful outcome, extensive vein thrombosis or extension into the vena cava should generally lead to open intervention, often with the assistance of vascular or cardiothoracic colleagues (16).

Severe hepato- or splenomegaly is a relative contraindication to transperitoneal laparoscopic nephrectomy. An enlarged or fatty liver, which must be retracted to allow access to the kidney, adds to the complexity of the overall procedure. In these patients, a retroperitoneal approach is preferred.

Severe hepato- or splenomegaly is a relative contraindication to transperitoneal laparoscopic nephrectomy. An enlarged or fatty liver, which must be retracted to allow access to the kidney, adds to the complexity of the overall procedure. In these patients, a retroperitoneal approach is preferred.

Obesity, however, is not a contraindication to laparoscopic nephrectomy. In fact, in obese patients whose renal pathology fits the criteria for laparoscopic nephrectomy, this endoscopic approach is the preferred treatment, although a modification of the standard port placement scheme may be required and excess adipose tissue can make dissection and landmark identification challenging (17).

PREOPERATIVE EVALUATION

As with any major open surgery, a complete history and physical exam, basic laboratory studies, electrocardiogram, and chest radiograph should be completed to identify any possible relative or absolute contraindications to laparoscopy. Additional studies may be necessary in patients with pulmonary or cardiac disease. In fact, such diseases

may be exacerbated secondary to the hypercarbia and acidosis noted with pneumoperitonium, which may result from prolonged exposure to CO_2.

Prior to removal of the diseased kidney, the function of the contralateral kidney should be assessed. A serum creatinine level and visualization of normal contrast uptake and excretion on an imaging study are usually adequate. If renal insufficiency is present or the function of the kidney is in question, a nuclear medicine renal scan and creatinine clearance level may be helpful. Partial nephrectomy should be considered in patients with marginal renal function if technically feasible.

A metastatic evaluation is employed in all patients who present with renal tumors prior to radical nephrectomy. In patients undergoing transperitoneal laparoscopic radical nephrectomy, there is particular emphasis on the intra-abdominal organs, specifically to rule out concurrent processes or direct tumor extension to adjacent organs. Three-dimensional computed tomography or magnetic resonance imaging imaging is often useful in directing surgical intervention. Attention to the renal hilum, in particular the size, location, and number of renal vessels is always helpful. Imaging may also define and quantify the extent of a renal vein thrombus. Three-dimensional computed tomography reconstruction produces clear images that can direct surgical technique. Magnetic resonance imaging imaging with three-dimensional reconstruction and magnetic resonance angiography is often particularly useful in patients with iodine-based intravenous contrast intolerance or with renal functional insufficiency contraindicating iodine-based contrast load. If clinically indicated, a bone scan or imaging of the central nervous system can define widespread disease preoperatively and may direct the surgeon to observation or potential palliative intervention.

In preparation for surgery, patients are instructed to refrain from nonsteroidal anti-inflammatory drug and multivitamins including vitamin E due to increased risk of perioperative bleeding. Patients with large lesions and those with a heightened risk of bleeding based on a clinical presentation are offered the opportunity to bank their own blood or have donor-directed blood prepared. Mechanical bowel preparation is essential when performing a transperitoneal laparoscopic nephrectomy, because colon cleansing increases the ease of bowel retraction and mobilization. In patients where direct tumor extension into the bowel is suspected, an oral antibiotic and mechanical bowel preparation is implemented, so that an en bloc resection of adjacent organs can be performed with primary bowel repair if necessary.

SURGICAL TECHNIQUE

Initial Intraoperative Steps and Patient Positioning

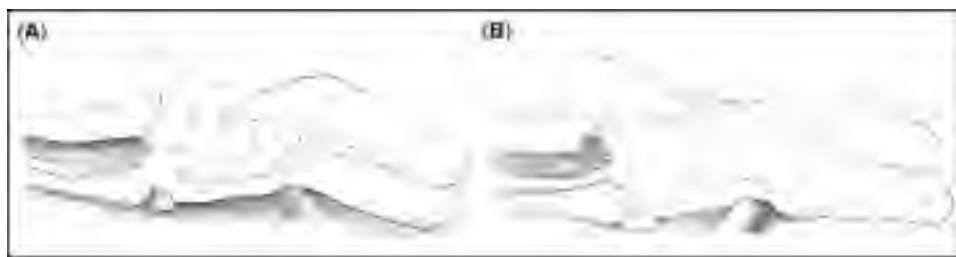
The patient is brought into the operating theater and a general endotracheal anesthesia is administered.

Combined team efforts of the operating surgeon and the attending anesthesiology staff lead to the best outcomes. Complete muscle relaxation is essential. In addition, the anesthesiologist should be experienced with the management of anesthetic agents and the monitoring of the patient during complex laparoscopic procedures, which may take several hours to complete. CO_2 monitoring and relaying the extent of the hypercarbic state during the procedure to the surgeon are particularly important.

After induction of a general anesthetic, the bladder is drained with a standard indwelling Foley catheter. The stomach is decompressed with either an oral or nasogastric tube, and large-bore intravenous access should be obtained. Central venous access or arterial access is useful in complex patients or in those patients with comorbidities requiring special monitoring.

The patient is positioned in a standard complete flank position or at 45° to the operating table with the surgical side being elevated (Fig. 1). The majority of surgeons perform transperitoneal laparoscopic surgery in a full flank position. When the patient is placed in the full flank position, an axillary roll is employed. A pillow and padding are placed to protect the lower extremities and all bony prominences. Compression boots are applied to help preventing deep venous thrombosis of the lower extremities. The upper extremities, head, and neck are carefully padded and protected. The kidney rest elevator can be employed based on the surgeon's preference, most frequently, for smaller lesions and in small-size kidneys. In addition, in particularly large or obese patients, the kidney rest is useful in defining the organ. The abdomen and flank are prepared and draped in standard fashion.

> Combined team efforts of the operating surgeon and the attending anesthesiology staff lead to the best outcomes. Complete muscle relaxation is essential. The anesthesiologist should be experienced in complex laparoscopic procedures, which may take several hours to complete. CO_2 monitoring and relaying the extent of the hypercarbic state during the procedure to the surgeon are particularly important.

FIGURE 1 ■ Patient positioning for a transperitoneal laparoscopic nephrectomy. (**A**) Patient in the complete lateral position for a left transperitoneal laparoscopic nephrectomy. (**B**) The 45°-midline lateral position is employed for large renal lesions and/or large kidneys (e.g., adult polycystic kidney disease).


Port Placement Schemes

Figure 2 shows three and four port placement schemes for transperitoneal laparoscopic radical nephrectomy. Port placement varies according to center and surgeon preference. Depending on the complexity of the procedure, the number of ports can vary from three to six.

> The minimal number of ports that are required is three, with additional ports placed when specific retraction is required, e.g., patients with a relatively large liver require the placement of a fourth port to retract the liver during dissection of the right upper renal pole.

The minimal number of ports that are required is three, with additional ports placed when specific retraction is required, e.g., patients with a relatively large liver require the placement of a fourth port to retract the liver during dissection of the right upper renal pole.

The location of the ports follows a variety of schemes. Traditionally, either a periumbilical or supraumbilical port was placed for the endoscope, with additional ports placed subcostally. In many centers, this has evolved to a scheme where a port is placed at the mid-clavicular line lateral to the kidney. This port is employed for visualization, and two additional ports are placed, one on either side, for working instruments.

CAVEATS

- Inadvertent puncture or laceration of the epigastric vessels can be prevented with port placement lateral or medial to the body of the rectus muscle.
- Ports that are placed too close to the rib cartilage, e.g., less than 1 cm from the costochondral margin, will be difficult to pivot during laparoscopic dissection.

Technical Surgical Steps

Once the three initial operating ports are placed, the surgeon can employ either a 1 cm or 5 mm laparoscopic lens to illuminate the intraperitoneal contents to rule out the pres-

FIGURE 2 ■ Various port placement schemes for transperitoneal laparoscopic nephrectomy. A 10/12-mm port is utilized for the camera; working ports are 5- or 10-mm; and a 5-mm port is usually sufficient for the additional retraction ports.

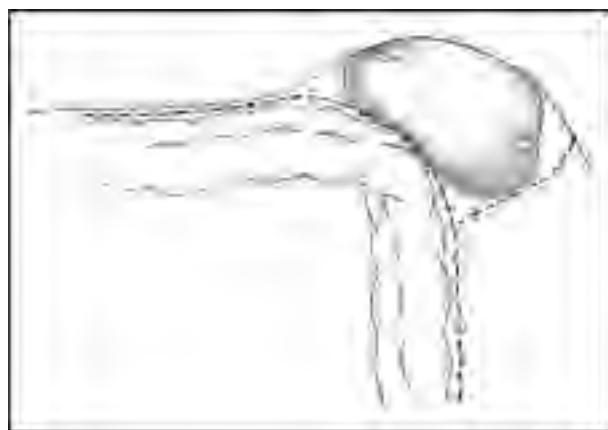
FIGURE 3 ■ Laparoscopic right radical nephrectomy. Resection begins with incision of the white line of Toldt and peritoneal attachments between the liver and right colon. Mobilization of the first portion of the transverse colon improves access to the right renal hilum.


FIGURE 4 ■ Laparoscopic left radical nephrectomy. The white line of Toldt is incised along the left colon, and the peritoneal attachments between the colon and spleen are divided. The distal end of the transverse colon is mobilized, as is the spleen laterally.

ence of distant metastases. On either side of the abdomen, the dissection begins with the mobilization of the colon medially and the entry into the retroperitoneum. On the right side, the colon is mobilized by incising the white line of Toldt and dividing the attachments between the liver and first portion of the transverse colon (Fig. 3).

- During right nephrectomy, the mobilization of the colon is continued along the first portion of the transverse colon to allow complete retraction of the right colon, which exposes the right retroperitoneum.
- On the left side, the same incision along the white line of Toldt is continued up along the distal end of the transverse colon with division of the attachments between the colon and the spleen for the same reason stated above (Fig. 4).

When performing a transperitoneal right laparoscopic radical nephrectomy, entry into the retroperitoneum should direct the surgeon to specific landmarks (Fig. 5). The vena cava should be defined and traced to the renal vein. Other landmarks including the gonadal vein are commonly noted during the dissection. The most common location of the renal artery is posterior to the main renal vein. Multiple renal veins like multiple renal arteries may be present. Variations in renal vascular anatomy are common, and the surgeon should take great care in defining the vessels and carefully dissecting them free from adjacent structures.

On the left side, after entering the retroperitoneum, the surgeon should seek to define the common anatomic constellation that includes the main renal vein crossing the aorta and the adrenal and gonadal veins entering this vessel (Fig. 6).

During transperitoneal radical nephrectomy, hilar vessels should be divided in a stepwise fashion. The arteries should be dissected free from the renal veins and carefully clipped and divided prior to addressing the main renal vein. Most surgeons place multiple clips on the arteries and divide these vessels with endoscopic shears between the clips.

When all the arteries have been clipped, the renal vein will flatten. A still engorged renal vein after arterial control commonly indicates the presence of an accessory renal artery that needs to be addressed.

The renal vein is addressed with an EndoGIA stapling device (Fig. 7). There are two techniques that may be employed: (i) the stapling device fires six rows of titanium staples and divides the vessel between row three and four and (ii) the stapling device fires six rows of staples with no blade. The unbladed device is particularly useful in the case of a short renal vein or in complex presentations where the surgeon would prefer to inspect the staple lines and then divide the vessel using endoscopic shears either between staple lines or between two fires of this device.

During transperitoneal radical nephrectomy, hilar vessels should be divided in a stepwise fashion. The arteries should be dissected free from the renal veins and carefully clipped and divided prior to addressing the main renal vein.

When all the arteries have been clipped, the renal vein will flatten. A still engorged renal vein after arterial control commonly indicates the presence of an accessory renal artery that needs to be addressed.

FIGURE 5 ■ Laparoscopic right radical nephrectomy. After entering the retroperitoneum, the colon is mobilized medially as needed to expose the right renal hilum. Cephalad retraction of the liver is essential. In this case, note the accessory upper-pole renal artery, which is a common variant.

FIGURE 6 ■ Laparoscopic left radical nephrectomy. Medial mobilization of the colon exposes the renal hilum. Landmarks include the branching left renal vein commonly overlying the renal artery.

EndoGIA staplers may misfire if a surgical clip is inadvertently caught between the jaws. Also, when separating the vessels, the surgeon should be well aware of the location of the clips on the renal artery or other vessels before employing the EndoGIA stapler.

EndoGIA staplers may misfire if a surgical clip is inadvertently caught between the jaws. Also, when separating the vessels, the surgeon should be well aware of the location of the clips on the renal artery or other vessels before employing the EndoGIA stapler.

When resection of the adrenal gland is planned as part of the radical nephrectomy procedure, then the hilar dissection should be extended cephalad, defining the adrenal vein and dividing it between clips. Multiple adrenal arteries may be present and need to be either clipped or sealed as the adrenal is mobilized during dissection. Left adrenal vein can be divided between clips as it enters the renal vein. Right adrenal vein usually enters directly into the inferior vena cava. Adrenal venous drainage is commonly based on multiple vessels, where a large cephalad phrenic vein may be encountered. Such vessels should be addressed in a similar fashion to the main adrenal vein, which is often inferior.

After control of the renal hilum is completed, mobilization of the kidney is continued cephalad under the diaphragm, often including the adrenal. The dissection is then continued laterally and posteriorly. The ureter is identified and divided between clips. If warranted, division of the gonadal vein as it courses through the retroperitoneum can be performed between clips at various locations.

Division of the gonadal vein is particularly useful for inferior tumors with local adhesion or involvement by the tumor mass.

Division of the gonadal vein is particularly useful for inferior tumors with local adhesion or involvement by the tumor mass.

Division of renal tumor friable neovascularity encountered in the retroperitoneum is performed by clipping or sealing, e.g., using the Ligasure device.

FIGURE 7 ■ Dissection of the left renal hilum. (**A**) The left gonadal vein is clipped and divided to allow mobility and retraction of the renal vein, providing exposure to the renal artery. (**B**) The renal artery is first clipped and then the renal vein is addressed with an EndoGIA stapler. Care must be taken to avoid catching a staple from the renal artery or gonadal vein when employing the EndoGIA stapler for it will misfire if a metallic foreign body is caught in its jaws.

The contents of Gerota's space, including all the adipose tissue surrounding the kidney, should be developed and removed en bloc.

Specimens can be extracted either by extending the umbilical trocar site incision or with a small suprapubic incision. Transvaginal extraction has also been reported.

Results of laparoscopic radical nephrectomy are similar if not better than traditional open radical nephrectomy.

Complications with laparoscopic radical nephrectomy are similar to those associated with open surgery, including injury to adjacent organs, bleeding, infection, port site or wound herniation, peritonitis, and postoperative ileus.

The contents of Gerota's space, including all the adipose tissue surrounding the kidney, should be developed and removed en bloc.

Once the specimen has been mobilized completely, it is brought centrally into the peritoneum and entrapped into an endocatch bag. Commonly the specimen is large and so the largest available laparoscopic sac is employed. There are various methods and locations utilized to remove the specimen. There is a general debate amongst surgeons on whether the specimen should be morcellated or removed intact. However, intact specimen removal rather than morcellation allows preservation of the histologic landmarks necessary to achieve adequate tumor staging.

Specimens can be extracted either by extending the umbilical trocar site incision or with a small suprapubic incision. Transvaginal extraction has also been reported (18).

After performing transperitoneal laparoscopic radical nephrectomy, the larger port sites, e.g., 10 mm or larger ports, are closed at the fascial level. A variety of fascial closure devices that place sutures through the fascia on either side of the defect may be employed to prevent herniation. Extraction incision is closed using standard surgical technique employing absorbable suture.

In the majority of patients, the gastric tube is removed at the end of the procedure. Diet is advanced when clinically indicated based on the general course of the patient postprocedurally. The Foley catheter is usually removed the morning after the procedure.

RESULTS

Table 1 presents outcomes of six series of transperitoneal laparoscopic radical nephrectomy. Tumor size and stage and perioperative parameters including blood loss and length of stay are presented.

Results of laparoscopic radical nephrectomy are similar if not better than traditional open radical nephrectomy.

As with any relatively new procedure, most authors describe a learning curve, with results improving over time. Comparative series show a trend with experience to shorter operative times and less blood loss. In addition, the indications for this procedure continue to grow as surgeons treat more complex presentations including larger tumors. Nevertheless, there is a growing enthusiasm for laparoscopic nephron-sparing surgery to treat smaller lesions.

Complications associated with laparoscopic radical nephrectomy are similar to those associated with open surgery (Table 2), including injury to adjacent organs, bleeding, infection, port site or wound herniation, peritonitis, and postoperative ileus (9,22–27).

The incidence and severity of intraperitoneal adhesions associated with transperitoneal laparoscopic surgery have been shown to be significantly less than noted after open abdominal surgery (28). However, specific vascular complications associated with the dissection and ligation of the renal vessels may occur, e.g., clip misfire during renal artery ligation due to significant atherosclerosis may lead to vessel

TABLE 1 ■ Laparoscopic Radical Nephrectomy Series

Author	No. of pts	Trans-peritoneal	Retro-peritoneal	Conversion to open (%)	Blood loss (mL)	Tumor size (cm)	Comp major	Comp minor	Specimen extraction	Postop. stay (day)	OR time (min)	Stage T1	T2	T3	T4

TABLE 2 ■ Complications Associated with Laparoscopic Radical Nephrectomy

Intraoperative bowel injury
Small bowel
Duodenum
Colon
Splenic injury
Liver injury
Vascular injury
Bleeding
Clip misfire and/or slippage
EndoGIA misfire
Abdominal wall hematoma
Intraperitoneal abscess
Peritonitis

Complications occurring during transperitoneal laparoscopic nephrectomy are slightly different compared to retroperitoneal laparoscopic nephrectomy. During dissection of the renal hilum, the renal vein, may require retraction to allow adequate visualization of the renal artery. Aggressive retraction, particularly on the left side, may lead to bleeding from venous tributaries. This is usually not an issue when employing a retroperitoneal approach.

crush injury proximal to the clips and hemorrhage. In addition, EndoGIA misfire can occur if a dense structure (i.e., fibrotic or calcified vessel, adjacent metal clip, etc.) is inadvertently caught within the jaws during engagement. Precise dissection of accessory vessels minimizes intraoperative blood loss.

The complications occurring during transperitoneal laparoscopic nephrectomy are slightly different compared to retroperitoneal laparoscopic nephrectomy. In fact, during dissection of the renal hilum, the renal vein, which is commonly anterior to the renal artery, may require retraction to allow adequate visualization of the renal artery. Aggressive retraction, particularly on the left side, may lead to bleeding from venous tributaries (including the adrenal vein). This is usually not an issue when employing a retroperitoneal approach. There is also a decreased risk of trauma to intra-abdominal organs when using the retroperitoneal approach.

SUMMARY

- Laparoscopic radical nephrectomy is standard treatment for renal cell carcinoma. The indications continue to broaden.
- The intraperitoneal approach is particularly useful for large lesions or in patients with a tumor in an ectopic or horseshoe kidney.
- Transperitoneal laparoscopic nephrectomy has a complimentary role with retroperitoneal laparoscopic nephrectomy.
- The retroperitoneal approach is preferred in patients with significant intra-abdominal scarring.

LAPAROSCOPIC RADICAL NEPHRECTOMY: RETROPERITONEAL TECHNIQUE

Howard Evans and Michael G. Hobart

Division of Urology, Department of Surgery, University of Alberta, Alberta, Canada

INTRODUCTION

During the early 1990s, pioneering work by Clayman and Gaur established the early technique and equipment that allowed retroperitoneal laparoscopy or retroperitoneoscopy to expand into extirpative surgery (Table 1). Initial problems with inadequate insufflation and dissection of the retroperitoneum were elegantly overcome by Gaur et al. with their description of atraumatic balloon dissection of the retroperitoneal space (1,11,12,14). Historically, these early reports and, similarly, the important early transperitoneal laparoscopy technical reports were all too often met with skepticism by the general urologic community.

Despite skepticism, the technique of retroperitoneal laparoscopic radical nephrectomy evolved into a standardized approach, which in turn resolved problems related to retroperitoneal landmark recognition (16).

During the intervening years, the laparoscopic radical nephrectomy has been firmly established as standard of care for renal masses not amenable to partial nephrectomy. Outcome analysis of surgical series from transperitoneal and retroperitoneal approaches has demonstrated similar intraoperative and postoperative results. Early reports of less postoperative ileus allowing earlier postoperative discharge with the retroperitoneal approach have not been consistently demonstrated in comparative analysis (2,3). Thus distinct advantages between these approaches appear indiscernible (24); however, both approaches are clearly superior to traditional open surgery (9,10).

Selection of a surgical approach should, therefore, be based on the following factors:

- Patient size
- Mass size
- Prior ipsilateral surgery
- Peritoneal dialysis
- Surgeon preference and experience

Regardless of individual surgeon preference, the retroperitoneal laparoscopic radical nephrectomy remains an important tool in the urologic armamentarium for minimally invasive surgical treatment (13,19). Ideally, it is advantageous for a laparoscopic urologic surgeon to have familiarity with both approaches.

> Despite skepticism, the technique of retroperitoneal laparoscopic radical nephrectomy evolved into a standardized approach, which resolved problems related to retroperitoneal landmark recognition.

TABLE 1 ■ Equipment List for Fetroperitoneal Laparoscopic Radical Nephrectomy

Scalpel blade—No. 15
S Retractors (*2*)
Retroperitoneal balloon dilator
Laparoscopic trocars
    Blunt-tip (10 or 12 mm) with fascial balloon (*1*)
    12-mm trocar (*1*)
    5-mm trocar (*1*)
Laparoscope—10 mm with 30° lens
Electrosurgical scissors—5 mm
Electrosurgical J or L hook—5 mm
Suction/irrigation device—5 mm
Laparoscopic right angle forceps—small (5 mm) and large (10 mm)
Laparoscopic forceps and small bowel forceps (*2*)
Laparoscopic 10-mm metal fan retractor (*1*)
Laparoscopic clip applicator (*1*) (single fire, multifire, or locking clips)
Laparoscopic Endo-GIA vascular stapler
Laparoscopic specimen bag

INDICATIONS AND CONTRAINDICATIONS

> The indications for laparoscopic retroperitoneal radical nephrectomy are similar to the indications for open radical nephrectomy, namely the presence of a renal mass not amenable to a partial nephrectomy.

The indications for laparoscopic retroperitoneal radical nephrectomy are similar to the indications for open radical nephrectomy, namely the presence of a renal mass not amenable to a partial nephrectomy.

In comparison to the transperitoneal approach, the retroperitoneal approach has some potential relative advantages and indications. These advantages include the following: (i) patients on peritoneal dialysis, who can continue peritoneal dialysis uninterrupted after the retroperitoneal approach and (ii) patients with extensive prior ipsilateral surgery in the quadrant of interest, which may result in problematic intra-abdominal peritoneal adhesions.

Contraindication of Laparoscopic Retroperitoneal Radical Nephrectomy

- Presence of a tumor thrombus
- Excessively large masses
- Inadequate cardiopulmonary reserve to tolerate CO_2 insufflation
- Bleeding diathesis

Although renal vein tumor thrombi have been successfully removed by a laparoscopic retroperitoneal approach, they should be approached with caution. The presence of an inferior vena cava tumor thrombus remains a firm contraindication. Renal masses larger then 10 cm are increasingly difficult to remove by the retroperitoneal technique. While there is no absolute size limitation, a mass larger than 10 cm should also be approached with caution.

PREOPERATIVE PREPARATION

> Full flexion of the operating table with elevation of the kidney bar helps to optimize the space between the iliac crest and the lower ribs.

A standard renal cell cancer metastatic workup is performed. Prior to surgery, the patient is assessed for surgical risk with a history and physical examination, routine blood work, and an electrocardiogram. Informed consent is then obtained. Bowel preparation is optional but no longer routinely necessary. Preoperative prophylactic antibiotics are administered and pneumatic compression stockings are utilized for deep vein thrombosis prevention. Foley catheters are routinely used while nasogastric tubes are not (Table 1).

PROCEDURE

> Although not essential, it is helpful to landmark the external surface anatomy with an operating room marking pen on the patient's abdomen.

Step 1: Patient Positioning

After establishing general anesthesia with endotracheal intubation and appropriate lines and monitoring devices, a Foley catheter is placed and pneumatic thromboembolic

FIGURE 1 ■ Patient is placed in the full flank position. Padding is placed under all pressure points. Patient is flexed and the kidney bar is raised to maximize the space between the lower ribs and the iliac crest. The patient is secured to the bed with three strips of tape placed circumferentially around the patient and table in the indicated positions. The primary camera port is placed at the tip of the 12th rib. The two working ports are placed at the angle of the 12th rib and psoas/paraspinal muscles and 3 cm above the iliac crest in the mid-axillary line.

FIGURE 2 ■ Optimized operating room configuration and surgical team positions for a right-sided retroperitoneal laparoscopic nephrectomy.

Occasionally, particularly in younger patients, the thoracolumbar fascia is too dense to be pierced with a fingertip. A hemostat is then employed to enter the retroperitoneal space.

Precise dissection between the psoas muscle and the posterior aspect of Gerota's fascia is critical. Failure to do so will adversely affect retroperitoneal balloon dilation.

Blind placement of the Verses needle can result in insufflation of retroperitoneal musculature or accidental pneumoperitoneum. The open Hasson technique is faster and safer and considered the preferred technique.

deterrent stockings are applied. The patient is then placed in the full flank position with the pathologic side up.

Full flexion of the operating table with elevation of the kidney bar helps to optimize the space between the iliac crest and the lower ribs.

Protective gel or foam padding is applied to all pressure points, the weight-bearing axilla is protected with an axillary role and the limbs are positioned in an ergonomically acceptable position. The patient is then secured to the operative table with circumferential 3-in. surgical tape at the chest/shoulder, hip, and lower leg (Fig. 1). Alternatively, a surgical bed "bean bag," such as the Olympic Vac Pac, can be used to secure the patient to the operating table.

Although not essential, it is helpful to landmark the external surface anatomy with an operating room marking pen on the patient's abdomen highlighting the following:

- Both tips of 11th and 12th ribs
- The psoas muscle
- The edge of iliac crest
- Sites for trocar placement

The operating room and surgical team are position in the manner shown in Figure 2. A Mayo stand is positioned at the foot of the bed so that the nurse can organize equipment. The surgeon and assistant are positioned on the posterior or backside of the patient. The scrub nurse stands at the foot of the bed on the other side or abdominal side. Display monitors are positioned on either side of the patient. To minimize the clutter of tubes and equipment, it is helpful to organize the cautery cords, insufflation tubing, camera, and suction and irrigation tubing so that all tubes and cords pass off away from the surgeon and are clamped under one edge of the pocket drape on the patient's abdomen.

Step 2: Retroperitoneal Access

Access to the retroperitoneum is obtained using an open technique. A 1-1.5- cm incision is made in the skin just below the tip of the 12th rib. The muscle fibers below the fascia are bluntly separated with S-retractors until the thoracolumbar fascia is identified, which is then bluntly entered with a fingertip (18,25).

Occasionally, particularly in younger patients, the thoracolumbar fascia is too dense to be pierced with a fingertip. In such an instance, a hemostat is employed to enter the retroperitoneal space.

After entering the retroperitoneal space, blunt finger dissection is used to initially develop and expand the potential space (Fig. 3). The dissection proceeds anterior to the psoas muscle and posterior to Gerota's fascia until sufficient space has been created to allow for further mechanical expansion of the space.

Precise dissection between the psoas muscle and the posterior aspect of Gerota's fascia is critical. In fact, failure to do so will adversely affect retroperitoneal balloon dilation.

Alternatively, access to the retroperitoneum can be obtained using a closed technique with a Veress needle (4,5). The Veress needle is inserted into Petit's inferior lumbar triangle. CO_2 insufflation creates a pneumoretroperitoneum, which allows blind insertion of the primary trocar.

The blind placement of the Verses needle can occasionally result in insufflation of retroperitoneal musculature such as the quadratus lumborum or too deep placement of the needle, resulting in accidental pneumoperitoneum. For these reasons, the open Hasson technique for retroperitoneal access is faster and safer and considered the preferred technique.

Step 3: Balloon Dilation of the Retroperitoneal Space

Further dissection and expansion of the retroperitoneal space is accomplished using blunt camera dissection or by using a retroperitoneal balloon (20,21,26). The working space in the retroperitoneum can be created with blunt camera dissection between Gerota's fascia and the psoas muscle (6). While this technique obviates the need for additional potentially expensive equipment, it is hampered by the need for frequent cleaning of the camera lens and limited by the small space.

Utilization of a retroperitoneal balloon dilator to dissect the retroperitoneal connective tissue is a more efficacious and precise technique to quickly establish the working space in the retroperitoneum.

Gaur et al. originally described balloon dissection with a self-fashioned balloon created from a red rubber catheter and a glove finger secured to the catheter with a suture (1,15). Although economical, self-fashioned balloons are hampered by imprecise placement of the balloon because of flexibility of the catheter and the potential for rupture of the finger balloon with resultant radiolucent foreign material being deposited into the patient. For these reasons, commercial retroperitoneal balloon dilators commonly used for dilation of the retroperitoneum are the Pre-Peritoneal Distention Balloon[a] and the Spacemaker[b] (Fig. 4). The retroperitoneal balloon is placed into the retroperitoneal space at an oblique cephalad orientation. The balloon should be positioned anterior to the psoas muscle and posterior to Gerota's fascia in the space previously created by the blunt finger dissection (16,17).

Failure to position the balloon between the psoas and Gerota's fascia will result in dissection between the peritoneum and the anterior surface of Gerota's fascia, leaving the kidney in a posterior orientation adherent to the psoas muscle.

With proper balloon placement, the balloon dissection mobilizes the kidney and Gerota's fascia anteromedially, allowing posterior access to the renal helium (Fig. 5). For an average-sized adult, the balloon is then inflated to 800 cc. Confirmation of balloon position within the retroperitoneum and the adequacy of the dissection are assessed by passing a laparoscope down the transparent balloon sheath (Fig. 4). Progressive sequential balloon dilation is performed in either the upper retroperitoneum to facilitate large upper pole tumor dissection or down toward the pelvis to facilitate dissection of the ureter as part of a nephroureterectomy.

Finger dissection and the balloon dilation in the proper surgical plane will allow the gas pressure obtained with the insufflation of the retroperitoneum to hold the kidney away from the surgeon, thus maintaining the working space and providing exposure to the renal hilum.

Step 4: Port Placement

The primary port or camera port is placed at the site of balloon dilator. While a reusable 10-mm Hasson type port secured with sutures can be used, nonsealing ports of this type will be problematic because of CO_2 leakage and CO_2 subcutaneous emphysema. As such, it is preferable to use a port with a sealing mechanism such as the 10- or 12-mm blunt-tip port (Fig. 6), which creates an airtight seal between an internal fascial balloon and a external foam ring. Pneumoretroperitoneum is then established with 15 mm Hg pressure of CO_2. Typically, only two other secondary ports are required.

> A retroperitoneal balloon dilator to dissect the retroperitoneal connective tissue is a more efficacious and precise technique to establish working space in the retroperitoneum.

> Failure to position the balloon between the psoas and Gerota's fascia will result in dissection between the peritoneum and the anterior surface of Gerota's fascia, leaving the kidney in a posterior orientation adherent to the psoas muscle.

> Finger dissection and balloon dilation in the proper surgical plane allows the gas pressure obtained with insufflation of the retroperitoneum to hold the kidney away from the surgeon, maintaining the working space and providing exposure to the renal hilum.

FIGURE 3 ■ At the tip of the 12th rib, access is gained to the retroperitoneum by bluntly piercing the thoracolumbar fascia. Finger dissection is then performed to establish the posterior plane between Gerota's fascia and the psoas muscle, while also mobilizing the peritoneum anteromedially away from the kidney.

FIGURE 4 ■ Balloon dissector used for retroperitoneal dissection and creation of retroperitoneal space.

Optimization of the positions for secondary ports is important due to the limited working space and potential for "clashing" of instruments.

Optimization of the positions for secondary ports is important due to the limited working space and potential for "clashing" of instruments. The secondary ports are placed under either direct vision or under bimanual control. One port is placed posterior at the inner angle of the 12th rib and the paraspinal muscles. An anterior port is placed approximately 3 cm superior to the iliac crest between the anterior and mid axillary line (Fig. 1). Placement of this port too close to the iliac crest will impede surgical dissection.

The secondary ports can be 5, 10, or 12 mm, disposable or reusable, depending on the clinical scenario.

A larger 12-mm port is placed on the ipsilateral side as the surgeon's dominant hand for clip application and vascular stapler application, and a smaller 5-mm port on the side of the surgeon's nondominant hand for retraction.

Step 5: Dissection and Ligation of the Renal Hilum

In comparison to the transperitoneal approach, the retroperitoneal approach allows the surgeon to achieve rapid and straightforward access to the renal hilum. The psoas is the most important early landmark to facilitate dissection.

Surgical orientation is achieved by orientating the psoas muscle in the horizontal plane, allowing the renal vessels to be orientated vertically.

Surgical orientation is achieved by orientating the psoas muscle in the horizontal plane, allowing the renal vessels to be orientated vertically.

After orienting the psoas muscle, the surgeon then looks for other surgical landmarks including: (i) the renal outline (easily appreciated), (ii) pulsations from the aorta or inferior vena cava, and (iii) the ureter (seen inferior to the kidney and medial to the psoas). Access to the renal hilum is initiated by dissecting in the fascial plane between the anteromedial aspect of the psoas muscle and posterior/inferior aspect of the kidney. The dissection is aided by the application of countertraction to the middle of the kidney with atraumatic laparoscopic forceps in the surgeon's nondominant hand. Dissection is accomplished with cautery or harmonic scalpel.

Dissection is performed one layer at a time, checking for the monophasic pulsations of the renal artery. The monophasic pulsations are in contradistinction to the biphasic pulsations seen from the inferior vena cava.

Dissection is performed one layer at a time, checking for the monophasic pulsations of the renal artery. The monophasic pulsations are in contradistinction to the biphasic pulsations seen from the inferior vena cava.

Once the artery is identified, it is mobilized by placing a right-angled instrument circumferentially around it. Branches of the renal artery are encountered if the dissection in the renal hilum occurs more distally. The artery is occluded with clips: three are placed on the aortic side and two on the kidney side, after which the artery is divided. The renal vein is identified anterior to the artery. Similarly, the vein is exposed with careful dissection until a right-angled instrument can be placed around it, giving enough exposure to accommodate an endo-GIA vascular stapler. The stapler is used to both occlude and ligate the vein (Fig. 7).

■ When performing a left-sided nephrectomy, the adrenal, gonadal, and lumber vein branches may also need to be clipped and divided.
■ When performing a right-sided nephrectomy, great care in the vein dissection is required to ensure that the vein dissected is the renal vein and not the inferior vena cava, which on occasion can have the appearance of the renal vein.

FIGURE 5 ■ Retroperitoneal working space is created with balloon dissection through the primary port site.

FIGURE 6 ■ The blunt port with internal fascial balloon and an external sponge cuff. The balloon and sponge cuff create an airtight seal, thus minimizing CO_2 leakage and subcutaneous emphysema.

The surgeon is more likely to mistake the inferior vena cava for the renal vein if the dissection is too posterior.

Step 6: Mobilization of the Kidney

After the renal hilum dissection has been completed, the kidney is sequentially mobilized using blunt and sharp dissection.

Dissection is initiated at the upper pole. The surgeon will then need to decide whether the adrenal will be spared or removed en bloc with the kidney. While established oncologic principles need to be adhered to, it is often easier to remove the left adrenal en bloc with the kidney because of the adrenal vein drainage into the already divided renal vein.

On the right side, additional dissection is required to expose and allow ligation and division of the right adrenal vein as it enters the inferior vena cava. Regardless, meticulous hemostasis with electrocautery is advisable. Inferiorly, the mobilization is performed with cautery and blunt dissection along the psoas muscle. The dissection is taken up to the diaphragm.

Separating the anterior aspect of Gerota's fascia from the peritoneum without creating a hole in the peritoneum requires care and meticulous dissection.

An incidental peritoneotomy will greatly increase the difficulty of further dissection because the hole allows normalization of the pressure gradient between the peritoneum and the retroperitoneum. As a consequence, the surgically created working space in the retroperitoneum will collapse. The 10-mm fan retractor is a useful instrument to facilitate blunt dissection and mobilization. Once the upper pole is mobilized, attention is turned to the inferior pole. The ureter is easily identified on the psoas muscle. The ureter is mobilized and clipped superiorly and inferiorly and then divided. The gonadal vein is seen with the ureter and is doubly clipped and ligated. The lower pole mobilization is then completed using the psoas muscle as the margin of mobilization. Dissection proceeds until the kidney is completely mobilized.

Step 7: Entrapment and Removal of Specimen

Entrapment of the specimen within a bag for specimen removal is a technically challenging procedure. While bags without a delivery system such as the Lap Sac[c] can be used, the relatively small space of the retroperitoneum combined with the limited port sites results in the entrapment procedure escalating an order of magnitude in difficulty compared to bags with a delivery system. The Endocatch I and Endocatch II bags[d], with their butterfly net type delivery hoop, aid in entrapment as the metal delivery ring holds open the plastic bag, allowing the specimen to be flipped into the open bag (Fig. 8).

In some instances, particularly when the specimen is very large, entrapment is facilitated by creating an intentional anterior peritoneotomy. The specimen is then negotiated into the larger space of the peritoneal cavity, resulting in easier entrapment.

After entrapment, the specimen is removed intact. The choice of the location for the specimen extraction incision is influenced by the size of the specimen, size of the patient, prior surgical history, and sex of the patient. Options include (i) enlargement of the primary camera port, (ii) a small posterior dorsolumbotomy incision, (iii) a Pfannenstiel incision, or, in a female, (iv) a vaginal extraction (7).

Step 8: Hemostasis and Closure

After removal of the kidney, careful inspection of the renal fossa at atmospheric pressure is necessary to ensure hemostasis. Once hemostasis is assured, the extraction incision is closed in layers. Ports 10 mm or larger are also closed with facial suture.

TECHNICAL CAVEATS AND TIPS

After access to the retroperitoneum has been achieved, precise finger dissection is critical to establish the proper surgical plane between the posterior reflection of Gerota's fascia and the anterior psoas muscle fascia.

---

[c]Cook, Bloomington, IN.
[d]Ethicon, Somerville, NJ.

FIGURE 7 ■ Division of the vascular pedicle. The renal artery has been ligated and divided with clips and the vascular stapler is positioned across the renal vein.

FIGURE 8 ■ Specimen is entrapped in the extraction bag with delivery ring to hold open the bag. This is accomplished by a scoop-and-roll technique.

Failure to accurately initiate this surgical plane will complicate balloon dissection of the retroperitoneum by allowing the balloon dissection to occur anteriorly between peritoneum and Gerota's fascia. When finger dissection and balloon dissection occur in the proper plane, the kidney will be mobilized and rotated anteriorly, and later insufflation of the retroperitoneum will hold the kidney in this position. Surgeons with limited experience in retroperitoneoscopy may find it beneficial to mark out external landmarks (tip of the 11th and 12th ribs, anterior margin of the psoas muscle, and the iliac crest) and to use bimanual palpation of both the posterior abdominal wall and the kidney anteriorly to help establish the proper surgical plane for finger dissection.

Because the working space in the retroperitoneum is small, optimal placement of the secondary working ports is also critical.

Because the working space in the retroperitoneum is small, optimal placement of the secondary working ports is also critical.

The posterior port needs to be placed approximately 1.5 cm inferior to the 12th rib and approximately 1.5 cm above the psoas/paraspinal muscles. If the port is placed too close to either of these structures, it will limit mobility of the laparoscopic instruments. Likewise, if the anterior working port is placed too close to the iliac crest, it will also have limited mobility. The anterior port should be placed approximately 3 cm above the iliac crest in the midaxillary line. If the anterior port is placed too far anteriorly without adequate prior finger dissection and mobilization of the peritoneum, the port may puncture the peritoneum.

Dissection of the renal hilum is aided by observing vascular pulsations.

Dissection of the renal hilum is aided by observing vascular pulsations.

Arterial pulsations are characteristically monophasic while venous pulsation or the pulsation of the inferior vena cava is typically biphasic. If the dissection occurs more distally into the renal hilum, multiple branches of the bifurcated renal artery are encountered, necessitating either more proximal dissection or clip occluding the branches individually. After clipping and dividing the renal artery, the renal vein should be collapsed. Failure of the vein to collapse may indicate addition renal arteries. Confirmation of additional renal arteries can be assessed by temporarily occluding the renal vein by passing a large right-angled dissector across the vein like a vascular Satinsky clamp.

Renal mobilization is accomplished by using a combination of sharp, blunt, and electrocautery dissection.

Renal mobilization is accomplished by using a combination of sharp, blunt, and electrocautery dissection.

A 10-mm fan retractor opened slightly is a useful instrument to facilitate renal dissection and mobilization. Anterior dissection should be performed with precision and care so that a peritoneotomy is avoided. If an incidental peritoneotomy is made, the potential space in the retroperitoneum will collapse because of equalization of the pressure gradient across the peritoneum and retroperitoneum. In such an instance, further mobilization of the kidney will be difficult and tedious but may be aided by the insertion of a third working port to help hold back the peritoneum. Electrocautery applied to anterior structures should be used cautiously so as to avoid potential bowel injury.

With the laparoscope positioned looking down on the kidney and the extraction bag, entrapment is aided by lifting the kidney with the surgeon's nondominant hand so the bag can be deployed with the delivery ring under the kidney. Alternatively, if the specimen is large, entrapment is aided by creating an intentional peritoneotomy and entrapping the kidney in the peritoneal cavity.

SPECIFIC MEASURES TAKEN TO AVOID COMPLICATIONS

Possible complications from a retroperitoneal laparoscopic radical nephrectomy are subdivided into: (i) complications related to retroperitoneal access and insufflation, (ii) complications related to the renal hilar dissection, and (iii) complications related to renal mobilization (22).

Complications Related to Retroperitoneal Access and Insufflation

The creation of an incidental peritoneotomy may occur during initial access to the retroperitoneum or during overzealous balloon dilation.

If a hole in the peritoneum occurs early in the procedure, the surgeon may elect to convert the procedure to a transperitoneal approach.

Prevention of a peritoneotomy is achieved by careful finger dissection, avoiding overinflation of the dissection balloon, and identification of retroperitoneal landmarks. Another potential complication in this category is subcutaneous emphysema and complications related to extension of CO_2 gas through the tissues. On occasions, the CO_2 gas can tract extensively into the tissues, resulting in potential pneumomediastinum, pneumothorax, or extension of the gas into the tissue around the upper airway.

The most efficacious way to prevent extension of CO_2 gas through the tissues is to limit CO_2 gas insufflation to 12–15 mm Hg pressure, and with the use of a primary camera port with a mechanism to create an airright seal between the retroperitoneum and the patient's external skin such as the blunt-tip port with its internal fascial balloon (Fig. 6).

Another mechanism that could result in a pneumothorax is during placement of the posterior port below the 12th rib. If the port is placed too close to the rib, the lower reflection of the pleura could be punctured by the port.

Placement of the posterior port 1.5 cm below the 12th rib and 4.5 cm above the psoas will result in safe port placement.

Complications Related to the Renal Hilar Dissection

Renal hilar complications can occur from bleeding, CO_2 gas embolus, or misidentification of the vascular structures Meraney et al. in 2002 (8). Reported an incidence of vascular complications of 1.7%.

Bleeding from the renal hilum is avoided by meticulous dissection with circumferential control and isolation of the vessels prior to applying clips or the vascular Endo-GIA™[e] stapler.

The use of metal surgical clips to correct surgical bleeding should be done judiciously so that clip placement does not interfere with later division of the renal vein with the Endo GIA vascular stapler. Clips caught in the jaws of the stapler will prevent firing of the stapler.

If a hole is made in the renal vein and the insufflation pressure within the retroperitoneum exceeds the venous pressure, CO_2 embolization through the hole is possible. Prompt recognition of the injury is necessary so that the problem can be safely corrected. The vein should be compressed with an atraumatic forceps or alternatively compressed with a forceps padded with absorbable Surgicel[e] after which the vein is sealed and divided with an endo-GIA vascular stapler.

Vascular structures that may be confused for renal vessels include the inferior vena cava on the right side, which can, on occasion, have the appearance of the right renal vein, and the superior mesenteric artery, which potentially could be confused on the left side with the renal artery. Complications to these vessels are avoided by correctly identifying these vessels as nonrenal vessels by observing the vessels not entering the renal hilum.

Complications Related to Renal Mobilization

Finally, complications may occur during mobilization of the kidney. During mobilization, there exists the potential to damage structures around the kidney. The risk, however, is small (8). Such structures include the colon, the duodenum, the pancreas, the small bowel, the major vascular structures, the spleen, and the liver.

Injury to surrounding structures is avoided by maintaining surgical orientation, recognition of retroperitoneal landmarks, and meticulous dissection.

Bleeding from the renal hilum is avoided by meticulous dissection with circumferential control and isolation of the vessels prior to applying clips or the vascular Endo-GIA stapler.

If a hole is made in the renal vein and the insufflation pressure within the retroperitoneum exceeds the venous pressure, CO_2 embolization through the hole is possible. The vein should be compressed with an atraumatic forceps or alternatively compressed with a forceps padded with absorbable Surgicel after which the vein is sealed and divided with an Endo-GIA vascular stapler.

Injury to surrounding structures is avoided by maintaining surgical orientation, recognition of retroperitoneal landmarks, and meticulous dissection.

SUMMARY

■ Despite the skepticism, the technique of retroperitoneal laparoscopic radical nephrectomy evolved into a standardized approach.

■ The indications for laparoscopic retroperitoneal radical nephrectomy are similar to the indications for open radical nephrectomy.

■ Precise dissection between the psoas muscle and the posterior aspect of Gerota's fascia is critical. In fact, failure to do so will adversely affect retroperitoneal balloon dilation.

■ Because the working space in the retroperitoneum is small, optimal placement of the secondary working ports is also critical.

■ Placement of the posterior port 1.5 cm below the 12th rib and 1.5 cm above the psoas will result in safe port placement.

■ If a hole in the peritoneum occurs early in the procedure, the surgeon may elect to convert the procedure to a transperitoneal approach.

■ The most efficacious way to prevent extension of CO_2 gas through the tissue is to limit CO_2 gas insufflation to 12–15 mm Hg pressure.

■ Bleeding from the renal hilum is avoided by meticulous dissection with circumferential control and isolation of the vessels prior to applying clips or the vascular endo-GIA stapler.

■ Injury to surrounding structures is avoided by maintaining surgical orientation, recognition of retroperitoneal landmarks, and meticulous dissection.

INTRODUCTION

The first laparoscopic nephrectomy was successfully performed in an 85-year-old woman with a 3-cm solid renal mass at Washington University, St. Louis, Missouri in 1990 (1). Five ports and 6 hours and 45 minutes later, the specimen was removed by morcellation. Oncocytoma was the final diagnosis. Since this pioneering work, the urologic community has accepted laparoscopic radical nephrectomy as a viable surgical option for renal cell carcinoma. The technique itself has evolved into three categories based on surgical approaches including (i) the pure transperitoneal laparoscopic procedure, (ii) the hand-assisted laparoscopic procedure, and (iii) the retroperitoneal procedure.

SURGICAL APPROACHES

The comparison of standard transperitoneal laparoscopy, hand-assisted laparoscopy, and retroperitoneoscopy is shown in Table 1. Overall, the three approaches do not have any significant difference in estimated blood loss, complication rate, amount of analgesic used, length of hospital stay, and time for convalescence (2–5).

Transperitoneal Laparoscopic Radical Nephrectomy

The transperitoneal approach is the most widely used technique because it optimizes movements of instruments by offering a wide working space and providing maximum distance between working ports. Another potential advantage of the transperitoneal laparoscopic radical nephrectomy is that the procedure can easily be converted to a hand-assisted approach in difficult cases.

The advantages of the transperitoneal approach are most obvious in standard laparoscopic cases where a large specimen is entrapped and morcellated prior to removal to minimize the length of incision.

The main disadvantage of the standard transperitoneal laparoscopic radical nephrectomy is the nearly one hour longer operative time compared to the retroperitoneal and hand-assisted approaches (6).

In circumstances where the plan is to remove the specimen intact, some authors have advocated the use of either a hand-assisted transperitoneal or a retroperitoneal approach. Specimen entrapment, with the latter approach, is more difficult.

> The transperitoneal approach is the most widely used technique: It optimizes movements of instruments by offering a wide working space and maximum distance between working ports. The procedure can easily be converted to a hand-assisted approach in difficult cases.

> The main disadvantage of the standard transperitoneal laparoscopic radical nephrectomy is the additional hour in operative time compared to the retroperitoneal and hand-assisted approaches.

Hand-Assisted Laparoscopic Radical Nephrectomy

In hand-assisted laparoscopic radical nephrectomy, a 7–8 cm incision is usually required to accommodate the surgeon's nondominant hand.

TABLE 1 ■ Operative Results of Transperitoneal Laparoscopy, Hand-Assisted Transperitoneal Laparoscopy, and Retroperitoneoscopy for Nephrectomy in Patients with Renal Cell Cancer

[c]Ref. 4.
[d]Ref. 5.
Abbreviation: OR, operating room.

Some authors have advocated the use of hand-assist devices because they can act as a bridge between open and purely laparoscopic surgery; to wit, in most circumstances, hand-assisted laparoscopic radical nephrectomy has reduced operating room time when compared to standard or, in some series, even retroperitoneal laparoscopic approaches (2,6,7).

Major disadvantages of the hand-assisted approach include difficult placements of working ports in small patients, hand fatigue, larger incisional scar, and increased rate of wound complications (8,9). Nevertheless, when compared to the standard laparoscopic approach, the use of the larger incision for the hand port did not translate into meaningful increases in the postoperative convalescence time (3,6,7,10). There are six types of commercially available hand ports at the present time. Although each device has its own merits, no clear pattern of preference was seen among laparoscopists (11). In general, we recommend a device that is self-coapting (e.g., LapDisc[a] or GelPort[b]), because this allows the surgeon to use either hand, eliminates the use of cuffs or sleeves, and provides rapid entry and exit.

Retroperitoneoscopic Radical Nephrectomy

The retroperitoneoscopic radical nephrectomy avoids the need to mobilize the colon and the surrounding organs in gaining access to the kidney while the renal artery is encountered early during the procedure.

Although hospital stay and convalescence are similar, operative times have been reported to be faster than the standard transperitoneal approach by as much as 30% (12). In patients who need peritoneal dialysis or have a history of multiple abdominal procedures, retroperitoneal radical nephrectomy is the surgical approach of choice.

The main disadvantage of the retroperitoneal approach is the small working space that largely precludes specimen entrapment and morcellation. As a result, the specimen is removed either transvaginally or with a muscle splitting flank or a Pfannenstiel incision (13,14). Also, most of these specimens are removed without first being entrapped in an impermeable sack; this practice risks possible wound contamination because the specimen is manipulated and pulled through a "tight" skin incision (15).

INTRAOPERATIVE AND PERIOPERATIVE RESULTS

In the world's literature, over 640 laparoscopic radical nephrectomies have been reported to date. The standard transperitoneal approach is the most commonly used technique, followed by hand-assisted, and lastly the retroperitoneoscopic method. Among the studies that have analyzed the operative results of laparoscopic radical nephrectomy (16–25),

[d]177 transperitoneal and 18 retroperitoneal laparoscopic radical nephrectomies.
[e]All retroperitoneal laparoscopic radical nephrectomies.
[f]15 transperitoneal, 18 hand-assisted laparoscopic radical nephrectomies.
[g]Conversion done electively for tumor extension into renal hilum.
Abbreviation: OR, operating room.

Overall, it takes longer to complete laparoscopic radical nephrectomy than open radical nephrectomy. However, laparoscopy groups tended to have smaller estimated blood loss, shorter length of hospital stay, and lower amount of analgesic use.

There are cosmetic advantages to laparoscopy; it was recently reported that a flank bulge following a standard flank incision was detected in almost 50% of patients.

Laparoscopy does not compromise oncologic outcome as long as the principles of surgical oncology are strictly followed.

Table 2 summarizes the six studies that compared the results of laparoscopic radical nephrectomy with those of contemporary series of open radical nephrectomy.

Overall, it takes longer to complete laparoscopic radical nephrectomy than open radical nephrectomy. However, laparoscopy groups tended to have smaller estimated blood loss, shorter length of hospital stay, and lower amount of analgesic use.

The time to convalescence for laparoscopy ranged from 23 to 25 days whereas that of the open procedure ranged from 57 to 59 days. The conversion rate to an open procedure was 1.5% to 3.6%.

The cosmetic advantage of laparoscopy is also evident as it was recently reported that a flank bulge following a standard flank incision was detected in almost 50% of patients (26).

ONCOLOGIC OUTCOME

The long-term follow-up data have clearly demonstrated that the results of laparoscopic and open retroperitoneoscopic radical nephrectomy are comparable (Table 3). The largest series to date was published by Saika et al. and showed that the five-year disease-specific survival was 94% in 195 patients treated with either a transperitoneal or a retroperitoneal laparoscopic radical nephrectomy for pathologic T1 renal cell carcinoma (19). Portis et al. (17) and Chan et al. (18) reported the five-year cancer-specific survival to be 98% and 86%, respectively, in smaller studies. The five-year disease-specific survival rate in two contemporary studies that examined the oncologic outcome after the traditional open nephrectomy for T1 renal cell carcinoma was 83% and 94% (27,28).

Laparoscopy does not compromise oncologic outcome as long as the principles of surgical oncology are strictly followed.

TABLE 3 ■ Comparison of Contemporary Oncological Outcome Data after Laparoscopic vs. Open Radical Nephrectomy

Authors	Approach	Patients	Mean follow-up (mo)	Stage	5-yr cancer-specific survival (%)
Chan et al. (18)	Lap	67	35.6	T1,T2	86
Portis et al. (17)	Lap	64	54	T1,T2	98
Saika et al. (19)	Lap	188	40	T1	94
Javidan et al. (27)	Open	205	–	T1	95
Tsui et al. (28)	Open	227	47	T1	83

In the literature, there are four cases of port-site seeding that have been reported after a laparoscopic radical nephrectomy for renal cell carcinoma; three cases involve morcellation of specimens and one case involves a recurrence at a hand-port site. In 2000, Fentie et al. reported the first recurrence in which the patient had a large Fuhrman grade IV/IV tumor, with sarcomatoid features (29); the specimen was entrapped and morcellated in a LapSac[c]. The authors noted that there was no leakage of contents from the sack during the fragmentation procedure. Castilho et al. reported the second case in 2001 (30). In this case, the surgical team used a plastic entrapment device for intra-abdominal morcellation of a Grade II, T1 renal cell cancer in a patient with ascites. These same authors also reported the third occurrence in a letter to the editor, again in a Grade II, T1 patient (31). These last two cases demonstrate the dangers of morcellation in patients with ascites and of intra-abdominal morcellation in non-nylon re-enforced plastic sack. It is noteworthy that there has been not a single case of seeding noted in the Johns Hopkins, Washington University, or University of Nagoya experience despite over a decade of laparoscopic radical nephrectomy at all three institutions in more than 300 patients among whom the majority had the specimen entrapped and morcellated.

Recommendations to minimize the risk of tumor seeding and spillage during the morcellation process (32) follow:

- Only a LapSac should be used, specifically for intra-abdominal morcellation, because it is constructed of a double layer of plastic and nondistensible nylon that is impermeable to bacteria and cells (33).
- Morcellation should not be used if the patient has ascites.
- The surgical team must be vigilant in monitoring the pneumoperitoneum and LapSac during morcellation; the entire process must be done under endoscopic control and any leakage seen from the sack should prompt immediate enlargement of the incision and intact removal.
- The neck of the sack should be triply draped.
- After morcellation, the surgeon and the assistant should change gloves and gowns and remove the three drapes that came into contact with the neck of the sack.
- The site of morcellation can be swabbed with Betadine after removal of the LapSac.

The lone case of hand-port site metastasis occurred in a patient with a 10×7 cm pT2 Fuhrman grade 3 renal cell carcinoma where the surgical team extracted the specimen without entrapment through an 8-cm midline incision (15). This report shows the potential danger of extracting unentrapped specimens. Indeed, in the editorial comment immediately following the aforementioned report, Nakada suggested that an entrapment sack be used to extract all tumor-bearing specimens after hand-assisted laparoscopic radical nephrectomies (34).

COMPLICATIONS

At the beginning of the surgery, the surgical team must be prepared for the possibility that an emergent open conversion may be necessary at any point during the procedure. Therefore, a general laparotomy set with vascular clamps must be available during the entire operation. Complications associated with laparoscopic radical nephrectomy may be divided into three categories: access related, intraoperative, and postoperative. As with any surgical technique, laparoscopic radical nephrectomy is associated with a significant learning curve. In a multi-institutional review involving 185 patients, it was noted that 71% of complications occurred during the initial 20 cases at each institution (35).

The rate of major complications following laparoscopic nephrectomy has ranged from 3.3% to 15% (Table 4) (12,16,18,21,36–39).

In the largest series, Siqueira et al. reported on the experience at Indiana University with 213 standard transperitoneal laparoscopic nephrectomy cases; of these, there were 61 radical nephrectomies, 81 live donor nephrectomies, 55 simple nephrectomies, and 13 nephroureterectomies (36). In this study, the major complication rate was 7.5% and the open conversion rate was 6%. Access-related complications included abdominal wall hematoma and liver injury in one and two patients, respectively, while intraoperative complications occurred in 11 patients. Intraoperative complications were composed of uncontrollable bleeding, injuries to spleen, injuries to bowel, and failed entrapment in seven, one, two, and one patient(s), respectively. Open conversion was

TABLE 4 ■ Major Complication Rates after Laparoscopic Radical Nephrectomy

	Number	Procedure	Major complications (%)
Dunn et al. (16)	61	Transperitoneal	3 (10)
Chan et al. (18)	67	Transperitoneal	10 (15)
Siqueira et al. (36)	213	Transperitoneal	16 (7.5)
Wille et al. (37)	125	Transperitoneal	7 (5.6)
Shuford et al. (21)	33	Transperitoneal, hand-assisted	1 (3.3)
Patel and Leveillee (38)	60	Hand-assisted	3 (5)
Lee et al. (12)	54	Hand-assisted	7.4 (4)
Cicco et al. (39)	50	Retroperitoneal	2 (4)

performed emergently in five and electively in eight patients. Postoperatively, the authors noted one case each of a respiratory distress requiring an endotracheal intubation and a gastrointestinal bleeding secondary to an inflamed duodenal ulcer.

FUTURES

Laparoscopic radical nephrectomy is being applied in two new areas: cytoreductive surgery and tumors with renal vein and small inferior vena caval thrombi.

Walther et al. first noted that patients undergoing laparoscopic cytoreductive surgery for renal cell carcinoma came to be treated nearly 30 days earlier than patients who had traditional open procedures (40). Mosharafa et al. also reported similar findings (41).

In another area, to date, nine cases of laparoscopic treatment of patients with T3b (renal vein involvement) have been successfully undertaken; blood loss has averaged 350 cc with a 3.3-hours operative time and a 2.3-day hospital stay (42–45). Indeed Sundaram et al. have recently reported treating a small inferior venal caval thrombus laparoscopically (46).

To date, a subhepatic thrombus with cavotomy has not been done laparoscopically; but it is likely only a matter of time before this is accomplished, as laparoscopic radical nephrectomy with level II vena caval thrombectomy has been reported in an experimental porcine model (47).

> It has been noted that patients undergoing laparoscopic cytoreductive surgery for renal cell carcinoma were treated nearly 30 days earlier than patients who had traditional open procedures.

> To date, a subhepatic thrombus with cavotomy has not been done laparoscopically. It is likely only a matter of time before this is accomplished, as laparoscopic radical nephrectomy with level II vena caval thrombectomy has been reported in an experimental porcine model.

SUMMARY

- Significant progress has been made since the first case of laparoscopic nephrectomy 14 years ago.
- As demonstrated by numerous studies, laparoscopic radical nephrectomy has clearly decreased patient morbidity while duplicating the standards of the open procedure.
- The spread of laparoscopic renal surgery among many urologic surgeons has been aided by the development of hand-assisted techniques along with better modalities for achieving hemostasis (Hem-O-Lok clips, bipolar devices, harmonic shears, argon beam coagulation, etc.).
- At this time, laparoscopic radical nephrectomy has become a "new" standard surgical technique for treating patients with localized renal cell carcinoma and it is applicable to T1a (i.e., not amenable to a partial nephrectomy), all T1b, most T2 (i.e., tumor <15 cm), and T3a stages of renal cell carcinoma

COMMENTARY

R. C. Flanigan
Department of Urology, Loyola University of Chicago, Chicago, Ilinois, U.S.A.

Certainly no one should underestimate the current value of laparoscopic nephrectomy or the skill and foresight of those who developed this technique. Nor should we underestimate the potential benefits to a patient who may experience less morbidity after nephrectomy when it is accomplished laparoscopically. On the other hand, there remain several important unanswered questions regarding the use of laparoscopic nephrectomy:

1. Will it be widely available?
2. How does a clinician retain the necessary skills to perform it safely and effectively?
3. Are decisions concerning the appropriateness of nephron-sparing surgery versus laparoscopic nephrectomy being made appropriately?
4. What are the limits of laparoscopic nephrectomy; is it indicated for large or high-stage cancers?

In this excellent review, Drs. Kim and Clayman have detailed the current experience with the various laparoscopic approaches to nephrectomy. As with many other areas of emerging practices, the real problem with comparative analyses of techniques is patient selection. Comparing "contemporary" series of open and laparoscopic cases or even cases of hand-assisted versus pure laparoscopy, even when patients are "matched" for tumor size, etc., by definition excludes the thought process that caused the surgeon to select one technique over another. This being said, there does not seem to be a disadvantage in terms of cancer management of organ-confined renal cancers when laparoscopic nephrectomy is used. What are the limits of this technique? Recent experience suggests that in very experienced hands, large tumors (greater than 7 cm) can be treated with similar complication rates as that seen in smaller tumors. The real issue for the individual surgeon is to know his/her limits, i.e., patient selection is imperative.

Given the facts that (i) the average urologist currently performs one to two nephrectomies per year and (ii) urology does not have a "commonly performed" laparoscopic procedure (e.g., cholecystectomy in general surgery practice), how does a surgeon, even one who is adequately trained, maintain competency in laparoscopy nephrectomy? It seems that the only realistic answer to this problem is referral of these procedures to experienced laparoscopically trained urologists inside or outside of one's practice.

Another area of concern is the dilemma of nephron-sparing surgery versus laparoscopic total nephrectomy. To date, nephron-sparing surgery seems to provide equal oncologic value in selected patients with localized renal cancer. What are the appropriate limits of nephron-sparing surgery and is it better for the patient to undergo a laparoscopic total nephrectomy or open nephron-sparing surgery? Patient selection, based on the depth of tumor involvement of the kidney, patient age, comorbidities, etc., is the key. Again the physician's self-judgment of his/her ability to perform any procedure safely and effectively should direct the approach used.

Finally, what limits should we apply to laparoscopic nephrectomy? Recent data from institutions with a wide experience with laparoscopic nephrectomy suggests that tumors greater than 7 cm in diameter can be removed with similar safety (complication rates, blood loss, length of stay, etc.) as is seen with smaller tumors. On the other hand, when large tumors involve extension to adjacent organs, blood vessels, and/or lymphatics, laparoscopic techniques probably are not currently indicated.

In summary, although laparoscopic nephrectomy is a gold standard (along with open nephrectomy and nephron-sparing surgery) for the management of localized renal cancers, it cannot be said too often that patient selection and an honest appraisal of one's expertise with any procedure is the key to management.

The surgical approach to removal of renal tumors is, and will continue to be, a moving target, as new techniques and systemic therapies are developed. It would seem clear that the urologic community should embrace research, which will yield less invasive, more effective therapies for this disease, which kills over 10,000 Americans annually.

SMALL RENAL TUMORS: OVERVIEW AND MANAGEMENT BY ACTIVE SURVEILLANCE

Alessandro Volpe and Michael A. S. Jewett

Division of Urology, Department of Surgical Oncology, Princess Margaret Hospital and the University Health Network, University of Toronto, Toronto, Ontario, Canada

- ■ NATURAL HISTORY OF SMALL RENAL TUMORS
- ■ ACTIVE SURVEILLANCE OF SMALL RENAL TUMORS
- ■ *SUMMARY*
- ■ REFERENCES
- ■ *COMMENTARY* : Morton A. Bosniak

Malignant tumors of the kidney cause about 2% of cancer incidence and mortality in the United States. It was estimated that 31,900 new cases of kidney cancer were diagnosed in 2003 and there were 11,900 deaths (1,2).

Since 1950, there has been a 126% increase in the incidence of renal cell carcinoma in the United States (3). Between 1975 and 1995, the incidence has been increasing by 2.3% annually among white and 3.9% among black men (4). A raising trend has been observed worldwide and is due in part to the widespread use of new and improved noninvasive abdominal imaging modalities, such as ultrasonography, computed tomography, and magnetic resonance imaging (3–14). The number of abdominal radiological examinations has been increasing steadily in the last two decades and almost doubled between 1986 and 1994 (4).

The increasing incidence of renal cell carcinoma has occurred in all age groups and in all clinical stages, but the greatest increase has been observed in localized tumors, which increased by 3.7% per year from 1973 to 1998 (4,7).

Most renal cell carcinoma are now incidentally detected by imaging as small renal masses in asymptomatic patients, while historically almost 80% of renal tumors presented with flank pain and/or hematuria. In the early 1970s, the reported incidental detection rate was 7% to 13%, which has increased to 48% to 66% in the recent years (15–23). Tumor size at diagnosis has also substantially decreased over time. Series from the Memorial Sloan Kettering Cancer Center and the Mayo Clinic report that the mean size of resected renal tumors has dropped from 7.8 to 5.3 cm from 1989 to 1998, and that there was a 32% decrease in mean tumor size at the time of diagnosis, respectively (24,25).

There are numerous reports that the incidentally detected lesions are on average smaller and present at an earlier stage than those detected in symptomatic patients (7,11,13,14,16,19,20,25–32).

Tsui et al. reviewed the records of 633 consecutive patients who underwent surgical treatment for renal cell carcinoma at University of California, Los Angels between 1987 and 1998. Stage I lesions were discovered in 62.1% of patients with incidental renal cell carcinoma and 23% with symptomatic renal cell carcinoma ($p = 0.001$). Mean tumor size was 5.1 cm versus 7.3 cm in incidental versus symptomatic cases ($p < 0.05$) (14). Patard et al. evaluated a series of 400 renal tumors and observed significantly smaller neoplasms in the incidentally detected group (5.7 cm vs. 8.7 cm; $p < 0.001$) (27).

Small asymptomatic tumors are more frequently benign. If proven to be renal cell carcinomas, they are on average lower grade than symptomatic ones (11,14,19,33–35).

Frank et al. recently reviewed the pathology of 2935 renal tumors at the Mayo Clinic and observed that as tumor size decreases there is a significant increase in the likelihood of having a benign tumor, a papillary compared to a clear cell histology and a low-grade compared to a high-grade malignancy. In their experience, 30% of tumors less than 4 cm in maximum dimension were benign and over 87% of those that were clear cell renal cell carcinoma were low-grade tumors (34).

Finally, several authors reported that small incidentally detected tumors are characterized by better survival outcomes (11,14,16,21,23,27,29,33,36). The five-year disease-free survival rate is 95% to 100% for incidental, less than 4 cm tumors treated with radical or partial nephrectomy (25,26,37). The first evidence of an association between tumor size

The increasing incidence of renal cell carcinoma has occurred in all age groups and in all clinical stages, but the greatest increase has been observed in localized tumors, which increased by 3.7% per year from 1973 to 1998.

There are numerous reports that the incidentally detected lesions are on average smaller and present at an earlier stage than those detected in symptomatic patients.

Small asymptomatic tumors are more frequently benign. If proven to be renal cell carcinoma, they are on average lower grade than symptomatic ones.

and prognosis was reported by Bell, who noted an increased rate of metastasis in patients found at postmortem to have renal cell carcinoma greater than 3 cm (38,39). Tumor size has always been incorporated in the tumor node metastasis staging system. In the 1997 version, the T1 stage was expanded from less than 2.5 to less than 7 cm, because the lower cutoff value was not associated with a significant difference in survival (40). The current version defines the cutoff point at 4 cm to subdivide stage T1 into T1a and T1b (41–43). Tumor size remains the most important prognostic factor for renal cell carcinoma.

NATURAL HISTORY OF SMALL RENAL TUMORS

Small renal neoplasms are generally removed soon after diagnosis. Therefore, their natural history has been historically poorly understood.

> Small renal neoplasms are generally removed soon after diagnosis. Therefore, their natural history has been historically poorly understood.

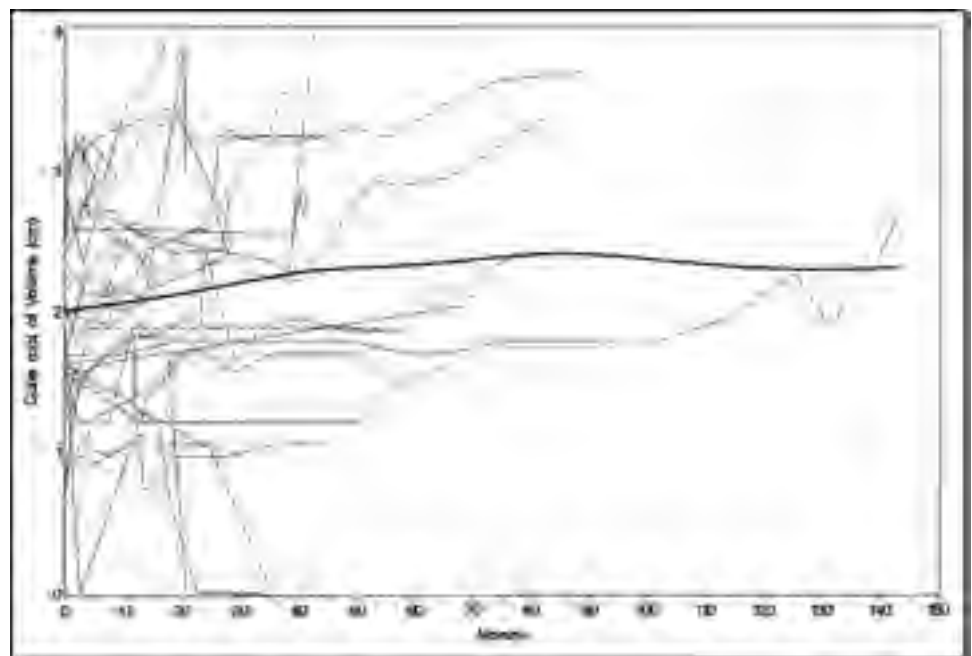
In the landmark report of surveillance of kidney tumors, Bosniak et al. retrospectively reviewed the imaging of 40 incidentally detected, less than 3.5 cm renal masses that had been followed for a mean of 3.25 years. Twenty-six tumors were eventually removed after an average of 3.8 years and 84.6% of them were histologically renal cell carcinomas. Variable tumor growth behaviors were observed and the overall mean linear growth rate was 0.36 cm/yr (0–1.1 cm/yr). Nineteen tumors grew less than 0.35 cm/yr and no patient developed metastatic disease (44–46).

More recently, 17 small renal tumors in chronic haemodialysis patients with acquired cystic kidney disease were followed for a median of 2.1 years before performing nephrectomy. The overall growth rate, reported as volume, was again variable (0.07–17.34 cm^3/yr) and significantly greater in high-grade carcinomas, while 65% of the tumors had a volume doubling time of more than a year (47).

In another retrospective study, Oda et al. observed 16 patients who were initially observed with incidentally diagnosed but histologically proven renal cell carcinoma. The tumor growth rate varied from 0.10 to 1.35 cm/yr and was significantly lower than that of metastatic renal cell carcinoma lesions observed in a second group of patients ($p = 0.016$) (48). Other authors have reported that localized primary tumors have a clinically significant lower rate of growth if compared to either primary advanced or metastatic lesions (7).

In the first prospective study of watchful waiting of renal tumors, we reported a series of 13 patients incidentally diagnosed with a small, less than 4 cm renal mass and followed expectantly because they were elderly or unfit for surgery. We hypothesized that the tumors that are destined to grow fast and possibly metastasize do so early, while most small tumors grow at a low rate or not at all (49).

More recently, we have reported the results of active surveillance of an expanded series of 32 renal masses in 29 patients (Fig. 1). Twenty-five tumors were solid and seven were complex cystic (four Bosniak III and three Bosniak IV) (50). The patients were prospectively followed with serial abdominal imaging for a mean of 27.9 months (5.3–143)

FIGURE 1 ■ Individual observed patterns of growth rate over time of 32 small renal masses managed with active surveillance. A summary curve indicating the average growth rate is superimposed (*heavy line*).


and each mass had at least three follow-up measurements. Tumor volume in addition to single and bidimensional diameters was calculated from each follow-up image or report. Nine masses in eight patients were surgically removed after an average of 38 months of follow-up because of the surgeon's concern or the patient's anxiety that the tumor was enlarging. All tumors were clear cell renal cell carcinoma except one which was an oncocytoma. The overall average growth rate, considering the cube root of the volume, was 0.1 cm/yr (not statistically significantly different from no growth; $p = 0.09$) and was not associated with either initial size ($p = 0.28$) or mass type ($p = 0.41$). Seven masses (22%) reached 4 cm in diameter after 12 to 85 months of follow-up. Eight (25%) doubled their volumes within 12 months. Overall, 11 (34%) fulfilled one of these two criteria of rapid growth. No patient progressed to metastatic disease, while two patients died of unrelated causes (51).

A similar experience has been recently reported by Kassouf et al., who serially imaged 24 patients with small renal masses. Most of the tumors did not demonstrate significant growth during the surveillance period. The mean growth rate of the five fast growing tumors was 0.49 cm/yr or 7.3 cm^3/yr. The four tumors that were removed during the follow-up were all histologically renal cell carcinoma (three clear cell and one papillary type). No metastasis was documented (52).

ACTIVE SURVEILLANCE OF SMALL RENAL TUMORS

The standard of care for small localized renal neoplasms is either radical or partial nephrectomy (53,54).

The rationale for immediate surgery is that early detection and treatment of a small tumor will lead to an improved cancer-specific prognosis.

Nephron-sparing surgery for smaller renal cell carcinomas, originally proposed for patients with a solitary kidney, impaired renal function or bilateral tumors, is becoming the standard of care as an alternative to radical nephrectomy (25,42,43,55,56). Cancer-free survival appears equivalent (25). Laparoscopic partial nephrectomy is now widely performed and is perceived to be the preferred alternative to open partial nephrectomy (57,58). Although morbidity from nephrectomy has decreased with improved techniques, it is still significant and is reported to occur in 11% to 40% of cases in recent series (25,55,59–61).

The median age at diagnosis of renal cell carcinoma is 66 years (2). More incidental tumors are detected in the elderly who are more likely to undergo radiological examinations for other medical issues. These patients frequently have significant comorbidities and have a higher risk of perioperative mortality and morbidity. With aging populations and the increased use of imaging in developed countries, it is therefore reasonable to predict that the issue of appropriate management of small renal tumors will become even more important (17,62).

The lack of a decrease in the mortality of renal cell carcinoma in the last decades, despite the significant increase in the diagnosis of localized neoplasms, may imply that a proportion of small incidentally detected tumors have an indolent behavior (7). In fact, there has been a modest increase in mortality compared to incidence of renal cell carcinoma in the United States, which may be due to a lead time bias or may indicate that many small renal tumors have a long natural history and are not destined to progress, while the ones likely to do so are probably resected too late despite their localized radiographic appearance (2–4,63).

Reports from autopsy series performed before the widespread use of imaging show that 67% to 74% of renal cell carcinoma remained undetected until death and that only 8.9% to 20% of undiagnosed renal cell carcinoma were eventually responsible for the patient's death (5,64,65). This supports the hypothesis that many incidentally detected renal tumors grow slowly. Finally, some authors report that the observation that the age at diagnosis is lower in symptomatic than in incidental cases does not support the concept of incidental tumors as inevitable preclinical phase of the symptomatic ones (14,19,64,66).

There are few reports of watchful waiting of small renal masses in the literature. Most studies are retrospective and have a small sample size, but the results are consistent and provide a better understanding of the previously unknown natural history of renal tumors.

There is important variability in the growth patterns of small renal masses. A small number of tumors grow rapidly after diagnosis, but most of them have a natural history of slow growth and are not likely to metastasize (44,48,49,51,52). In our experience, only 34% renal masses had a clinically significant growth over time (51). The association between growth rate and tumor size at diagnosis was not found to be statistically significant (48,51). It is important to note that in all the series no tumor progressed with metastases during the surveillance period.

The standard of care for small localized renal neoplasms is either radical or partial nephrectomy.

There is important variability in the growth patterns of small renal masses. A small number of tumors grow rapidly after diagnosis, but most of them have a natural history of slow growth and are not likely to metastasize.
In our experience, only 34% renal masses had a clinically significant growth over time. The association between growth rate and tumor size at diagnosis was not found to be statistically significant. It is important to note that in all the series no tumor progressed with metastases during the surveillance period.

A single or bidimensional diameter has been generally used to measure the tumor growth rate (44,48). We prefer to use tumor volume because we believe that it may better estimate the tumor cell burden. Small tumors are often spherical but may be ellipsoid, especially with increasing size. In our opinion, using three dimensions can therefore improve accuracy although error of measurement will be exponentially expressed (49,51).

In most studies, the small renal masses were radiologically consistent with renal cancer, but not all were histologically proven renal cell carcinoma. The accuracy of contemporary imaging modalities in the diagnosis of renal cell carcinoma is considered 85% to 90%, but this percentage may need to be revised downwards as recent reports suggest that the chance of benign pathology increases as the mass diameter decreases (34,67,68). Furthermore, the large majority of small renal cell carcinomas are low-grade tumors (34). This may explain why most small masses grow slowly or do not grow at all.

Based on these observations and interpretation of current data, it seems appropriate to reexamine the current practice of immediate surgery for all newly diagnosed small renal masses (19,44,45,48,49,63,66,69). In fact, many small incidentally discovered renal neoplasms may not be histologically or clinically malignant and therefore may not be an immediate threat to the patient's life. A period of initial observation with surgical treatment reserved for those tumors that exhibit fast growth, i.e. those that have rapid doubling times or whose volumes or bidimensional diameters reach a threshold demonstrated to be unsafe may be appropriate in patients who are elderly or infirm. This is the definition of active surveillance. In our study, we arbitrarily defined a fast growing mass as a mass that doubles its volume within one year and/or reaches 4 cm in maximum dimension (51). An upper limit of 3–4 cm in diameter is commonly used to identify the renal masses that are at very low risk of developing metastases and have a better survival rate (38,39,41,45,70–72). Further experience is required before we can define thresholds for treatment, but these appear to be conservative and reasonable upper limits for size and growth rate until which continued surveillance might be considered before triggering therapeutic intervention in selected patients.

Possible measurement error at imaging is a concern in the conservative management of patients with small renal tumors.

> Possible measurement error at imaging is a concern in the conservative management of patients with small renal tumors.

Several authors reported reproducible and accurate tumor volume measurements by the use of computed tomography scan and magnetic resonance imaging (73–76). A higher degree of inter- and intraobserver variability in measurements seems to occur with the use of ultrasonography (77,78). Edge detection of an irregular mass at imaging may be difficult or inaccurate, particularly when features such as cystic masses, haemorrhage, pyelonephritis, localization near or invasion of the collecting system, cysts or dilated calices adjacent to the tumor, and multiple cysts within the kidney are present (79). We have performed a study of inter- and intraobserver variability in computed tomography measurement of small renal masses and compared imaged with postoperative volumes (80). It is well known that these measurements may be different with a reduction in diameter after surgery, presumably largely due to initial ligation of the arterial blood supply with a decrease in kidney and tumor blood volume (74,81). We have demonstrated that the measurement of tumor dimension based on computed tomography and magnetic resonance imaging of the mass is an effective method of assessing tumor growth (80).

Masses with cystic components represent a special problem because there can be a significant difference between overall volume and tumor cell volume. Tumor growth rate can be easily either overestimated or underestimated if the volume of cystic fluid grows at a different rate than the tumor cell volume. Some authors observed that the prognosis for patients with cystic renal cell carcinoma is better than that for patients with solid tumors but, as the tumors were all managed by surgery, these reports do not give us information about the natural history of this type of tumor (82–85). In our experience, the complex cystic renal masses had a comparable growth rate compared to the solid ones ($p = 0.41$) (51).

SUMMARY

- In the absence of other prognostic factors, the measurement of tumor growth rate may be helpful for initial conservative management of patients with small renal tumors.
- The risk of progression to metastatic disease during the surveillance period appears to be minimal, but longer follow-up is needed to confirm this observation.
- At the present time, active surveillance of small renal masses is an experimental approach that should only be considered for the elderly or patients with significant comorbidity.

■ New techniques of functional imaging or molecular and genomic studies, possibly using needle biopsies, may be useful in identifying small renal tumors with different aggressiveness and metastatic potential, therefore allowing the clinician to differentiate those that are likely to progress and require immediate surgery from those that are indolent and may benefit from active surveillance avoiding unnecessary surgery.

COMMENTARY

Morton A. Bosniak

Department of Radiology, NYU Medical Center, New York, New York, U.S.A.

It is very appropriate (and admirable) that in this textbook on laparoscopic urology, a chapter and commentary on a nonsurgical approach to some tumors of the kidney are included. It is an inclusion that reminds us that even with these great advances in surgical (and ablative) techniques, a nonoperative management approach (at least initially) is justified and wise in some cases.

Whether one calls this initial nonsurgical management of some small renal neoplasms "active surveillance," "watchful waiting (1,2)," or "expectant follow-up (3)," this approach to the small incidentally discovered renal neoplasm particularly in older and poor surgical risk patients by initially observing the lesion's growth pattern, and therefore its potential, is a management strategy that should not be abandoned because of the emergence of laparoscopic partial nephrectomy, cryoablation, and radiofrequency ablation of small tumors. For while these techniques are less invasive and nephron sparing, they still are invasive with potential for complications.

In their chapter, Drs. Volpe and Jewett put forth a compelling presentation (with an extensive literature review) to justify "active surveillance" management of small renal masses in appropriate cases. This is an approach that many of us have practiced over the past many years (1) and I am aware of a large number of unreported cases that have been managed and are being managed in this fashion. The results of recently published studies on renal cancer growth further support this approach. While the use of a "watchful waiting" scheme of management has decreased somewhat over the past few years with the emergence of laparoscopic partial nephrectomy and ablative techniques, there still exists a sizeable population of elderly, poor surgical risk patients who will benefit from a noninvasive approach. As the population ages, there will be an increase in the number of elderly, poor surgical risk patients and some will be found to have incidentally discovered small lesions. The knowledge that it is "safe" to follow these patients expectantly will increase the use of this type of management. With the increasing amount of data accumulating on renal tumor growth, urologists can feel confident that a nonoperative approach with expectant follow-up can be instituted, which is safe and without risk to their patients.

When should a patient be managed by "active surveillance?" Obviously each case must be individualized with clinical and imaging factors taken into account. The obvious clinical factors are patient age, comorbidities, and potential life expectancy. The imaging factors include lesion size, imaging appearance, and the position of the lesion in the kidney.

1. It has been my experience that well-circumscribed, well-marginated, homogeneous lesions are more likely to have a slower growth pattern than irregularly marginated, necrotic, or markedly heterogeneous lesions (4).
2. Location of the lesion in the kidney might be important in some cases. Lesions that could be managed by partial nephrectomy should not be allowed to progress so that a total nephrectomy becomes necessary. This would be particularly relevant in a patient with a tumor in a single kidney, or in a patient with diminished renal function.
3. Cystic and solid tumors have different growth rates and using the same criteria of surveillance may not be appropriate for these lesions in my opinion. A 3.5 cm solid mass is more worrisome than an equal-sized cystic lesion and a malignant cystic lesion that is progressing may not grow in size but its solid components may be increasing within the cystic mass. Also there is a wide range in the appearance of cystic malignancies. Some have a large amount of solid tissue associated (Bosniak Category IV) while others have much more fluid and perhaps just thickened, enhancing wall or septae (Bosniak Category III) (5). In elderly, surgical risk patients, this type of Category III lesion might be managed by follow-up studies just as Category IIF lesions are managed (6). For these reasons, size may not be as an important factor as morphology in cystic malignancies and the progression of cystic tumors can be much more difficult to predict. There is little data on the growth of cystic malignancies though there is some evidence that cystic lesions are less aggressive than solid tumors as noted in Drs. Volpe's and Jewett's chapter and as suggested in the literature (7). And finally, two observations on the imaging of cystic masses; extensive necrosis in a malignancy should not be mistaken for a cystic neoplasm and calcification in the wall of a cyst is in itself not a sign of malignancy unless associated with contrast enhancement (8).

In those cases in which surgery is to be performed, it is essential that high-quality imaging studies are available with accurate, careful interpretation. We must be certain that the lesion being removed or ablated is truly a neoplasm. Most solid (enhancing) masses are renal cell carcinomas, although approximately 10% are oncocytomas and less than 1% are hamartomas without macroscopic fat. These latter two benign lesions cannot be diagnosed preoperatively. However, angiomyolipomas that contain just a tiny amount of fat should be recognized and do not need intervention (9,10) and "pseudoenhancement" of renal cysts needs to be appreciated so that a benign cyst is not mistakenly removed (11–13).

In conclusion, to cure a patient with a small renal cancer, surgical removal is definitive. But not all small renal tumors have to be removed to manage the patient correctly. By including Drs. Volpe's and Jewett's chapter and this commentary in this textbook, the Editor is reminding us that though laparoscopic urologic surgery is a great advance in the surgical treatment of renal tumors, there is still a place for "watchful waiting" or "active surveillance" in the management of appropriate cases. This noninvasive approach should not be abandoned or minimized in the management of some small renal neoplasms even in this age of laparoscopic urology.

LAPAROSCOPIC PARTIAL NEPHRECTOMY: TECHNIQUE

Jihad H. Kaouk

Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

Over the last decade, indications for laparoscopy have evolved from ablative procedures to more complex reconstructive surgeries. Open partial nephrectomy remains the standard approach for localized kidney tumors when nephron-sparing surgery is indicated (1). Mounting experience in laparoscopic intracorporeal suturing and availability of refined laparoscopic vascular instruments facilitated the emergence of laparoscopic partial nephrectomy as a viable surgical approach for selected patients, wherein laparoscopic partial nephrectomy attempts to duplicate established principles of open surgical techniques (2).

Laparoscopic partial nephrectomy is a technically advanced procedure with challenges posed when accomplishing complete tumor excision, and securing renal parenchymal hemostasis in a limited time of warm ischemia. Achieving renal hypothermia remains a technical challenge.

> Laparoscopic partial nephrectomy is a technically advanced procedure with challenges posed when accomplishing complete tumor excision, and securing renal parenchymal hemostasis in a limited time of warm ischemia. Achieving renal hypothermia remains a technical challenge.

INDICATIONS AND CONTRAINDICATIONS

The indications for laparoscopic partial nephrectomy have been expanded beyond small, exophytic, and peripheral renal tumors to include patients with more involved tumors placed deep in the kidney, abutting the collecting system or renal sinus, completely intraparenchymal, adjacent to the renal hilum, or tumor in a solitary kidney. Laparoscopic partial nephrectomy for such complex tumors is performed only when nephron sparing surgery is indicated. Contraindications for laparoscopic partial nephrectomy include renal vein thrombus, multiple (>2) renal tumors, uncorrectable bleeding diathesis, and a history of prior ipsilateral renal surgery. Relative contraindications for laparoscopic partial nephrectomy include morbid obesity and baseline azotemia (3).

PERIOPERATIVE PATIENT PREPARATION

Preoperative routine blood tests are performed with special attention to screening for bleeding tendency and evaluation of kidney function. Formal bowel preparation is not necessary and is thus limited to clear fluids and two bottles of magnesium citrate administered the evening before surgery. Adequate preoperative hydration is mandatory and parenteral broad-spectrum antibiotic is given on-call to the operating room.

Ureteral Catheterization

> All patients are placed in the lithotomy position and ipsilateral ureteral catheterization is performed cystoscopically up to the renal pelvis.

All patients are placed in the lithotomy position and ipsilateral ureteral catheterization is performed cystoscopically up to the renal pelvis.

A 60 cc syringe with dilute indigo carmine dye (1 ampoule dye in 500 cc normal saline) is attached to the ureteral catheter and used during surgery to inject retrogradely and check for entry in the collecting system after excision of the kidney tumor. The ureteral catheter is kept for one to two days postoperatively if suture-repair of the collecting system is performed.

Patient Positioning

The patient is placed in the 90° flank position or in the 45° modified flank position depending on whether the retroperitoneal or the transperitoneal approach is employed, respectively. Pneumatic compressors are applied over both legs and the patient is taped to the operative table after carefully padding all bony prominences. The operative table is mildly flexed mainly during the retroperitoneal approach to increase the distance between the costal margin and the iliac crest (Fig. 1).

Preoperative and Intraoperative Imaging

Preoperative computed tomography with volume-rendered three-dimensional video reconstruction is performed to aid in surgical planning. Intraoperative flexible contact renal ultrasonography is performed to precisely determine tumor size, depth of intra-parenchymal extension, distance from the collecting system, proximity to major renal vessels, and further evaluation of any suspicious satellite renal lesions. The renal capsule is incised circumferentially including a small margin of normal renal parenchyma surrounding the tumor under sonographic guidance (Fig. 2) (4).

SURGICAL TECHNIQUES

Selection of the laparoscopic approach is based upon tumor location to ensure adequate surgical exposure. The transperitoneal approach is preferred for anterior, anteriolateral, lateral, and apical tumors. The retroperitoneal approach is reserved for posterior or posterolateral tumors. The Cleveland Clinic technique of laparoscopic partial nephrectomy has been described previously (2). Operative steps include renal hilum cross-clamping after kidney mobilization and exposure of the tumor. Temporary hilar control provides a dry surgical field essential for accurate tumor excision and kidney reconstruction.

Transperitoneal Approach

For the transperitoneal approach, the patient is placed in the 45° modified flank position. The surgeon and the assistant stand facing the abdomen of the patient.

Step 1: Initial Access and Port Placement

Initially, peritoneal insufflation is performed by inserting a Veress needle into the ipsilateral lower abdominal quadrant along the mid-clavicular line. CO_2 insufflation is started and continued until a 15 mmHg pneumoperitoneum is achieved. The Veress needle is replaced by a 12 mm laparoscopic port into which a 10 mm laparoscopic tele-scope with a 30° angle lens is inserted. A total of four to five ports are employed. Under

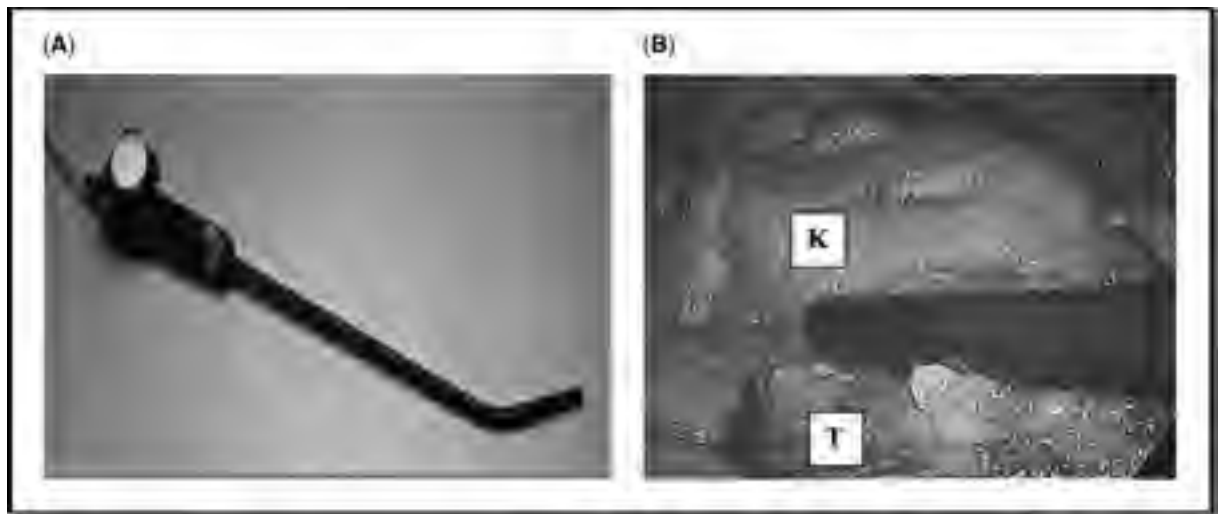
FIGURE 1 ■ During retroperitoneal laparoscopic partial nephrectomy the patient is positioned in the 90° flank position. **(A)** Anterior view showing the arms placed on a double arm board in a neutral position. An axillary roll is placed and the patient is taped to the operating table. **(B)** Posterior view showing the operative table flexed and the kidney rest elevated to maximize the space between the iliac crest and the subcostal margin. Foam pads are placed under the hip, knees, and ankles. The head is supported to keep a neutral neck position. Similar patient positioning is needed during transperitoneal laparoscopic partial nephrectomy with some variation including tilting the patient to a 45° position and minimizing table flexion.


FIGURE 2 ■ (A) Intraoperative laparoscopic ultrasound is performed using a flexible ultrasound probe with a steerable tip. (B) Intraoperative illustration of excision margin planning using ultrasound guidance. *Abbreviations*: K, kidney; T, tumor.

direct vision, a 12 mm port is placed at the lateral edge of the ipsilateral rectus muscle along the level of the 12th rib, and a 5 mm port at the angle of the costal margin with the lateral edge of the ipsilateral rectus muscle. The laparoscope is then shifted to the middle port.

During right partial nephrectomy, an additional 5 mm port is inserted at the subxiphiod location for cephalad retraction of the liver (Fig. 3).

> During right partial nephrectomy, an additional 5 mm port is inserted at the subxiphiod location for cephalad retraction of the liver.

Step 2: Preparation of the Renal Hilum

The colon is mobilized medially to expose the renal hilum. On the right side, gentle mobilization of the duodenum may be needed and the liver is retracted cephalad above the renal upper pole. The ureter is identified and dissected off the psoas muscle toward the renal hilum to avoid inadvertent clamping of the ureter along with the renal hilum. The renal artery and vein are not dissected individually and the renal hilum is clamped en bloc using a Satinsky clamp.

The port used to insert the Satinsky clamp is placed in the lower abdomen such that the Satinsky is applied parallel to the aorta and vena cava. Thick tissue surrounding the renal vessels should be dissected to avoid incomplete Satinsky occlusion (Fig. 4).

> The port used to insert the Satinsky clamp is placed in the lower abdomen such that the Satinsky is applied parallel to the aorta and vena cava.

Step 3: Kidney Mobilization and Tumor Exposure

Gerota's fascia is incised and kidney is mobilized generously from within the Gerota, enough to expose the tumor and surrounding normal renal parenchyma. Fatty tissue covering the tumor is maintained en bloc with the tumor.

Step 4: Renal Hilar Clamping

After adequate hydration and intravenous administration of Mannitol (12.5 g), a Satinsky clamp is introduced through a separate port placed in the ipsilateral lower quadrant, and the renal hilum is clamped en bloc (Fig. 4). Care is taken to ensure that any accessory renal arteries or veins are included within the jaws of the clamp. If necessary, additional individual bulldog clamps can be employed.

Step 5: Tumor Excision

After renal hilar control, the tumor is excised including a margin of normal renal parenchyma. Cold endoshears is used to cut the renal parenchyma along the previously scored renal capsule (Fig. 5).

Step 6: Kidney Reconstruction and Hemostasis

Pelvicalyceal integrity is tested by retrograde injection of dilute indigo carmine through the previously placed ureteral catheter. Any entry is identified and is laparoscopically sutured using continuous 2-0 Vicryl suture on a computed tomography-1 needle in a watertight fashion (Fig. 6). Parenchymal hemostatic sutures are

FIGURE 3 ■ Illustration of port positioning during laparoscopic left partial nephrectomy. The Satinsky port is placed in the lower abdominal quadrant such that the Satinsky is almost parallel to the aorta and vena cava. An additional 2 mm miniport (*arrow*) is placed in the lateral flank position for additional traction. During right partial nephrectomy, an additional subxiphiod port (X) is inserted for cephalad retraction of the liver.

FIGURE 4 ■ Transperitoneal laparoscopic partial nephrectomy. Laparoscopic Satinsky clamp is used to control the renal hilum en bloc. Individual dissection of the renal artery and vein is not necessary. Intraoperative illustration of en bloc renal hilum clamping.

placed using GS-25 needle and 0 Vicryl suture over a prepared surgicel bolsters (Fig. 7). The biologic hemostatic agent, Floseal, is layered directly onto the partial nephrectomy bed, deep to the surgical bolster. After securing hemostasis, renal hilum is unclamped and warm ischemia time is noted. Hemostasis is rechecked after desufflating the abdomen to zero intraperitoneal pressure for 10 to 15 minutes. Occasionally, bleeding temporarily tamponated by pneumoperitoneal pressure can be unveiled and controlled (Fig. 8).

Step 7: Laparoscopic Exit
The excised renal tumor is entrapped within an Endocatch bag[a] and extracted intact from the lower port site.

A Jackson-Pratt drain is placed if pelvicalyceal repair was performed. Ports are removed under vision after securing hemostasis.

A Jackson-Pratt drain is placed if pelvicalyceal repair was performed. Ports are removed under vision after securing hemostasis.

Retroperitoneal Approach
During the retroperitoneal approach the patient is positioned in the standard 90° full flank position. The surgeon and the assistant stand facing the patient's back (5).

Step 1: Initial Access and Port Placement
A three-port technique is usually employed. The initial retroperitoneal access is achieved using the open (Hasson) technique. A 1.2 cm transverse skin incision is made at the tip of the 12th rib, and flank muscles are bluntly split. The thoracolumbar fascia is exposed and incised. Using blunt finger dissection, the retroperitoneum is entered and a space is developed anterior to the psoas muscle and posterior to Gerota's fascia. A balloon dilator is inserted in the created retroperitoneal space, and then inflated with 800 cc of air. The balloon is subsequently deflated and replaced with a 10 mm blunt tip cannula with a 30 cc balloon mounted tip which is cinched against the abdominal wall in an air tight fashion. CO_2 pneumoretroperitoneum is established at 15 mmHg, and a 30° lens laparoscope is introduced into the retroperitoneal space. Under direct vision, two secondary laparoscopic ports are placed. An anterior port is inserted 3 cm cephalad to the iliac crest along the anterior axillary line, and a posterior port is inserted at the junction of the lateral border of the erector spinae muscle with the undersurface of the 12th rib (Fig. 9).

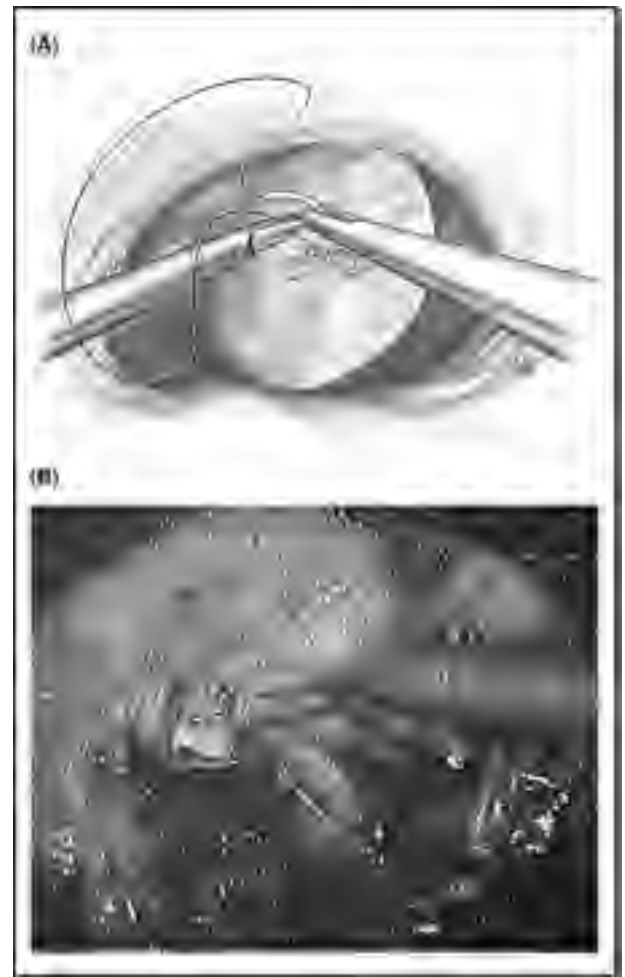

FIGURE 6 ■ Illustration (A) and intraoperative photo (B) showing suture repairing of any calyceal opening in a watertight fashion. After tumor excision, retrograde injection of methylene blue help identify and, later, confirm watertight repair of calyceal entry.

Step 2: Preparation of Renal Hilum
The renal hilum is put on stretch by anteriolateral retraction of the kidney. The renal artery and vein are individually dissected in preparation for temporary clamping.

Step 3: Kidney Mobilization and Tumor Exposure

> In contradistinction to the transperitoneal approach, identification and individual dissection of the renal artery and renal vein is the first surgical step in the retroperitoneal approach.

In contradistinction to the transperitoneal approach, identification and individual dissection of the renal artery and renal vein is the first surgical step in the retroperitoneal approach.

The kidney is mobilized from within the Gerota's fascia in a fashion similar to the transperitoneal approach. Nevertheless, the retroperitoneal space is limited adding difficulty to the procedure.

Step 4: Renal Hilar Clamping
Bulldog clamps are placed on the renal artery and vein separately during a retroperitoneal partial nephrectomy (Fig. 10).

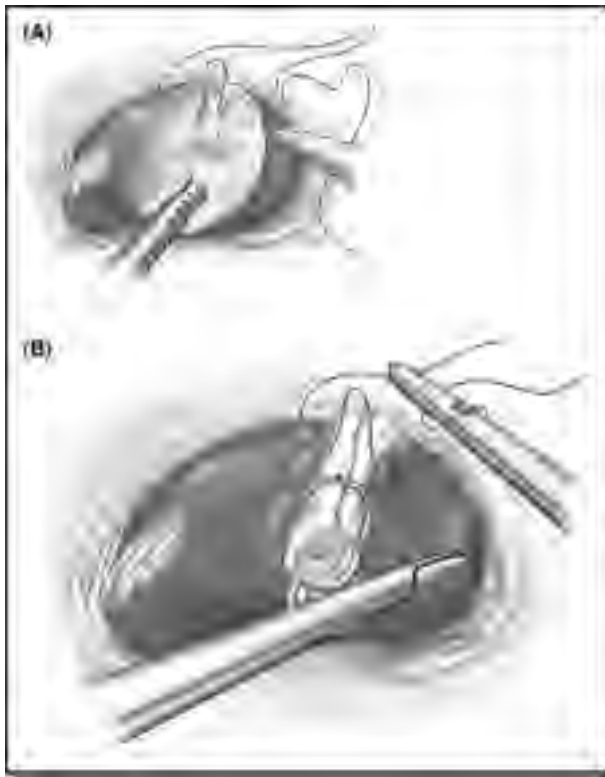
Step 5: Completion of Partial Nephrectomy
Following hilar control, surgical steps including tumor excision, reconstruction of the renal parenchyma and collecting system, tumor extraction, and laparoscopic exit are similar to the transperitoneal approach.


FIGURE 7 ■ (A) Hemostatic sutures are placed deep in the renal parenchyma using a CTX needle. The sutures are cinched tightly over prepared Surgicel® bolsters positioned in the parenchymal defect. (B) Intraoperative illustration of renal parenchymal repair.

FIGURE 8 ■ Intraoperative photo of completed parenchymal suturing and unclamped renal hilum. Surgicel® bolsters fill the parenchymal defect at the site of excised renal tumor.

ALTERNATIVE TECHNIQUES

Renal Hilar Clamping

Renal hilar clamping is not necessary for every laparoscopic partial nephrectomy. Several centers have reported wedge-resection without hilar clamping for excision of small exophytic tumors with minimal parenchymal extension (6–8).

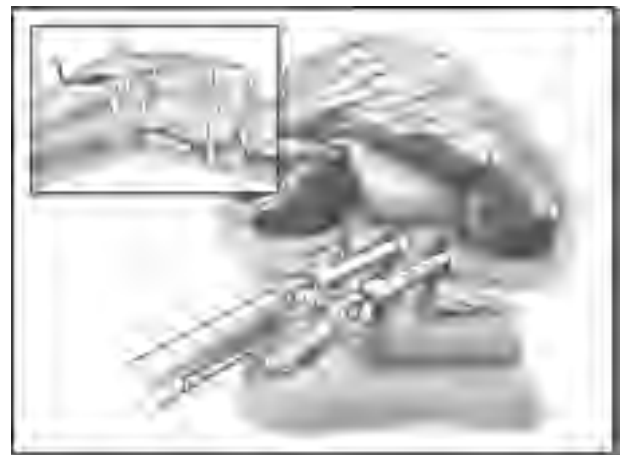
FIGURE 9 ■ Three ports are needed during retroperitoneal laparoscopic partial nephrectomy. The initial port is at the tip of the 12th rib. The posterior port is at the junction of the costal margin and the paraspinal muscle. The anterior port is 3–5 cm cephalad to anterior superior iliac spine.


FIGURE 10 ■ During retroperitoneal laparoscopic partial nephrectomy laparoscopic bulldog clamps are used to clamp the renal artery and vein separately. Intraoperative illustration of the renal artery and vein individually dissected and controlled.

Laparoscopic Renal Hypothermia

Reliable method of achieving renal hypothermia during laparoscopic partial nephrectomy remains a technical challenge. An accepted practice has been to limit warm renal ischemia to 30 minutes or less, beyond which ischemic renal injury is likely to occur, especially in the elderly or those with compromised baseline renal function.

Although several novel techniques for achieving laparoscopic renal hypothermia have been investigated in the laboratory, a simple and reliable method has not been established yet.

Currently reported techniques of laparoscopic hypothermia include renal cooling jacket, renal artery cold perfusion (9), and retrograde cold perfusion of the pelvicalyceal system through a ureteral catheter (10). At the Cleveland Clinic, laparoscopic renal hypothermia has been performed by the surface contact technique, akin to open surgery. Ice slush is instilled through a laparoscopic port into an Endocatch bag placed around the kidney. Using 600–750 cc of ice slush around the kidney, a nadir core renal parenchymal temperature of 5°C to 19°C was documented (11).

Hemostatic Techniques

Securing hemostasis during laparoscopic partial nephrectomy requires advanced laparoscopic skills and has thus limited the wider use of the laparoscopic approach for nephron-sparing surgery. Various techniques of parenchymal hemostasis have been reported in an attempt to establish a technically simpler method of securing hemostasis (12–14). Employment of laparoscopic harmonic scalpel, microwave coagulator, argon beam coagulator and application of fibrin glue may be helpful for mild parenchymal surface oozing.

The most effective method to control significant segmental parenchymal vessels remains the application of hemostatic parenchymal sutures duplicating the open surgical technique.

Vascular control by circumferential compression of the renal parenchyma using renal tourniquets and cable tie devices has been used during polar partial nephrectomies (15,16). Generally speaking the effectiveness of such devices is not clinically investigation. Other investigational hemostatic aids include prior microwave thermotherapy (17), or radiofrequency coagulation of the tumor with a needle probe followed by laparoscopic partial nephrectomy without hilar control (18). Laser tissue welding using human albumin as a solder to control bleeding and seal the collecting system during laparoscopic heminephrectomy system was described in the porcine model (19).

Potent bioadhesives may become an effective method for obtaining renal parenchymal hemostasis in the future.

SUMMARY

- The surgical technique for laparoscopic partial nephrectomy is now secure and reproducible.
- Effective duplication of standard open surgical principles is possible laparoscopically for select patients requiring nephron-sparing surgery.
- Laparoscopic partial nephrectomy is a technically advanced procedure requiring considerable laparoscopic skills and experience.
- Simplified methods for achieving renal hypothermia and securing hemostasis will facilitate wider dissemination of the laparoscopic approach.

LAPAROSCOPIC PARTIAL NEPHRECTOMY: CURRENT STATUS

Massimiliano Spaliviero and Inderbir S. Gill

Section of Laparoscopic and Robotic Surgery, Glickman Urological Institute, Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

Epithelial tumors of the kidney account for 3% of all adult malignancies. Approximately 35,710 new renal cancer cases are estimated in the United States for the year 2004, and 12,480 patients will die of the disease (1). Occurring twice as often in men, it is the eighth and the 10th most common cancer in men and women, respectively (2).

Since the 1970s, the evaluation of unrelated abdominal complaints by widely available radiologic tests such as ultrasonography and computed tomography scan has led to a 2.3%–4.3% per year increase in detection of renal cancer case. As a consequence, the rate of incidental detection of small ($\leq$4 cm) renal tumors of lower stage, with low metastatic potential has increased by 60%. This has led to an improvement in the five-year survival rates (3–5). During the past decade, the management of these small tumors has shifted gradually from radical nephrectomy to nephron-sparing surgery.

Clear cell carcinoma is the most common histologic type of renal cancer case (approximately 85% of renal neoplasm); it is typically sporadic, unifocal, and unilateral. Although papillary renal cancer case (10–15%) is more likely to be multifocal, it correlates with a better prognosis (90% five-year survival) compared with clear cell carcinoma. Other histologic types include chromophobe carcinomas (5% of renal cancer case; >90% long-term survival), collecting duct carcinoma (<1% of renal cancer case; in younger patients; more aggressive, survival <2 years in most patients). Usually considered benign tumors, renal oncocytomas are rarely metastatic (6).

Radical nephrectomy remains the cornerstone of curative treatment for this disease (7). However, comparably excellent results with nephron-sparing surgery for treatment of small, localized renal carcinoma have been reported.

NEPHRON-SPARING SURGERY: CURRENT CONCEPTS

Five-year survival rates after radical nephrectomy for stage I (T_1–T_2) renal cancer case are 75% or more (8). Risk of recurrence is increased in patients with advanced stage T and positive lymph nodes.

Whenever preservation of functioning renal parenchyma is an important concern, nephron-sparing surgery is the preferred substitute for radical nephrectomy. The goal of nephron-sparing surgery is two-fold: (i) oncologically complete tumor excision, and (ii) preservation of a well-functioning renal remnant. Cancer-specific survival rates after nephron-sparing surgery for small (≤4 cm) renal cancer case are excellent (72–100%), and comparable to those obtained after radical nephrectomy (Table 1). At the same time, nephron-sparing surgery minimizes the risk of nephron loss (17).

Incidence of multifocal renal cancer case is 7–25%, with this incidence decreasing to 0–5% when the primary tumor is 4 cm or smaller in size. Risk of local recurrence after nephron-sparing surgery is less than 10% and is most likely a manifestation of previously undetected microscopic multifocal renal cancer case in the "normal" part of the kidney, i.e., the renal remnant (Table 2). Given concerns regarding renal cancer case multifocality, skeptics have raised the specter of parenchyma-sparing surgery to be cancer-sparing surgery. However, no linear or predictable relationship between multifocality and local recurrence has been reported (29).

To minimize local recurrences after nephron-sparing surgery, tumor excision including an adequate margin of normal parenchyma is essential (30,31). What constitutes an oncologically adequate width of parenchymal margin has been addressed recently. Long-term follow-up data confirm that a negative margin for tumor on histology is the primary criterion, with margin width having no practical consequence. Castilla et al. (32) found no correlation between long-term disease progression and width of the resection margin at a mean follow-up of 8.5 years. Other authors reported appropriate and comparable cancer control without local recurrence with resection margins ranging from 1 to 5 mm (33–37). Although surgical margin width appears to be ultimately irrelevant, during laparoscopic partial nephrectomy a margin of approximately 0.5 cm is aimed for to prevent inadvertent compromise of tumor margins.

A randomized controlled trial comparing radical and partial nephrectomy for small (<4 cm) tumors showed similar median survival time at comparable follow-up (11). Belldegrun et al. (14) compared 146 patients undergoing nephron-sparing surgery for unilateral, solitary, or bilateral renal cancer case with a matched group of 125 patients who underwent radical nephrectomy for renal cancer case. In the partial nephrectomy group, survival in patients with T_2 versus T_1 lesions was 66% versus 100%, respectively ($p < 0.001$). Survival was comparable for patients with T_1 renal cancer case treated with either radical nephrectomy or nephron-sparing surgery, while survival was significantly better in patients with T_2 lesions treated with radical nephrectomy ($p = 0.001$). The authors concluded that nephron-sparing surgery benefits the select patient with localized unilateral renal cancer case less than 7 cm in size (ideally, <4 cm). In patients with renal cancer case ≤4 cm in size, Lee et al. (15) reported a five-year disease-free survival rate of 96% after nephron-sparing surgery and 96% after radical nephrectomy, with no local recurrence in each group.

In a study of sporadic localized renal cancer case in 485 patients treated with nephron-sparing surgery, Hafez et al. (25) reported a five-year cancer-specific survival of 93%, with an renal cancer case recurrence rate of 10% (3.2% local recurrence; 5.8% metastatic disease).

Reporting on a 10-year follow-up of patients treated with nephron-sparing surgery, Fergany et al. (38) documented cancer-specific survival of 88% at five and 73% at 10 years, respectively. Recurrences occurred locally (4%), at metastatic sites (21.5%), or combined (locally and distant metastases, in 6.5%). Cancer-specific survival in patients with unifocal, <4 cm tumor was 100% at 10 years with no local recurrence. Krejci and colleagues (39) documented a significantly inferior 10-year cancer-specific survival rate after nephron-sparing surgery for patients with clear cell renal cancer case compared to papillary/chromophobe renal cancer case (91.5% vs. 99%, $p = 0.029$). As such, these clinicopathologic features should be considered in preoperative decision-making, patient counseling, and surveillance.

NEPHRON-SPARING SURGERY: CURRENT INDICATIONS

Absolute indications include synchronous bilateral renal cancer case, tumor in solitary kidney (unilateral renal agenesis or previous contralateral nephrectomy), or unilateral tumor with poorly/nonfunctioning contralateral kidney, wherein radical nephrectomy would render the patient anephric (with a subsequent immediate need for dialysis) (40). As shown by Ghavamian et al. (28), open nephron-sparing surgery in a solitary kidney can be performed safely: 5- and 10-year cancer-specific survival rates were 80.7% and 63.7%, respectively, and local recurrence-free survival rates were 89.2% and 80.3%, respectively.

Relative indications for NS include clinical circumstances where the contralateral kidney is at threat or risk for future impaired function due to systemic disease: hereditary renal cancer case syndromes, genetic diseases increasing the risk of metachronous kidney cancer, diabetes, hypertension, stone disease, or renovascular disease. Elective indications for partial nephrectomy comprise small (≤4 cm) slid renal tumors or suspicious indeterminate cystic renal lesions with malignant potential in the presence of a normal contralateral kidney.

Comparing 164 radical nephrectomy versus 164 elective nephron-sparing surgery for renal cancer case, Lau et al. (16) reported a five-year cancer-specific survival of 97% and 98%, respectively. Ipsilateral adrenal fossa recurrence occurred in one patient after radical nephrectomy, while local recurrence occurred in four nephron-sparing surgery patients. Progression to renal insufficiency at 10 years (increase in serum creatinine >2 mg/dL) occurred in 22.4% of radical nephrectomy and 11.6% of nephron-sparing surgery cases ($p = 0.01$).

Elective nephron-sparing surgery in patients with a normal contralateral kidney remains somewhat controversial (41). In this setting, Novick (42) detailed the results of nephron-sparing surgery for unilateral localized renal cancer case in 315 patients with a normal opposite kidney. Accurate patient selection with small tumor size (<3.5 cm) resulted in a favorable mean cancer-specific survival rate of 95% (only two patients with local tumor recurrence) at approximately three years of follow-up after nephron-sparing surgery. Comparing radical nephrectomy versus elective nephron-sparing surgery in patients with a normal contralateral organ, Lerner et al. (10) reported five-year cancer-specific survival rates of 96% and 92%, respectively, concluding that radical

nephrectomy and nephron-sparing surgery achieve equivalent cure in select patients with renal cancer case. In a recent study by Herr (43), 10-year cancer-free survival rate after elective nephron-sparing surgery for small (mean size 3 cm), unifocal, low-grade and low-stage tumors and normal contralateral kidney was a robust 97%.

In patients with small (<4 cm), unilateral stage $T_{1-2}N_0M_0$ renal cancer case, Licht et al. (24) reported no postoperative tumor recurrences and a cancer-specific five-year survival rate of 100%. Considering that a significant 23% of 292 tumors preoperatively suspicious for malignancy were found to be benign on final histology, McKiernan et al. (27) recently emphasized their rationale of routinely performing partial nephrectomy.

The bulk of reported data indicate nephron-sparing surgery to be an acceptable therapeutic option with improved survival in patients with a single, small (<4 cm), low pathologic stage renal cancer case in the presence of a normal contralateral kidney. However, nephron-sparing surgery results may be somewhat less satisfactory in patients with larger (>4 cm) or multiple localized renal cancer case. In such patients, radical nephrectomy likely remains the treatment of choice when the opposite kidney is normal.

OPEN PARTIAL NEPHRECTOMY VS. LAPAROSCOPIC RADICAL NEPHRECTOMY

Laparoscopic radical nephrectomy is now an accepted option for treatment of $T_1–T_{3a}N_0M_0$ renal tumors (44). Laparoscopic radical nephrectomy is associated with diminished postoperative discomfort and shorter recovery compared with open surgery, while providing similar local control and oncologic cure rates.

Cadeddu et al. (45) reported a multi-institutional study of 157 patients undergoing LRN for clinical stage I ($T_1–T_2$) renal cancer case. The five-year actuarial disease-free rate for patients was 91%. Matin et al. (46) retrospectively compared outcomes of 35 LRN versus 82 open nephron-sparing surgery. Strict study inclusion criteria included patients with a solitary ≤4 cm renal tumor, normal serum creatinine, and normal contralateral kidney. Mean blood loss, operative time, narcotic use, and hospital stay were significantly decreased in the laparoscopic group. Patients undergoing open nephron-sparing surgery experienced a lesser postoperative increase in serum creatinine (0% vs. 25%, $p < 0.001$). The authors concluded that the significant short- and intermediate-term benefits of the laparoscopic approach as regards superior patient recovery and decreased morbidity should be weighed against the long-term advantage of better renal function associated with nephron-sparing surgery.

LAPAROSCOPIC PARTIAL NEPHRECTOMY

Laparoscopic partial nephrectomy is an emerging minimally invasive nephron-sparing alternative to open partial nephrectomy. However, before laparoscopic partial nephrectomy can be recommended for widespread use, reproducible technical, perioperative, pathologic, functional, and oncologic outcomes comparable to open partial nephrectomy must be confirmed. Advances in laparoscopic skills and technology have allowed efficacious achievement of renal hilar vascular control, renal hypothermia (if required), tumor excision, calyceal suture repair, and hemostatic parenchymal suture repair. As such, current laparoscopic partial nephrectomy techniques duplicate the established principles of open nephron-sparing surgery (47). Since its development in a porcine model by McDougall et al. (48), several successful clinical experiences of laparoscopic partial nephrectomy have been reported. The first application of transperitoneal laparoscopic partial nephrectomy was reported by Winfield et al. (49) in a woman with a stone-bearing lower pole calyceal diverticulum. Retroperitoneoscopic partial nephrectomy was first described by Gill and coworkers (50). Depending upon the radiologic features and location of the individual tumor, laparoscopic partial nephrectomy may be performed by the transperitoneal or the retroperitoneal approach (51).

Laparoscopic partial nephrectomy was initially limited to the treatment of select small, solitary, peripheral, superficial, exophytic tumor (49,50,52–56). With increasing experience, these indications have been carefully expanded to include patients with tumor infiltrating the parenchyma up to the collecting system or the renal sinus, completely intrarenal tumors, tumor abutting the renal hilum, tumor in a solitary kidney, large-size tumor requiring heminephrectomy, or a renal mass in the presence of concomitant renovascular disease (47,51,57).

Morbid obesity and the presence of more than two renal tumors increase the technical difficulty of performing laparoscopic partial nephrectomy. Relative contraindications for laparoscopic partial nephrectomy include a central intrarenal located tumor, and prior open kidney surgery. Current contraindications for laparoscopic partial nephrectomy include the presence of a renal vein thrombus, and a locally advanced tumor. Patients with impaired coagulation, such as hemorrhagic diathesis, platelet dysfunction due to azotemia, or anticoagulant therapy must be approached cautiously with adequate medical preparation to minimize their hemorrhagic risk (58). Patients with atherosclerotic renovascular disease or those with status post-percutaneous renal artery stenting are at increased risk of intimal injury during renal artery clamping. Adequate laparoscopic experience is necessary before embarking on laparoscopic partial nephrectomy.

A recent questionnaire-based survey assessed the current attitude of community urologists towards novel surgical options for renal cancers (59). An anonymous questionnaire was mailed to 174 members of the Minnesota Urological Society, with a response rate of 49%. Two clinical scenarios were proposed: (i) the case of a 6-cm lesion with no indication for nephron-sparing surgery, and (ii) the case of a 3-cm lower pole exophytic mass suitable for nephron-sparing surgery. In the first scenario, 14% of respondents would have offered laparoscopic surgery only, 43% open surgery only, and 43% either form of therapy. For the second scenario, 10% of responders would have offered minimally invasive treatment only, 55% open surgery only, and 35% either forms of therapy. In the latter scenario, laparoscopic partial nephrectomy would have been offered by 38% of respondents. The authors concluded that minimally invasive surgery for renal tumors is evolving into a standard of care, with a trend that is increasingly reaching the community urologist. Nevertheless, appropriately so, there remains a heavy reliance on referrals to select tertiary-referral centers with extensive laparoscopic experience.

RESULTS

The evolving worldwide experience with laparoscopic partial nephrectomy for tumor is listed in Table 3. A multicenter European experience in 53 patients was reported by Rassweiler et al. (61) The average tumor size was 2.3 cm (range, 1.1–5). Transperitoneal approach was used in 28% of cases. Mean operating time was 3.2 hours (range, 1.5–5.3), and estimated blood loss 725 mL (range, 20–1500). Intraoperative complications included pneumothorax in one patient, and bleeding in four, of whom two underwent open conversion. Postoperative complications included bleeding requiring reintervention in one patient, and urinary leak in five patients. Two patients with urinary leak also had concomitant bleeding and were treated with nephrectomy. Histology showed 37 pT_1 renal cancer case (69%), and 100% overall disease-free survival rate at three-year follow-up.

Jeschke et al. (62) reported outcomes of laparoscopic partial nephrectomy without hilar clamping in 51 patients with small (<2 cm), peripheral, exophytic, solid renal tumors. The Ultracision device[a] was employed for tumor wedge resection, and hemostasis was achieved with bipolar coagulation with fibrin glue-coated cellulose. Mean

operative time was 2.2 hours (range, 1.2–5), mean blood loss was 282 mL (range, 20–800), and no open conversion was necessary. Complications occurred in 10% of patients, including pneumothorax (one), urinary leak (three), and late hemorrhage requiring open reintervention (one). Pathology confirmed renal cancer case in 76% of patients. At a mean follow-up of 34.2 months (range, 3–78), neither local recurrence nor distant metastasis occurred. One patient with papillary carcinoma presenting with metachronous de novo renal cancer case in the operated kidney one year after wedge resection was treated with laparoscopic radical nephrectomy.
