February 25 Notes:
Definitions:

- A convex quadrilateral is a parallelogram if the opposite sides are parallel.
- A rhombus is a parallelogram having two adjacent sides congruent.
- A square is a rhombus having two adjacent sides perpendicular.

A cascade of theorems, all of which rely on cutting things into triangles and using congruence theorems and transversal theorems:

- A diagonal of a parallelogram divides it into congruent triangles.
- A convex quadrilateral is a parallelogram iff its opposite sides are congruent.
- Opposite angles of a parallelogram are congruent
- Adjacent angles of a parallelogram are supplementary
- A convex quadrilateral is a parallelogram iff its diagonals bisect each other.
- A parallelogram is a rhombus iff its diagonals are perpendicular.
- A parallelogram is a rectangle iff its diagonals are congruent.
- A parallelogram is a square iff its diagonals are both perpendicular and congruent.
- Etc. These make good exercises. Try a few!!

Definition: A trapezoid is a convex quadrilateral if a pair of opposite sides parallel. The parallel sides are called bases and the other two sides are called legs. The segment joining the midpoint of the legs is called the median.

Our definition allows trapezoids to be parallelograms. Some books insist that trapezoids have exactly one pair of parallel sides.

If a trapezoid is not a parallelogram in disguise, then if its two legs are congruent, it is called an isosceles trapezoid.

Theorem (Midpoint Connector Theorem for Trapezoids): If a line segment bisects one leg of a trapezoid and is parallel to the base, then it is the median and its length is one-half the sum of the lengths of the two bases. Conversely, the median of a trapezoid is parallel to each of the two bases and has length equal to one-half the sum of the length of the bases.

Proof: Given trapezoid $\diamond \mathrm{ABCD}$ with $\overline{A B} \| \overline{C D}$, let line $l$ intersect leg $\overline{A D}$ at midpoint L . Draw diagonal $\overline{A C}$. Then $l$ must intersect $\overline{A C}$ at a midpoint M by the midpoint connector theorem for triangles. Applying this again to $\triangle \mathrm{ABC}$, line $l$ must intersect $\overline{B C}$ at a midpoint N . Segment $\overline{L N}$ is thus the median of the trapezoid. A straightforward argument establishes that $\mathrm{L}-\mathrm{M}-\mathrm{N}$, so $\mathrm{LN}=\mathrm{LM}+\mathrm{MN}$. Again by the midpoint connector theorem for triangles,
$L N=L M+M N=\frac{1}{2} C D+\frac{1}{2} A B=\frac{1}{2}(C D+A B)$

The converse is Problem 18 in Section 4.2, which you get to do as an exercise.

Parallel Projection: Given two lines $l$ and $m$, locate points A and $\mathrm{A}^{\prime}$ on the two lines. We set up a correspondence $\mathrm{P} \leftrightarrow \mathrm{P}^{\prime}$ between the points of $l$ and $m$ by requiring that $P P^{\prime} \| A A^{\prime}$, for all P on $l$. We claim that this mapping, called a parallel projection, 1) is one-to-one, 2) preserves betweeness, and 3) preserves ratios of segments.

1) follows almost immediately from the Parallel Postulate.
2) follows almost immediately from the fact that parallel lines cannot cross (given P-Q-R, if $\mathrm{P}^{\prime}-\mathrm{R}^{\prime}-\mathrm{Q}^{\prime}$, then Q is on one side of $\overleftrightarrow{R R^{\prime}}$ and $\mathrm{Q}^{\prime}$ is on the other, segment $\overrightarrow{Q Q^{\prime}}$ must cross $\overleftrightarrow{R R^{\prime}}$ ).

We spend the rest of our time proving 3 .

We claim that $\frac{P Q}{Q R}=\frac{P^{\prime} Q^{\prime}}{Q^{\prime} R^{\prime}}$. If the lines $l$ and $m$ are parallel, then the quadrilaterals become parallelograms, and opposite sides are equal, so $P Q=P^{\prime} Q^{\prime}$ and $Q R=Q^{\prime} R^{\prime}$, and the result is trivial. So we assume that the lines meet at point A, forming a triangle $\triangle \mathrm{ABC}$. We prove the following:

Theorem: Given triangle $\triangle \mathrm{ABC}$, if E lies on $\overline{A B}$ and F on $\overline{A C}$ such that $\overline{E F} \| \overline{B C}$, then $\mathrm{AE} / \mathrm{AB}=\mathrm{AF} / \mathrm{AC}$.

Proof: We assume that $\overline{E F}$ is not parallel to $\overline{B C}$, then show that $\mathrm{AE} / \mathrm{AB} \neq \mathrm{DF} / \mathrm{DC}$. Begin by constructing the parallels $\overline{E H}$ and $\overline{G F}$ to $\overline{B C}$ through E and F , respectively. We have two cases, A-E-G or A-G-E. We will argue the case A-E-G, the other case being analogous. Since betweenness is preserved under parallel projection, A-H-F.

Now: Bisect segments $\overline{A B}$ and $\overline{A C}$, then bisect the segments determined by those midpoints, and so on, continuing the bisection process indefinitely. We claim that at some point, one of our bisecting points P will fall on $\overline{E G}$, and the corresponding midpoint Q will fall on $\overline{H F}$. This is true since for some $n, n \cdot \mathrm{EG}>\mathrm{AB}$ (the Archimedean Property of real numbers). So, it is also true that for some $m, 2^{m} \cdot \mathrm{EG}>\mathrm{AB}$, so $\mathrm{AB} / 2^{m}<\mathrm{EG}$. This is illustrated below.

Note that the segments joining midpoints (like $\overline{P Q}$ ) are parallel to $\overline{B C}$ by the midpoint connector theorems.

Moreover, the process of repeatedly finding midpoints partitions the segments $\overline{A B}$ and $\overline{A C}$ into $n$ congruent segments of length $a$ and $b$, respectively. There are also some number $k$ parallel lines
between A and
$\overline{P Q}$, (counting
$\overline{P Q})$. Then:

$\mathrm{AP}=k a \quad \mathrm{AQ}=k b$
$\mathrm{AB}=n a \quad \mathrm{AC}=n b$.
By algebra, $\frac{A P}{A B}=\frac{k a}{n a}=\frac{k}{a}$ and $\frac{A Q}{A C}=\frac{k b}{n b}=\frac{k}{n}$; therefore,
$\frac{A P}{A B}=\frac{A Q}{A C}$.
However, because A-E-P-G and A-H-Q-F, AE $<$ AP and AQ $<$ AF. So,
$\frac{A E}{A B}<\frac{A P}{A B}=\frac{A Q}{A C}<\frac{A F}{A C}$.

Thus, $\frac{A E}{A B} \neq \frac{A F}{A C}$.
If it happens that A-G-E, an exactly analogous argument gives us $\frac{A E}{A B}>\frac{A F}{A C}$ so again $\frac{A E}{A B} \neq \frac{A F}{A C}$.

We have shown the contrapositive of the statement we wanted to prove. In summary,

If $\frac{A E}{A B}=\frac{A F}{A C}$, then $\overline{E F} \| \overline{B C}$.

Now we prove:
Theorem (The Side-Splitting Theorem): Parallel projection preserves ratios of line segments. Specifically, if a line $\stackrel{\rightharpoonup F}{ }$ parallel to the base $\overline{B C}$ of $\triangle \mathrm{ABC}$ cuts the other two sides $\overline{A B} \& \overline{A C}$ at points E and F , respectively, then $\mathrm{AE} / \mathrm{AB}=$ $\mathrm{AF} / \mathrm{AC}$, and $\mathrm{AE} / \mathrm{EB}=\mathrm{AF} / \mathrm{FC}$.

Proof: We locate $\mathrm{F}^{\prime}$ on $\overline{A C}$ such that $\mathrm{AF}^{\prime}=\mathrm{AC} \cdot(\mathrm{AE} / \mathrm{AB})$, so that $\mathrm{AE} / \mathrm{AB}=\mathrm{AF}^{\prime} / \mathrm{AC}$, and construct line $\overleftarrow{E F^{\prime}}$. By the preceding theorem, $\overleftrightarrow{E F^{\prime}} \| \overrightarrow{B C}$. But $\overleftrightarrow{E F} \| \overline{B C}$ by hypothesis, so $\overleftrightarrow{E F^{\prime}}=\overleftrightarrow{E F}$. Therefore, $\mathrm{F}^{\prime}=\mathrm{F}$, and $\mathrm{AE} / \mathrm{AB}=\mathrm{DF} / \mathrm{DC}$.

To get the other ratio, note that $\mathrm{A}-\mathrm{E}-\mathrm{B}$ and $\mathrm{A}-\mathrm{F}-\mathrm{C}$ so that $\mathrm{AB}=$ $\mathrm{AE}+\mathrm{EB}$ and $\mathrm{AC}=\mathrm{AF}+\mathrm{FC}$. Then
$\frac{A E}{A E+E B}=\frac{A F}{A F+F C}$, or taking reciprocals,
$\frac{A E+E B}{A E}=\frac{A F+F C}{A F}$. Thus $1+\frac{E B}{A E}=1+\frac{F C}{A F}$, or
$\frac{E B}{A E}=\frac{F C}{A F}$. Taking reciprocals gives the desired result.

A final note: Everything we have done here could have been done on a trapezoid instead of a triangle. (Indeed, an earlier edition of the text did all of this on a trapezoid, and noted that it could have been done on a triangle.) In the case of a trapezoid, the point A at the top of the triangle is replaced by a segment $\overline{A D}$, and the major theorem is then stated as:

Given trapezoid $\diamond \mathrm{ABCD}$, if E lies on $\overline{A B}$ and F on $\overline{C D}$ such that $\stackrel{\rightharpoonup}{E F} \| \overline{B C}$, then $\mathrm{AE} / \mathrm{AB}=\mathrm{DF} / \mathrm{DC}$.

The picture is slightly different, but the main ideas are exactly the same.

All this forms the foundation for our study of similarity in the next section.
